## ABSTRACT

We report a Middle Ordovician metagranitoid from the northern margin of the Anatolide-Tauride Block, the basement of which is generally characterized by voluminous Latest Proterozoic to Early Cambrian granitoids. The Ordovician metagranitoid forms an ~400-m-thick body in the marbles and micaschists of the Tavşanlı Zone. The whole sequence was metamorphosed in the blueschist facies during the Late Cretaceous (c. 80 Ma). Zircons from the metagranitoid give a Middle Ordovician Pb-Pb evaporation age of  $467.0 \pm 4.5$  Ma interpreted as the age of crystallization of the parent granitic magma. The micaschists underlying the metagranitoid yield Cambro-Ordovician

(530–450 Ma) and Carboniferous (c. 310 Ma) detrital zircon ages indicating that the granitoid is a pre- or syn-metamorphic tectonic slice. The Ordovician metagranitoid represents a remnant of the crystalline basement of the Anatolide-Tauride Block and provides evidence for Ordovician magmatism at the northern margin of Gondwana. Prismatic Carboniferous detrital zircons in the micaschists indicate that during the Triassic, the northern margin of the Anatolide-Tauride Block was close to Variscan terranes.

Terra Nova, 20, 280–288, 2008

## Introduction

Pan-African granitoids with ages of 600–500 Ma crop out over large areas in Arabia and northern Africa (e.g. Veevers, 2004). The Anatolide-Tauride Block of southern Turkey was attached to Africa during the Palaeozoic (e.g. Şengör and Yılmaz, 1981) and its basement, as exposed in the Menderes Massif, also comprises widespread granitoid plutons with ages of 570–520 Ma (e.g. Satır and Friedrichsen, 1986; Kröner and Şengör, 1990; Hetzel and Reischmann, 1996; Loos and Reischmann, 1999; Gürsü and Gönçüoğlu, 2006). Here we report a Middle Ordovician (c. 467 Ma) granitoid from the northern margin of the Anatolide-Tauride Block and discuss its tectonic significance. The Ordovician granitoid reported here is the first of its age from the northern margin of Gondwana in the Eastern Mediterranean realm.

## Geological setting

The Ordovician metagranitoid occurs in the Tavşanlı Zone, a blueschist-

facies metamorphic belt, ~250 km long and ~50 km wide, immediately south of the main Tethyan İzmir-Ankara suture (Fig. 1, Okay, 2002; Droop *et al.*, 2005; Davis and Whitney, 2006). The blueschist sequence in the Tavşanlı Zone consists of basal micaschists, overlain by marbles, which are in turn overlain by a series of metabasite, metachert and phyllite. The blueschists represent a segment of the subducted and subsequently exhumed passive continental margin of the Anatolide-Tauride Block (Okay, 1984). Phengite Rb-Sr and Ar-Ar data from the blueschists indicate a Late Cretaceous ( $80 \pm 5$  Ma) age for the HP/LT metamorphism (Sherlock *et al.*, 1999). The blueschist sequence is tectonically overlain by a Cretaceous oceanic accretionary complex of basalt, radiolarian chert and pelagic shale. Large tectonic slabs of ophiolite, predominantly peridotite, lie over the coherent blueschists or over the accretionary complex (Fig. 1).

The Kapanca metagranitoid crops out in the western part of the Tavşanlı Zone southeast of the town of Orhaneli (Fig. 2). In this region, the blueschists are represented predominantly by micaschist and marble (Lisenbee, 1971; Okay and Kelley, 1994; Okay, 2002). The micaschists form grey, finely banded, hard, medium-grained rocks, at least ~800 m in thickness, representing metamorphosed pelites and

sandstones. The base of the micaschist sequence is not exposed; the schists are overlain by white marbles, over 400 m in thickness. Marble and micaschist bands, several metres thick, are intercalated in the transition zone between the schist and marble series.

