The presence of cool, dense mass in the hot, rarefied solar corona, in the form of prominences, has mystified scientists for over a century. Its more fragmentary and dynamic manifestation, coronal rain, was discovered more recently but has been equally perplexing. Several processes have been proposed to explain this phenomenon: levitation (bulk lifting of chromospheric mass into the corona), injection (bulk expulsion of chromospheric mass), and evaporationcondensation methods. This talk addresses the last category, which has received the greatest quantitative scrutiny over the past 20 years, particularly in the form of thermal nonequilibrium (TNE). Thermal nonequilibrium has specific requirements and observable signatures, which have been explored thoroughly with theoretical analyses, numerical simulations, and comparison with known characteristics of prominences and coronal rain. I will discuss the basic physical processes at the heart of TNE, the parameter studies that have established the strengths and limitations of this mechanism as applied to these solar phenomena, the latest extensions to multidimensional magnetic geometries and more realistic physics, and future research directions.

D2.2-0003-18 EVOLVING CLASSIFICATIONS OF SOLAR PROMINENCES

Sara F. Martin, sara@helioresearch.org

Helio Research, La Crescenta, California, United States

Classification schemes with main classes and subclasses began with Sechi in 1875 who categorized prominences mostly from their shapes. With the aid of spectroheliograms and photography, the number of different categories of prominences maximized with Petit from 1925-1950 who added classes according their dynamics, and relationships to active regions and solar flares. With the recognition that not all prominences seen at the limb corresponded to features seen against the disk, many observers began referring to disk prominences as "filaments." With the greater abundance of data enabled by the use of birefringent, interference filters and timelapse photography, many attempts were made through the 1960s to created physically significant prominence (filament) classifications as cited in the two books on solar prominences by Tandberg-Hanssen. Reversal of the trend for increasingly complex classifications began in the 1950s after invention of the magnetograph. Filaments in Hα were all found to lie between areas of opposite polarity, line-of-sight magnetic fields. Features, such as flare loops, spicules, and surges acquired separate identities and no longer needed to be classified as prominences. Observations with increased spatial resolution allowed the identity of fine thread-like structure within the basic spine and barb structure of filaments. The recognition of chirality in the threads of filaments and of fibrils in their filament channels enabled the unifying of all filaments under the name channel filaments (channel prominences). 304Å observations aided detection of greater numbers of coronal cloud prominences, funnel prominences, and coronal rain. Funnel prominences and coronal cloud prominence are deduced to be the same basic structures seen from different perspectives but not all coronal rain comes from coronal cloud prominences. Therefore, prominence classifications are reduced to three physically-different phenomena: channel prominences, coronal cloud prominences and coronal rain. An open question is whether all features called coronal rain are fundamentally the same.

D2.2-0004-18 A MODEL FOR HOW INDUCED REVERSED-CURRENTS FORM CAVITIES ABOVE PROMINENCES

Magnus Haw, mhaw@caltech.edu

California Institute of Technology, Pasadena, California, United States Pakorn Wongwaitayakornkul, pwongwai@caltech.edu

California Institute of Technology, Pasadena, California, United States Hui Li, hli@lanl.gov

Los Alamos National Laboratory, Los Alamos, New Mexico, United States Paul Bellan, pbellan@caltech.edu

California Institute of Technology, Pasadena, California, United States

Solar prominences are often observed to have an associated cavity, i.e., a region of depleted density and twisted magnetic field. Cavities are traditionally assumed to be the projection of a surrounding magnetic flux rope and are observed above both stable and erupting prominences [1]. How cavities form is of particular interest because cavity formation is an observable feature closely associated with the large-scale structure of the magnetic field [1,2].

Existing theories of cavity formation use 1D hydrostatic models along fixed magnetic field lines [1,2]. These theories are limited to specific magnetic equilibria and are characterized by hydrostatic scaling resulting from stratification in the presence of a gravitational field. However, measurements of cavity density have shown that the density depletion relative to the background is maximum at low altitude and minimum or zero at the top of the cavity [3]. This implies that a mechanism independent of gravitational stratification is likely responsible for cavity formation.

We propose a model whereby a dynamic, magnetically driven mechanism is responsible for cavity formation, equilibrium, and evolution. The model is motivated by experimental measurements of cavity formation above an erupting flux rope in the Caltech single-loop experiment and also by matching results from 3D numerical MHD simulations. This model provides a detailed explanation for cavity evolution in terms of the repulsion between primary and induced reverse currents in a prominence. The model explains several observed trends including (i) why cavity density depletion is greatest at low altitude and (ii) why prominences with larger cavities are more likely to erupt.

D2.2-0005-18 FORMATION OF MOLECULAR GAS PROMINENCES IN GALACTIC CENTRAL REGION

Ryoji Matsumoto, matsumoto.ryoji@faculty.chiba-u.jp Chiba University, Chiba, Japan

Chih-Han Peng, julian8128@chiba-u.jp Chiba University, Chiba, Japan

We present the results of magnetohydrodynamic simulations of the formation of molecular loops (loops of dense molecular gas) found by Fukui et al. (2006) in our galactic central region. The length of the molecular loops is several hundred pc, and their height exceeds 100pc. The total mass of a molecular loop is around 106 solar mass. The galactic center molecular loops are similar to solar prominences because dense, cold ($T < 100K$) medium is floating in warm (T 6000K) medium.

Since it is hard to form molecular loops by uplifting dense molecular gas, we considered an in-situ formation model of molecular gas by applying the reconnection-condensation model of solar prominences, in which prominences are formed by cooling instability in helical magnetic flux ropes formed by footpoint motions of the magnetic arch. We conducted two-dimensional and three-dimensional resistive magnetohydrodynamic simulations taking into account the cooling/heating of the interstellar medium. The galactic gravitational field is simulated by using the Miyamoto-Nagai gravitational potential. The simulation region is a local part of the galactic disk corotating with the disk. At the initial state, we assumed force-free magnetic arcades and hydrostatic layer in thermal equilibrium in warm state.

Numerical results indicate that magnetic reconnection taking place in the current sheet formed inside the rising magnetic arcade creates dese blobs confined by helical magnetic flux ropes. Thermal instability in the flux ropes forms dense filaments floating at 100-200pc above the galactic plane. The mass of the filament increases with time and exceeds 105 solar mass. The position-velocity diagram depicted by numerical results reproduces the position-velocity diagram obtained by CO observations.

The region just outside the Central Molecular Zone (CMZ) in our galactic center is the most suitable place for the molecular loop formation because the equilibrium density of the warm gas is high due to the enhanced heating in the galactic center. Strong magnetic fields in the galactic center also helps to sustain the dense loops against gravity.

D2.2-0006-18 THE IMPACT OF MAGNETIC FIELDS ON THERMAL INSTABILITY

Suoqing Ji, jisuoqing@gmail.com

University of California, Santa Barbara, Santa Barbara, California, United States

Cold filaments or prominences are ubiquitous in our universe, which exist in a wide range of astrophysical objects from solar corona to galaxy halos and galaxy clusters. In this talk, I will raise thermal instability as a possible mechanism leading to filaments or prominences, and investigate how magnetic fields can significantly enhance thermal instability and modify the structure of multiphase gas, which is applicable for both galaxy halos and galaxy clusters, and is potentially illuminating for the formation of prominences in solar corona.

D2.2-0007-18 A LONG-LIVED CORONAL CONDENSATION SITE LASTING EIGHT MONTHS

Cool plasma material, such as prominences or coronal rain, can form in-situ by condensation in the solar corona due to a runaway radiative cooling instability (a.k.a. thermal non-equilibrium). Recent observations and numerical simulations suggest that such condensations are quite common. In quiet-Sun regions, they occur preferentially in locations where magnetic field is weak (e.g., null points) or discontinuous (e.g., current sheets). Such events usually have short lifetimes of hours to days. Surprisingly, we observed a high-latitude condensation site lasting over eight months in 2014 with recurrent and episodic condensations fueling a funnel-shaped prominence. Uplifting V-shaped features suggest sustaining reconnection inside the funnel. We analyze the coronal magnetic topology to investigate the necessary condition of such a long-lived condensation site. We find that the site was directly above a poleward photospheric flux surge when the polar field polarity was close to its solar cycle reversal. The large-scale magnetic cancellation front may have sustained interchange reconnection at this location, creating suitable conditions for coronal plasma condensation.

D2.2-0008-18 LARGE-SCALE MAGNETIC FUNNELS IN THE SOLAR CORONA

Olga Panasenco, panasenco.olga@gmail.com

Advanced Heliophysics, Inc., Pasadena, California, United States Marco Velli, mvelli@ucla.edu

University of California, Los Angeles, Los Angeles, California, United States Aram Panasenco, panasencoaram@gmail.com

University of California, Los Angeles, Los Angeles, California, United States

The existence of open coronal magnetic fields with peculiar geometry - large-scale coronal magnetic funnels - can be attributed to two main factors: (i) the presence of two or more coronal holes of the same polarity forming coronal pseudostreamers, (ii) specific configurations of closed magnetic field in the low corona - filament channels. The important property of magnetic funnels is their strongly non-monotonic expansion factor below 2 solar radii. In the case study presented here we consider a double pseudostreamer near the equator, formed between a triplet of isolated coronal holes of the same polarity, and harboring two pairs of twin filaments in its base. Following the evolution of these coronal holes we find that the pseudostreamer and, therefore, magnetic funnel topology, changes when two coronal holes have merged together. Using a potential field source-surface (PFSS) extrapolation to compute the coronal field from photospheric maps (SDO/HMI), we show that the funnel - like geometry of the open magnetic field changes to a regular one with monotonic expansion factor after the merging of coronal holes. The presence of coronal magnetic funnels becomes directly visible when sufficient plasma accumulates inside them: when the plasma density grows to become observable, coronal cloud prominences appear in the corona, mostly in 304 A spectral line. We study the evolution of the funnel - like open magnetic fields during several solar rotations and find a direct relation between magnetic funnels and the presence of coronal clouds at great heights in the solar corona. 1D numerical analysis of pseudostreamers with funnel topology shows that the properties of the solar wind from coronal magnetic funnels depend on the presence/absence of filament channels, number of channels and chirality at the pseudostreamer base low in the solar corona.

D2.2-0009-18 THE CORONAL MONSOON: THERMAL NONEQUILIBRIUM REVEALED BY PERIODIC CORONAL RAIN

Institut d'Astrophysique Spatiale, ORSAY, France

We report on the discovery of periodic coronal rain in an off-limb sequence of SDO/AIA images. The showers are co-spatial and in phase with periodic (6.6 hr) intensity pulsations of coronal loops of the sort described by Auchère et al. (2014) and Froment et al. (2015, 2017. These new observations make possible a unified description of both phenomena. Coronal rain and periodic intensity pulsations of loops are two manifestations of the same physical process: evaporation / condensation cycles resulting from a state of thermal nonequilibrium (TNE). The fluctuations around coronal temperatures produce the intensity pulsations of loops, and rain falls along their legs if thermal runaway cools the periodic condensations down and below transition-region (TR) temperatures. This scenario is in line with the predictions of numerical models of quasi-steadily and footpoint heated loops.