The micaschists show a strong ductile deformation with the development of penetrative foliation and mineral lineation. Isoclinal folds are present from the scale of thin section to 200–300 m with generally east-west trending fold axes, parallel to the stretching lineation (Lisenbee, 1971). Thin marble layers in the schists are stretched out in the fold limbs and are seldom continuous for more than a few hundred metres.

The Kapanca metagranitoid is preserved in the core of an open synform south of Orhaneli, and occupies an area of 1.5 km by 1 km with a thickness of ~400 m (Fig. 3). It is underlain either by marble or, where the marble pinches out, by the micaschists. The Kapanca metagranitoid is massive, extremely hard, white to pale grey with medium to coarse grain size and a homogeneous texture. Compared to the surrounding micaschists, it has undergone a small amount of strain; the granitic texture, with equant quartz and jadeite grains or grain aggregates is recognizable in the massive outcrops (Fig. 4). A fine-grained, dark bluish grey metabasite

body, ~100 m across, occurs in the core of the metagranitoid. It is cut by metaaplitic and metapegmatitic veins, and probably represents a co-magmatic intrusion or a large xenolith.

During syn-metamorphic stretching the Kapanca metagranitoid behaved as a rigid body, with marble forming pinch-and-swell structures and boudins, and the micaschist deforming plastically. These differences in rheology led to the juxtaposition of the Kapanca metagranitoid both with the marble and with the micaschists (Fig. 3). However, there is no evidence for post-metamorphic shearing along the contacts. The common high-pressure mineral assemblages in the Kapanca metagranitoid and the surrounding micaschists indicate that they have undergone a common high-pressure metamorphism.

### Geochemistry and petrology

The Kapanca metagranitoid shows a range of  $\text{SiO}_2$  (71–62 wt.%) and low  $\text{MgO}$  (1.0–1.3 wt.%) contents