This event of periodic coronal rain is compared with a similar event showing only pulsations at coronal temperatures but no significant cool rain fall. For both events we have stereoscopic observations from the SDO and STEREO spacecraft which allows reconstruction of the 3D loop geometries. Comparison with numerical simulations suggest that these two events correspond to two regimes of TNE: one with "full condensations" (coronal rain) and another in which "incomplete condensations" start to develop but are pushed down one loop leg before they can reach chromospheric temperatures.

These new observations impose severe constrains on the spatio-temporal distribution of coronal heating.

The numerical solution of the magnetohydrodynamic (MHD) equations allows us to investigate prominences/filaments represented by cold and dense plasmas suspended against gravity, and supported by the magnetic field. Our interest is in models that connect the magnetic field to the photosphere and include an overlying arcade. Two basic types of such structures are considered, prominences incrusted in shear magnetic arcades, and prominences embedded in three-dimensional magnetic flux ropes. Depending on the parameters, we find structures that are suspended above the photosphere, but also configurations resembling curtain or hedgerow prominences. During their evolution magnetic Rayleigh-Taylor instabilities and Kelvin-Helmholtz instabilities develop, producing a reach dynamics in the system. Special attention is devoted to all the oscillatory phenomena that takes place during the time evolution of the prominences. Finally, the problem of how the neutral component of the plasma in prominences is supported against gravity is addressed. We find that the system is able to relax in the vicinity of magnetic dips to a stationary state in which both neutrals and ionized species are dynamically suspended above the photosphere.

D2.2-0011-18 NUMERICAL MODELING OF PROMINENCE FORMATION FROM RECONNECTION TO RADIATIVE CONDENSATION

Takafumi Kaneko, kaneko@isee.nagoya-u.ac.jp

Institute for Space-Earth Environmental Research, Nagoya University, Nagoya, Japan Takaaki Yokoyama, yokoyama.t@eps.s.u-tokyo.ac.jp

University of Tokyo, Tokyo, Japan

We briefly review recent progress in numerical modeling for prominence formation and introduce our model, reconnection-condensation model. Origin of cool dense plasmas and mechanism of mass maintenance in the hot tenuous corona is one of the most important subjects in studies of solar prominences. Radiative cooling condensation is a promising process to supply mass for prominences. The formation mechanism of fine structures and turbulence in prominence and their physical role for mass condensation are also unclear.

Numerical modeling is useful to investigate these issues. In previous numerical studies, it is known that chromospheric evaporation driven by parameterized footpoint heating leads to in-situ coronal condensation. The evaporation-condensation model was demonstrated in a three-dimensional flux rope structure using magnetohydrodynamic (MHD) simulations including thermal conduction and radiative cooling, and succeeded in reproducing prominences with fine structures by fragmented condensations. Despite these efforts, the issue on unclear origin of the footpoint heating still remains.

We attempt to consider a different process leading to radiative condensation. In observations, prominences always appear along polarity inversion lines, suggesting that cancelation or reconnection must be related to radiative condensation. In the previous simulations on radiative condensation, self-consistent multi-dimensional reconnection process were absent. We propose reconnection-condensation model and demonstrate it using three-dimensional MHD simulations including nonlinear anisotropic thermal conduction and optically thin radiative cooling. In our model, a flux rope is created by reconnection via converging footpoint motion. By elevation of dense coronal plasmas and topological change in coronal magnetic fields, radiative condensation is triggered inside the flux rope. Our results show clear link between reconnection and radiative condensation, and suggest that evaporation is not always necessary.

Recently, we improved the model to include dynamic fine structures by the Rayleigh-Taylor instability. We found that mass condensation rate is enhanced to balance with mass drainage rate by coupling with the Rayleigh-Taylor instability. We compare the simulation results with observations and discuss remained issues in numerical modeling for prominence formation.

D2.2-0012-18 MULTIDIMENSIONAL SIMULATIONS ON EVAPORATION-CONDENSATION IN COMPLEX CORONAL MAGNETIC FIELD

Chun Xia, chun.xia@ynu.edu.cn Yunnan University, Kunming, China

Rony Keppens, rony.keppens@kuleuven.be KU Leuven, Leuven, Belgium

We present multidimensional simulations to illuminate that evaporation-condensation process can produce both prominence and coronal rain depending on the complexity of magnetic topology. On a two-dimensional (2D) magnetic arcade, we demonstrate how evaporationcondensation can induce in-situ cross-field condensations which fall along arcade loops as coronal rain. The virtual coronal rain displays the deformation of blobs into V-shaped features and streaming lines. The transition region between cool dense material and hot coronal plasma is revealed with high-resolution simulation. We found shear flows along neighboring loops are siphon flows set up by multiple blob dynamics and they affect the deformation of the falling blobs. On a three-dimensional (3D) weak magnetic bipolar arcade, we found fast in-situ condensation across loop top due to symmetry. The first large-scale condensation on the loop top suffers Rayleigh-Taylor instability and becomes fragmented into smaller blobs. The blobs fall vertically dragging magnetic loops until they enter the lower region with stronger magnetic field and start to fall along the loops from loop top to loop footpoints as coronal rain. On a 2D quadrupolar magnetic system with a coronal null point and four groups of magnetic loops, we present how evaporation-condensation produce a prominence in the dipped magnetic region. And subsequent descending of the prominence triggers magnetic reconnection near null point, which leads to redistribution of prominence material to underlying loops to be coronal rain. In a 3D helical magnetic flux rope, we reproduced a prominence formation as a result of in-situ plasma condensations collected in the dipped magnetic regions of the flux rope. The prominence is born and maintained in a fragmented, highly dynamic state with a continuous reappearance of multiple blobs and thread structures that move mainly downward dragging along massloaded field lines. A plasma circulation is found by self-organized dynamic balance between the drainage of prominence plasma back to the chromosphere and the formation of prominence plasma via continuous condensation. Common features, such as, rebound shocks generated by the siphon inflows during condensation and counter-streaming shearing flows around dynamic condensed blobs, are discussed.

D2.2-0013-18 THE EFFECT OF THERMAL NONEQUILIBRIUM IN STREAMERS

Spiro Antiochos, spiro.antiochos@nasa.gov

NASA Goddard Space Flight Center, GREENBELT, Maryland, United States Emily Mason, emily.mason@nasa.gov

Catholic University of America, Washington DC, District of Columbia, United States

Thermal nonequilibrium (TNE) is the process in which a solar coronal loop undergoes a nonsteady cycle of condensation formation due to the spatial localization of coronal heating near the loop base. Since the requirements for TNE onset is that the loop length is large compared to the scale of the heating, we investigate the effects of TNE on the largest loops in the corona, those of a helmet streamer. Our numerical study uses a 2.5D MHD code that includes the full magnetic field dynamics as well as the detailed plasma thermodynamics. As in previous 1D loop studies, we find that TNE occurs in coronal loops with sufficiently large length, but in contrast to 1D studies, we find that the process also drives substantial magnetic dynamics, especially near the top of the streamer where the plasma beta becomes of order unity. From the simulation results we determine predictions for spectroscopic and imaging observations of both the hot and cool helmet streamer plasma. We conclude that TNE occurring in the largest closed loops in the corona may explain several puzzling observations of the corona, such as the ubiquitous blue shifts observed at the edges of active regions. We also discuss the implications of our results for the solar wind.

IAS, CNRS / Univ. Paris Sud XI, Orsay, France

Long-period intensity pulsations have been recently detected in coronal loops with EUV images of both SoHO/EIT (Auchère et al., 2014) and SDO/AIA (Froment et al., 2015). These pulsations have been interpreted as resulting from thermal non-equilibrium (TNE), thus providing a signature of a highly-stratified and quasi-constant heating at the loops footpoints (Froment et al., 2017; Auchère et al., 2016). Depending on the adequacy between the geometry of the loop and the characteristics of the heating, this can result in either complete (at chromospheric temperatures) or incomplete (> 1 MK) condensation and evaporation cycles, that are responsible for the observed intensity pulsations. Using 1D hydrodynamic simulations, Froment et al. (2017) were able to reproduce the observed pulsations, with incomplete condensation for the active region studied in their previous paper. The simulations also predict periodic plasma flows along the loops footpoints, with velocities up to 40 km/s.

We try to detect these flows by using time series of spatially resolved spectra from the EUV spectrometer Hinode/EIS. We systematically search for EIS datasets that correspond to the observation of pulsation events among the 3000+ that were detected in AIA data, between 2010 and 2016. For the 9 datasets that are found, we derive series of Doppler velocity maps, which allows us to track the evolution of the plasma velocity in the loop over several pulsation periods. We then compare these data to the results of previous simulations and observations. However the expected pulsations in velocity cannot be identified in any of the datasets that we analysed. We demonstrate that line of sight ambiguities, combined with low signal to noise ratio or lack of time cadence, can explain this non-detection.

D2.2-0015-18 EVOLUTION OF MAGNETIC-TOPOLOGY DURING ERUPTION OF A LABORATORY ARCHED MAGNETIZED PLASMA

Shreekrishna Tripathi, tripathi@physics.ucla.edu

University of California Los Angeles, Los Angeles, California, United States Kamil Krynski, kkrynski@g.ucla.edu

University of California Los Angeles, Los Angeles, California, United States Walter Gekelman, gekelman@physics.ucla.edu

University of California Los Angeles, Los Angeles, California, United States

The solar atmosphere is carpeted with arched magnetic structures that confine plasma and store energy over a broad range of spatio-temporal scales. Solar eruptive events (e.g., coronal mass ejections and flares) are triggered when these structures become unstable by a variety of fundamental processes (e.g., force-imbalance, magnetic-reconnection, current-driven instabilities). Contemporary research on these topics is at the forefront of solar and heliospheric physics due to its relevance to space weather. After briefly reviewing the progress made in this area and highlighting the importance of laboratory experiments, new results from the UCLA

experiment on arched magnetized plasmas (plasma β 10−3, Lundquist number = 102-105,

plasma radius/ion-gyroradius 20, B 1000 Gauss at footpoints) will be presented. The arched magnetized plasma was created using a lanthanum hexaboride (LaB6) plasma source and it evolved in an ambient magnetoplasma produced by another source. The experiment runs continuously with a 0.5 Hz repetition rate and produces tens of thousands of nearly identical eruptions within a day. This unique feature provides flexibility in recording the plasma parameters with a good-resolution in three-dimensions. During the time-evolution of the arched magnetoplasma, multiple-frames were captured using a fast-CCD camera and correlated with the magnetic-topology recorded using a three-axis magnetic-loop probe. The relative magnitudes of the parameters of the arched and ambient magnetoplasma were varied to simulate conditions relevant to arched magnetized plasmas on the Sun. This laboratory research provides important details of physical processes that occur before and after eruption of arched magnetized plasma structures (e.g., spontaneous excitation of Alfven waves and kink-mode oscillations, ejection of large scale flux ropes).