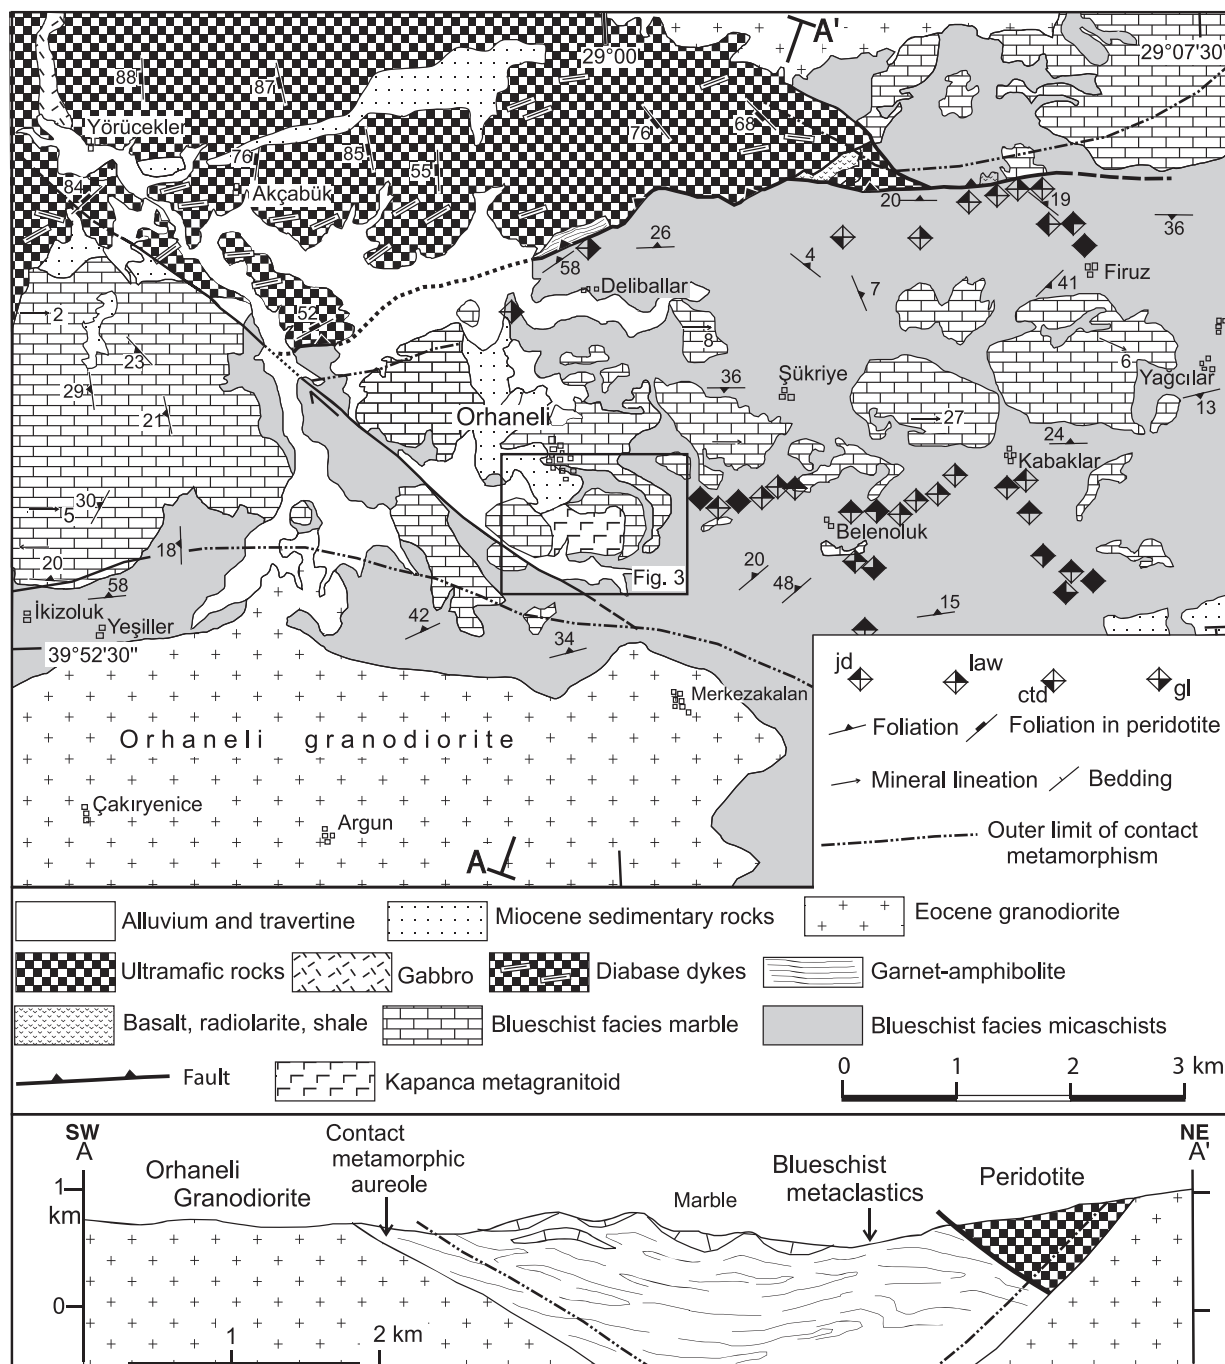

and has a meta-aluminous to weakly peraluminous composition [molar  $\text{Al}_2\text{O}_3/(\text{CaO} + \text{K}_2\text{O} + \text{Na}_2\text{O}) = 0.9 - 1.1$ ] (Table 1). Low Cr and Ni contents together with low Mg number [molar  $\text{MgO}/(\text{MgO} + \text{FeO}^{\text{total}}) = 0.3 - 0.5$ ] suggest a crustal derivation of the granitic magma. A peculiar feature of the metagranitoid is the high  $\text{Na}_2\text{O}$  (5–6 wt.%) and very low  $\text{K}_2\text{O}$  (<1.0 wt.%) contents leading to  $\text{K}_2\text{O}/\text{Na}_2\text{O}$  ratios of <0.2. The surrounding metapelitic micaschists are also highly sodic (Okay and Kelley, 1994) suggesting that the enrichment in  $\text{Na}_2\text{O}$  may be a secondary feature arising from interaction with seawater in a subduction zone, a phenomenon analogous to spilitization. On the basis of molar  $\text{Al}_2\text{O}_3$ ,  $\text{CaO}$ ,  $\text{Na}_2\text{O}$  and  $\text{K}_2\text{O}$  contents, the Kapanca metagranitoid plots in the field of continental-arc granitoids in the plate-tectonic discrimination diagram of Maniar and Piccoli (1989).