D2.2-0016-18 EXPERIMENTAL INVESTIGATION OF COAXIAL-GUN-FORMED PLASMAS INJECTED INTO A BACKGROUND TRANSVERSE MAGNETIC FIELD OR PLASMA

Yue Zhang, yzhang16@uw.edu

University of Washington, Seattle, Washington, United States Dustin Fisher, dufisher@unm.edu

University of New Mexico, Albuquerque, United States Mark Gilmore, mgilmore@unm.edu

University of New Mexico, Albuquerque, United States Scott Hsu, scotthsu@lanl.gov

Los Alamos National Laboratory, Los Alamos, New Mexico, United States

Injection of coaxial-gun-formed plasma jets (open B-field) and plasma spheromak/bubbles (closed B-field) into a background transverse vacuum magnetic field or into a background magnetized plasma has been studied in the helicon-cathode (HelCat) linear plasma device at the University of New Mexico.[1] These situations may have bearing on astrophysical settings (e.g. astrophysical jet stability, coronal mass ejections, etc.) and fusion plasmas (e.g. plasma injection for tokamak fueling, ELM pacing, or disruption mitigation). The magnetic Reynolds number of the gun plasma is 100, so that magnetic advection dominates over magnetic diffusion. The gun plasma ram pressure, ρjetV 2 >B2/2μ0, the background magnetic pressure, so jet 0

that the jet or bubble can easily penetrate the background B-field, B0. When the gun axial B-field is weak compared to the gun azimuthal field, a current-driven jet is formed with a global helical magnetic configuration. Applying the transverse background magnetic field, it is observed the emergent kink stabilization of the jet due to the formation of a sheared flow in the jet above the threshold 0.1kVA.[2] We conclude that the tension force arising from increasing curvature of the background magnetic field induces the measured sheared flow gradient, resulting in the emergent kink stabilization.[3] In the case of injected bubbles, spheromak-like plasma formation is verified. However, launching into a transverse background magnetic field led to the observation of finger-like structures on the side with a stronger magnetic field null between the spheromak and background field. The finger-like structures are consistent with magneto-Rayleigh-Taylor instability. Jets or spheromaks launched into a background, low-β magnetized plasma show similar behavior as above, respectively, in both cases.

D2.2-0017-18 OBSERVATIONS OF A SHEAR-FLOW INSTABILITY DRIVEN BY DYNAMIC PROMINENCE MOTIONS

Andrew Hillier, a.s.hillier@exeter.ac.uk

University of Exeter, UK, Exeter, United Kingdom

V. Polito, vp323

Cambridge University, Cambridge, United Kingdom

Prominences are incredibly dynamic across the whole range of their observable spatial scales, with observations revealing gravity-driven fluid instabilities, waves, and turbulence. With all these complex motions, it would be expected that instabilities driven by shear in the fluid motions contained in the prominence body would develop. However, evidence of these have been lacking. Here we present the discovery in a prominence, using observations from the Interface Region Imaging Spectrograph (IRIS), of a shear flow instability, a mode of the Kelvin-Helmholtz instability that makes streams of fluid develop serpentine patterns, driven by transonic motions in the prominence body. This finding presents a new mechanism through which we can create turbulence from the flows observed in quiescent prominences. The observation of this instability in a prominence highlights their great value as a laboratory for understanding the complex interplay between magnetic fields and fluid flows that play a crucial role in a vast range of astrophysical systems.

D2.2-0018-18 THREE-DIMENSIONAL VELOCITY MEASUREMENTS IN SOLAR PROMINENCE BUBBLES AND COMBINED KELVIN-HELMHOLTZ/ RAYLEIGH-TAYLOR INSTABILITY

Thomas Berger, thomas.berger@colorado.edu

University of Colorado at Boulder, Boulder, Colorado, United States
Wei Liu, weiliu@lmsal.com

Bay Area Environmental Research Institute / Lockheed Martin Solar and Astrophysics Laboratory, Moffett Field, California, United States

Andrew Hillier, a.s.hillier@exeter.ac.uk

University of Exeter, UK, Exeter, United Kingdom

We present measurements of flow velocities in solar prominences that display so-called "prominence bubble" events. Prominence bubbles are large-scale buoyant intrusions into prominences that rise from below and penetrate into the overlying plasma. They are believed to be due to magnetic flux emergence below prominences and can trigger Rayleigh-Taylor and KelvinHelmholtz instability flows as they interact with the overlying prominence. Prominence bubbles frequently result in the formation of plumes that rise into, or entirely through, the overlying prominence. This presents a mechanism for increasing magnetic flux and helicity in the associated coronal magnetic flux tubes, which are key for their eventual loss of equilibrium and eruptions as coronal mass ejections (CMEs).

In this presentation, Hinode/Solar Optical Telescope (SOT) and Interface Region Imaging Spectrograph (IRIS) observations are analyzed to infer three-dimensional flow vectors in the "boundary layer" above several prominence bubble events. IRIS Doppler velocity measurements indicate flow speeds of 50–100 km/sec perpendicular to the sky plane, consistent with flow speeds inferred from combined Kelvin-Helmholtz/Rayleigh-Taylor instability analysis using typical quiescent prominence density and magnetic flux density values. With these typical values, flow speeds and magnetic flux densities within the bubbles can be inferred to be on the order of 100 km/sec and 10 Gauss, respectively. We discuss the implications of these novel results, and in particular, the potential for strong shear flows at the bubble boundary to trigger Kelvin-Helmholtz instability waves that develop into large-scale Rayleigh-Taylor instability plumes.

Spain

Coronal rain blobs usually fall toward the solar surface with a smaller than free-fall acceleration. After conducting numerical simulations with different setups, we conclude that once a dense blob forms and starts to fall along a coronal loop, a pressure gradient is established along the loop such that higher (smaller) pressure can be found below (above) the blob. This pressure gradient produces an upward force that partially counteracts gravity and leads to the observed non-free-fall dynamics.

D2.2-0020-18 EXCITATION AND EVOLUTION OF TRANSVERSE LOOP OSCILLATIONS BY CORONAL RAIN

Erwin Verwichte, erwin.verwichte@warwick.ac.uk University of Warwick, Coventry, United Kingdom Petra Kohutova, p.kohutova@warwick.ac.uk University of Warwick, Coventry, United Kingdom

Coronal rain is composed of cool dense blobs that form in solar coronal loops and are a manifestation of catastrophic cooling linked to thermal instability. The nature and excitation of oscillations associated with coronal rain is not well understood. We present an overview of observations of coronal rain oscillations seen in data from IRIS, SOT/Hinode and AIA/SDO as well as ground-based observatories. We follow this with detailed analytical and numerical MHD modelling to elucidate the excitation mechanism and evolution of wave characteristics in rain. We will discuss the possibility for rain blobs to excite transverse oscillations due to gravitational or inertial forces as well as acoustic oscillations due to a piston effect. In particular, we shall highlight the first evidence of the excitation of vertically polarised transverse loop oscillations triggered by a catastrophic cooling at the loop top and consistent with inertial excitation due to two thirds of the loop mass comprising of cool rain mass. The seismological capability of the oscillation is exploited to deduce the relative rain mass. It is shown to be consistent with the evolution of the oscillation period showing the loop losing a third of its mass due to falling coronal rain in a 10-15 minute time period.

D2.2-0021-18 NUMERICAL SIMULATIONS OF CORONAL LOOP HEATING BY TRANSVERSE WAVES

Andrei Afanasev, andrei.afanasev@kuleuven.be KU Leuven, Leuven, Belgium

Konstantinos Karampelas, kostas.karampelas@wis.kuleuven.be KU Leuven, Leuven, Belgium

Tom Van Doorsselaere, tom.vandoorsselaere@wis.kuleuven.be KU Leuven, Leuven, Belgium

The problem of heating of coronal loops by transverse magnetohydrodynamic waves is addressed. Recently, it has been shown that the plasma mixing effect due to the Kelvin-Helmholtz instability occurring at the loop boundaries contributes significantly to the temperature distribution inside a loop. Using the MPI-AMRVAC code, we perform three-dimensional numerical simulations of the behaviour of transverse magnetohydrodynamic waves driven at the loop footpoint to understand the efficiency of that mechanism for coronal loop heating. We consider different driver frequencies and polarisations, and analyse their effect on the heating of gravitationally stratified loops. We compare our results with the previous ones to reveal the effects of mentioned physical factors on heating of coronal loops by transverse waves.

D2.2-0022-18 TRANSVERSE OSCILLATIONS IN CORONAL RAIN

Vaibhav Pant, vaibhavpant55@gmail.com

Indian Institute of Astrophysics, Bangalore, India Patrick Antolin, patrick.antolin@st-andrews.ac.uk University of St Andrews, St Andrews, United Kingdom Dipankar Banerjee, dipu@iiap.res.in

Indian Institute of Astrophysics, Bangalore, India Erwin Verwichte, erwin.verwichte@warwick.ac.uk University of Warwick, Coventry, United Kingdom

Coronal rains are the plasma condensations which fall, with velocity less than free fall, to chromosphere along the loop like paths. They are usually associated with active region loops. They consists of cool and dense plasma that appear in the solar atmosphere in a period of few minutes. They are believed to be formed in coronal loops because of thermal instability. We report the transverse oscillations in coronal rain as observed by Interface Region Imaging Spectrograph (IRIS). Such oscillations are also reported before using SST in H-alpha. We find the evidence of both standing and propagating waves. These oscillations are found to be decayless. Using IRIS, we investigate different properties of coronal rain at transition region. We perform seismology to estimate magnetic fields and Alfven speed in such structures. These oscillations are also seen in AIA 304 extreme ultraviolet images. Thus combining IRIS and AIA we investigate the properties of coronal rain at different heights in the solar atmosphere. In addition to this, we also perform the spectroscopic analysis at different phases of the evolution of the coronal rain.

D2.2-0023-18 A STATISTICAL STUDY OF FILAMENT OSCILLATIONS ASSOCIATED WITH FLARES/CMES

Yingna Su, ynsu@pmo.ac.cn

Purple Mountain Observatory, Chinese Academy of Sciences, Nanjing, China Jialin Chen, jlchen@pmo.ac.cn

Purple Mountain Observatory, Chinese Academy of Sciences, Nanjing, China Haisheng Ji, jihs@pmo.ac.cn

Purple Mountain Observatory, Chinese Academy of Sciences, Nanjing, China

Filament oscillation is gathering attention these years. Through filament seismology, it is becoming a promising way to probe coronal magnetic field in a simpler way without lowering much accuracy. In certain cases, filaments are seen oscillating before CMEs and/or flares. That means filament oscillation is a possible precursor of these two phenomena. To verify such an assumption, we take out a statistical research over the SDO/AIA filament eruption catalog. We focus on those oscillations followed by flares/CMEs. What we concern are the triggers of the oscillations and their connection with the following eruptions. For each main trigger, we will pick out a case in the catalog for a more detailed study. We are interested in the relation between the oscillations and the following flares, as well as the time interval between filament eruption and flare onset. The latter would be a useful parameter for space weather forecast.