The mineral assemblage in the Kapanca metagranitoid is quartz + jadeite + chloritoid + lawsonite +

glaucofan + phengite  $\pm$  albite  $\pm$  chlorite  $\pm$  sericite. Quartz and jadeite constitute over half of the mode. The four minerals, jadeite, chloritoid, sodic amphibole and lawsonite, occur in close proximity and are inferred to be in textural equilibrium. Chlorite, albite and sericite are late minerals. Similar mineral assemblages exist in the surrounding micaschists and indicate peak pressure–temperature conditions for the blueschist-facies metamorphism of  $24 \pm 3$  kbar and  $430 \pm 30$  °C (Okay, 2002).

### Geochronology

Zircons from two samples of Kapanca metagranitoid were dated using the single-grain-stepwise Pb–Pb evaporation method developed by Kober (1986, 1987). The details of the dating procedure are given in Okay *et al.* (2006). The dated zircons, eight grains from each sample, were reddish, 0.063–0.125 or 0.125–0.200 mm long, medium to thick and prismatic. The ages obtained are  $467 \pm 9$  for sample

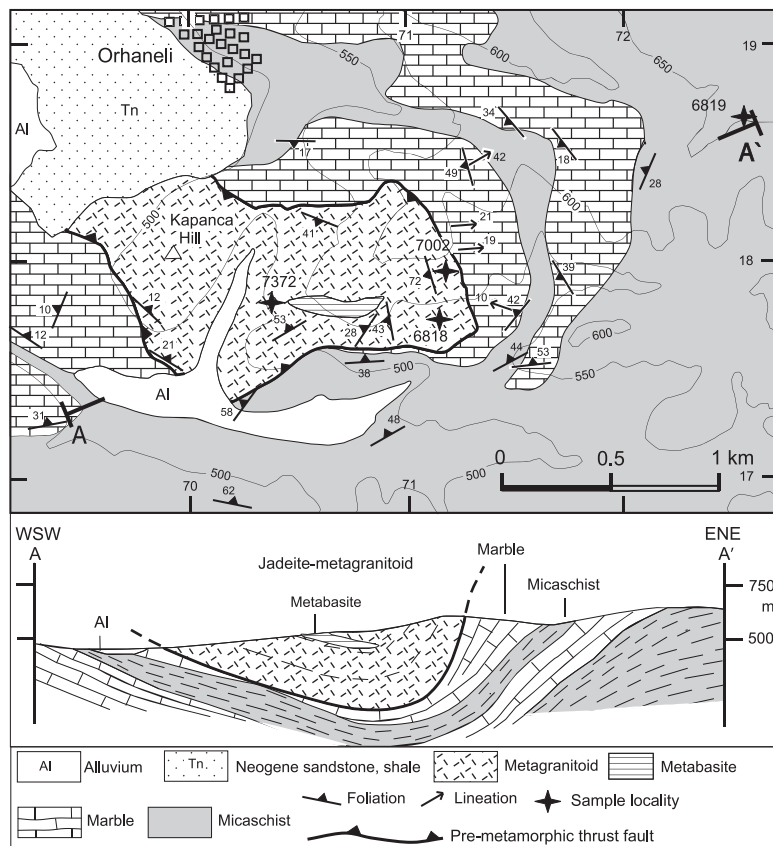

**Fig. 2** Geological map and cross-section of the Orhaneli region (modified from Lisenbee, 1971; Okay, 2002) showing the distribution of the high-pressure mineral assemblages. For location see Fig. 1.