D2.2-0024-18 SIMULTANEOUS TRANSVERSE AND LONGITUDINAL OSCILLATIONS IN A QUIESCENT PROMINENCE TRIGGERED BY A CORONAL JET

Qingmin Zhang, zhangqm@pmo.ac.cn

Purple Mountain Observatory, Chinese Academy of Sciences, Nanjing, China

In this paper, we report our multiwavelength observations of the simultaneous transverse and longitudinal oscillations in a quiescent prominence. The prominence was observed by the GONG and by SDO/AIA on 2015 June 29. A C2.4 flare took place in NOAA active region 12373, which was associated with a pair of short ribbons and a remote ribbon. During the impulsive phase of the flare, a coronal jet spurted out of the primary flare site and propagated in the northwest direction at an apparent speed of 224 km/s. Part of the jet stopped near the remote ribbon. The remaining part continued moving forward before stopping to the east of prominence. Once the jet encountered the prominence, it pushed the prominence to oscillate periodically. The transverse oscillation of the eastern part (EP) of prominence can be divided into two phases. In phase I, the initial amplitude, velocity, period, and damping timescale are 4.5 Mm, 20 km/s, 25 minutes, and 7.5 hr, respectively. The oscillation lasted for two cycles. In phase II, the initial amplitude increases to 11.3 Mm while the initial velocity halves to 10 km/s. The period increases by a factor of 3.5. With a damping timescale of 4.4 hr, the oscillation lasted for about three cycles. The western part (WP) of prominence also experienced transverse oscillation. The initial amplitude is only 2 Mm and the velocity is less than 10 km/s. The period (27 minutes) is slightly longer than that of EP in phase I. The oscillation lasted for about four cycles with the shortest damping timescale (1.7 hr). To the east of prominence, a handful of horizontal threads experienced longitudinal oscillation. The initial amplitude, velocity, period, and damping timescale are 52 Mm, 50 km/s, 99 minutes, and 2.5 hr, respectively. To our knowledge, this is the first report of simultaneous transverse and longitudinal prominence oscillations triggered by a coronal jet.

D2.2-0025-18 HIGH RESOLUTION OBSERVATIONS OF PROMINENCE ROTATION BY HINODE AND IRIS

Joten Okamoto, joten.okamoto@nao.ac.jp

National Astronomical Observatory of Japan, Mitaka, Japan Wei Liu, weiliu@lmsal.com

Bay Area Environmental Research Institute / Lockheed Martin Solar and Astrophysics Laboratory, Moffett Field, California, United States

Fine structures of prominences, especially threads, and their dynamics provide physical information about the magnetic configuration and property in the corona. Here we report two events of prominence rotation observed by the Hinode and IRIS satellites. In the first event, we found transverse motions of brightening threads at speeds up to 55 km/s seen in the plane of the sky. Such motions appeared as sinusoidal space-time trajectories with a typical period of 390 s, which is consistent with plane-of-sky projections of rotational motions. At least 15 episodes of such motions occurred in two days, none associated with any eruption. For these episodes, the plane-of-sky speed is linearly correlated with the vertical travel distance, suggestive of a constant angular speed. In the second event, spectral data taken by IRIS showed strong blueshifts in the top portion of the prominence with a speed of 30-40 km/s, while redshifts of similar speeds were detected at the bottom. Line width of the bright threads were significantly larger than those of stationary threads. These behaviors indicate rotations of helical prominence threads. We interpreted the activations as evidence of unwinding motions caused by magnetic reconnection between twisted prominence fields and ambient coronal fields.

D2.2-0026-18 PROMINENCE/TORNADO PLASMA PARAMETERS

Brigitte Schmieder, brigitte.schmieder@obspm.fr Observatoire de Paris, LESIA, Meudon, France Nicolas Labrosse, n.labrosse

University of Glasgow, United Kingdom Arturo Lopez Ariste, alopezariste@gmail.com

IRAP/University of Toulouse-France/CNRS, Toulouse, France Pierre Mein, pierre.mein@obspm.fr

Observatoire de Paris Meudon, Meudon, France Maciej Zapior, zapior

Astronomical Institute, University of Wroclaw, Wroclaw, Poland

We present a comparison of the plasma physical parameters in prominences and tornadoes using IRIS data and ground based polarimetry measurements obtained with THEMIS. Mg II lines give a good diagnostics of the temperature and optical thickness of the structures. The Stokes parameters from the He D3 line allow to distinguish the behaviour of the magnetic field in typical prominences and atypical prominences (e.g. bubbles, eruptive prominence).

We concentrate on the Dopplershifts in a tornado observed in transition region lines and in Halpha. Our results support the existence of oscillations in tornadoes but not rotation. A reconstruction of the 3D geometry of a helical prominence obtained by following the trajectory of kernels yields surprising results. The loops are shown to be quasi-horizontal structures with no curvature. We conclude that it is important to take into account the 3D structure of the prominence to study the dynamics of the prominence plasma.