6818A and  $467.0 \pm 4.8$  Ma for sample 6818B (Fig. 5a, Table 2) and yield a mean of  $467.0 \pm 4.5$  Ma (95% confidence level). All 16 zircon grains from the two samples gave similar ages indicating that they reflect the crystallization age of the parent granitic magma during the Middle Ordovician. The temperatures of the

Cretaceous high-pressure metamorphism were too low ( $< 450$  °C) to reset the zircon ages.

We have also dated detrital zircons from an adjacent micaschist to establish whether the Kapanca metagranitoid is a small intrusion or is allochthonous. The dated micaschist (6819) was collected 1.5 km northwest

of the Kapanca metagranitoid and lies structurally underneath the metagranitoid (Fig. 3). It consists of quartz + jadeite + phengite + chlorite + albite. Seventeen zircon grains, all in the range of 0.125–0.200 mm, from the micaschist produced two prominent age peaks (Fig. 5b, Table 2). A broad peak of Cambrian

**Fig. 3** Geological map and cross-section of the jadeite-metagranitoid with sample localities. The geographic coordinates are in UTM and the contours are at every 50 m.

**Fig. 4** Field photo of the jadeite-metagranitoid. The white grains are jadeite and the glassy greyish areas consist of quartz aggregates. Note the lack of strain. The coin is 2 cm across.

and Ordovician ages between 450 and 530 Ma, and a narrow Late Carboniferous peak at *c.* 310 Ma. In addition, one rounded and colourless zircon grain gave a late Archean age of 2563 Ma. Carboniferous zircons were prismatic and reddish, whereas Cambro-Ordovician zircons were rounded and colourless.

The Carboniferous zircon ages from the micaschists indicate that the Kapanca metagranitoid represents either a tectonic sliver from the basement or an olistolith. We favour the former as no metaconglomerates that could be interpreted as debris flows were observed in the micaschist and marble sequence.

We have also dated another micaschist sample, which lies structurally and stratigraphically lower down in the schist series. The sample locality lies 28 km east of Orhaneli in the vicinity of one of the Eocene granodiorites (Fig. 1). The micaschists in this region are overprinted by an Eocene dynamothermal metamorphism that resulted in the loss of the high-pressure mineral assemblages (Okay and Satir, 2006). Sample 5980 contains quartz, albite, muscovite, biotite and chlorite. Three colourless zircon grains with dark inclusions (0.063–0.125 mm, one rounded, one short-prismatic and one long-prismatic) from the biotite-micaschist yielded Proterozoic ages between 1915 and 694 Ma, whereas a fourth grain gave a Carboniferous age, similar to that obtained from the jadeite-micaschist.

The zircon age data indicate that the depositional age of the micaschists is Late Carboniferous or younger. In the Anatolide-Tauride Block, a clastic dominated succession of Palaeozoic to Mid-Triassic age passes up into a Late Triassic to Cretaceous carbonate sequence (e.g. Gutnic *et al.*, 1979). Comparison with this stratigraphy suggests an Early to Mid Triassic depositional age for the micaschists.

## Discussion

The Kapanca metagranitoid forms a pre- to syn-metamorphic tectonic slice immediately south of the İzmir-Ankara suture (Fig. 1), which might suggest a tectonic derivation from the Pontides. However, the deformation and metamorphism in the Tavşanlı Zone pre-dates the Palaeocene – Early

Eocene collision with the Pontides and is related to the Cretaceous subduction of the Anatolide-Tauride Block at a mid-oceanic trench (e.g. Okay and Tüysüz, 1999). Hence, the Kapanca metagranitoid cannot be an exotic thrust sheet from the Pontides, but represents a fragment from the basement of the Anatolide-Tauride Block.

Palaeogeographic reconstructions place the Anatolide-Tauride Block at the northern margin of Gondwana between Egypt and Cyprus during the Palaeozoic with separation from Gondwana occurring in the Triassic (Fig. 6, e.g. Şengör and Yılmaz, 1981; Stampfli and Borel, 2002; Garfunkel, 2004). The recent recognition of Late Ordovician glacial deposits in the Anatolide-Tauride Block and in the Arabian Platform of southeast Anatolia also place constraints on the Ordovician palaeogeography of the Eastern Mediterranean region (Monod *et al.*, 2003). However, it is uncertain what lay to the north of the Anatolide-Tauride Block during the Ordovician. Although the Pontides are also Gondwana derived, they do

**Fig. 5** Histograms showing the distribution of radiogenic lead isotope ratios derived from the evaporation of: (a) 16 zircon grains from the jadeite-metagranitoid samples 6818A and 6818B, (b) 18 zircon grains from the jadeite-micaschist sample 6819, (c) five grains from the biotite-micaschist sample 5980.

not constitute a conjugate margin with the Anatolide-Tauride Block (e.g. Stampfli, 2000; Okay *et al.*, 2006). Therefore, their basement, which includes minor Ordovician (c. 460 Ma) granitoids (Okay *et al.*, 2008) does not represent the northern extension of the Anatolide-Tauride basement.

No Ordovician magmatic rocks are reported from the Palaeozoic sequences of the Anatolide-Tauride Block. In the Tauride Palaeozoic series, Lower Ordovician shales and siltstones (the Seydişehir Formation) are generally unconformably overlain by Upper Ordovician deposits with glacial conglomerates and sandstones (e.g. Monod *et al.*, 2003). Ordovician magmatism is also not known from the Arabian platform. In contrast, Ordovician magmatic rocks are described from peri-Gondwana terranes, such as the Massif Central (e.g. Roger *et al.*, 2004), the Pyrenees

(Deloule *et al.*, 2002), the Saxothuringian (Schätz *et al.*, 2002) and the Alps (von Raumer *et al.*, 2002). The tectonic setting of the Ordovician magmatism in these peri-Gondwana terranes possibly includes rift, magmatic arc as well as late- to post-collisional settings (von Raumer *et al.*, 2003; Mattauer, 2004). In the plate-tectonic discrimination diagrams based on major elements the Kapanca metagranitoid plots in the field of continental-arc granitoids. However, these diagrams make use of alkali elements, which can be highly mobile during metamorphism (e.g. Pearce, 1976; Allen *et al.*, 1985). The Ordovician sequences in the Anatolide-Tauride Block do not comprise any volcanic rocks or volcanic-derived detritus (e.g. Gutnic *et al.*, 1979; Monod *et al.*, 2003), and this is not compatible with the presence of a major magmatic arc on the northern margin of the Anatolide-Tauride Block. On the other hand, most

All age errors are 2 sigma plus assumed error of 0.1% which includes potential bias caused by mass fractionation of Pb isotopes and uncertainty in linearity of the multiplier signal. See error calculation formula below.

The age error of each temperature step was calculated according to the formula:

The number of  $^{207}\text{Pb}/^{206}\text{Pb}$  isotope ratio scans ( $n$ );

The 2sigma (2 $\sigma$ ) standard error of the Gaussian distribution function;

$\Delta f$  an assumed error of 0.1% which includes potential bias caused by mass fractionation of Pb isotopes and uncertainty in linearity of the multiplier signal

$$\Delta \text{age} = \sqrt{\left(\left(\frac{2\sigma}{\sqrt{n}}\right)^2 + \Delta f^2\right)}.$$

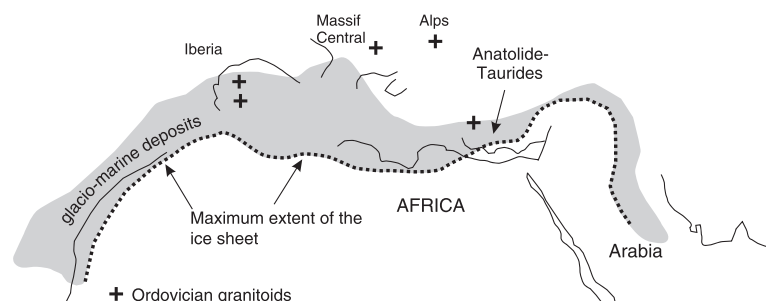

Fig. 6 Distribution of Ordovician granitoids (von Raumer *et al.*, 2002) and the glacial deposits (Monod *et al.*, 2003) in the Eastern Mediterranean realm.

palaeogeographic reconstructions show Ordovician rifting of a continental sliver, corresponding to the eastern extension of Avalonia, from the northern margin of the Anatolide-Tauride Block (e.g. Stampfli, 2000; Cocks and Torsvik, 2002). Based on subsidence analysis from the Welsh basin, the rifting of Avalonia from Gondwana is considered to have occurred between 480 and 462 Ma (Prigmore *et al.*, 1997), compatible with the  $467.0 \pm 4.5$  Ma age of the Kapanca granitoid. Many of the peri-Gondwana terranes in western and central Europe comprise Cambro-Ordovician orogenic units including ophiolites and volcanic rocks (e.g. von Raumer *et al.*, 2002). Absence of such sequences in the Anatolide-Tauride Block indicate that it lay closer to the stable interior of Gondwana during the Early Palaeozoic, implying a rift-related origin for the Kapanca metagranitoid.

Although most of north-east Africa is characterized by Pan-African crystalline rocks (500–900 Ma, e.g. Kröner *et al.*, 1994), detrital zircons of this age range are rare in the blueschist micaschists, which are dominated by Carboniferous zircons; the prismatic detrital Carboniferous zircons indicate a nearby magmatic source. As Carboniferous intrusives are not known from the Anatolide-Tauride Block, the source must have lain farther north or northwest possibly in the Strandja and Rhodope massifs in the Balkans, where Carboniferous and Early Permian granitoids with ages of 315–285 Ma are widespread (Wawrzenitz and Krohe, 1998; Okay *et al.*, 2001; Carrigan *et al.*, 2005, 2006). This is compatible with palaeogeographic reconstructions, which show a westward termination of Palaeo-tethys in the vicinity of Turkey resulting in the Variscan

belt being positioned close to the Anatolide-Tauride block during the Triassic (e.g. Stampfli, 2000; Matte, 2001; Zanchi *et al.*, 2003; Okay *et al.*, 2006).

## Conclusions

The Middle Ordovician Kapanca metagranitoid occurs within the micaschists and marbles of the Tavşanlı Zone in northwest Turkey. It shares a common metamorphic and structural history with the host rocks, all having undergone a Late Cretaceous high pressure metamorphism. Field relations and zircon age data from the underlying micaschists show that the Kapanca metagranitoid is not an intrusion but rather a pre- or syn-metamorphic tectonic sliver from the basement. The major-element geochemistry of the Kapanca granitoid is compatible with a continental-arc tectonic setting. However, the absence of volcanic rocks or volcanic-derived detritus in the Ordovician sequences of the Anatolide-Tauride Block implies a rift-related setting possibly related to rifting of terranes that lay north of the Anatolide-Tauride Block.

The presence of prismatic detrital zircons of Carboniferous age in the micaschists with a Triassic depositional age shows that the northern margin of the Anatolide-Tauride Block was close to the Variscan orogen during the Triassic.

## Acknowledgements

This study was completed during the tenure of a Fulbright fellowship in UCSB to the senior author. The fieldwork in the Orhaneli region was supported by the TÜBİTAK grant YDABÇAG 419/G. We thank G. Batholomae for the help with the XRF analysis, Necdet Özgül for discussions. P.Ö. Ustaömer, Antonio Garcia-Casco, Dimitrios Kostopoulos and an anonymous reviewer provided constructive comments, which markedly improved the manuscript.