D2.2-0027-18 TWO SOLAR TORNADOES OBSERVED WITH THE INTERFACE REGION IMAGING SPECTROGRAPH

Zihao Yang, yangzihao96@pku.edu.cn Peking University, Beijing, China

Hui Tian, huitian@pku.edu.cn Peking University, Beijing, China Hardi Peter, peter@mps.mpg.de

Peking University, Beijing, China Jingwen Zhang, zjwhale@pku.edu.cn Peking University, Beijing, China Yajie Chen, chenyajie@pku.edu.cn Peking University, Beijing, China

The barbs or legs of some prominences show an apparent motion of rotation, which are often termed solar tornadoes. It is under debate whether the apparent motion is a real rotating motion, or caused by oscillations or counter-streaming flows. We present analysis results from spectroscopic observations of two tornadoes by the Interface Region Imaging Spectrograph. Each tornado was observed for more than 2.5 hours. Doppler velocities are derived through a single Gaussian fit to the Mg ii k 2796Å and Si iv 1393Å line profiles. We find coherent and stable red and blue shifts adjacent to each other across the tornado axes, which appears to favor the interpretation of these tornadoes as rotating cool plasmas with temperatures of 104K105K. This interpretation is further supported by simultaneous observations of the Atmospheric Imaging Assembly on board the Solar Dynamics Observatory, which reveal periodic motions of dark structures in the tornadoes. Our results demonstrate that spectroscopic observations can provide key information to disentangle different physical processes in solar prominences.

D2.2-0028-18 IRIS OBSERVATIONS AND MODELING OF MGII FLARE LOOPS

Petr Heinzel, pheinzel@asu.cas.cz

Astronomical Institute, Academy of Sciences, Ondrejov, Czech Republic Katarzyna Mikula, mikula@astro.uni.wroc.pl

Astronomical Institute, University of Wroclaw, Wroclaw, Poland Arkadiusz Berlicki, berlicki@astro.uni.wroc.pl

Astronomical Institute, University of Wroclaw, Wroclaw, Poland Wenjuan Liu, wenjuan.liu@asu.cas.cz

Astronomical Institute, The Czech Academy of Sciences, Ondrejov, Czech Republic

Solar chromospheric flares are often associated with cool loops which are rooted in the ribbons. These loops extend into coronal altitudes and usually are modelled as prominence-like structures illuminated from the solar disk. The loops exhibit large down-flows (coronal rain) and they evolve in time in accordance with the characteristic cooling times of the loop plasmas. Cool loops are visible in various spectral lines formed at chromospheric temperatures. We exploit novel observations of such loops in MgII h and k lines obtained by the IRIS satellite, analyse selected observations where the cool loops are well visible and study their temporal evolution. Our spectroscopic diagnostics is based on 2D non-LTE modelling of MgII lines in flare loops taking into account the flows along the loops. From these models we determine various plasma parameters and the rates of radiation cooling. These results allow us to better understand the structure, dynamics and evolution of cool flare loops.

D2.2-0029-18 MASS FLOWS WITHIN A SOLAR PROMINENCE OBSERVED BY THE NEW VACUUM SOLAR TELESCOPE

Yu Liu, lyu@ynao.ac.cn

Yunnan Observatories, Chinese Academy of Sciences, Kunming, China Hongbo Li, hbli@ynao.ac.cn

Yunnan Observatories, Chinese Academy of Sciences, Kunming, China

The material of solar prominences is often observed in a state of flowing. These information about mass flows (MF) is important and useful for us to understand the internal structures and dynamics of prominences. By using the New Vacuum Solar Telescope, we have carefully studied the MFs in a solar prominence, and found that there are two types of MF existing in the middle and leg of the prominence, respectively. The plasma mainly flowed back and forth in the middle of the prominence, while in its legs the plasma mainly dropped to the photosphere. The observation indicates that a prominence may has a piecewise structure, which results in the different behaviors between the middle and legs of the prominence. According to this explanation, a magnetic distribution of the prominence can be estimated from the observed MFs. Besides, it also suggests that these MFs may have a significant influence on the magnetic structure of the prominence.

D2.2-0030-18 DISAMBIGUATED MAGNETIC FIELD MEASUREMENTS IN A QUIESCENT PROMINENCE

Veronique Bommier, v.bommier@obspm.fr LESIA, Observatoire de Paris, Meudon, France Thomas Kalewicz, tkalewicz@gmail.com Observatoire de Paris, LESIA, Meudon, France

The magnetic field vector was measured in a prominence by interpretation of the Hanle effect, following the method described in Bommier, V., Leroy, J.L., and Sahal-Bréchot, S., 1981, A&A, 100, 231, but with the difference that the measurements were spatially resolved in the prominence body, because the prominence was observed with the French THEMIS telescope (Izaña, Tenerife, Canarias). The prominence was observed on two following days, and the measurement ambiguity was resolved by selecting the closest pair in the ambiguous solutions, whose symmetry changes along the days due to solar rotation. The method successfully worked. The observed line was He I D3. The polarisation was integrated along the line profile for accuracy purposes, and the two line components were not resolved. The magnetic field was then assumed to be horizontal, as shown by Athay et al. (1983, Solar Phys. 89, 3). The magnetic field strength and the α angle between the field vector and the prominence long axis were unambiguously obtained for nearly each pixe 0.5e−4G/km (increasing with height) is found above h = 34M m, in excellent agreement with Leroy et al.(1983 0.6e−4G/km (decreasing with height), contrarily to the model. In this region, the α angle is also found decreasing with height, but in a quicker manner and with more scattered values. The prominence is found of Inverse Polarity at all heights.

D2.2-0031-18 SCOOPING UP A PROMINENCE: EMBEDDING A FILAMENT IN A CME

Rony Keppens, rony.keppens@kuleuven.be KU Leuven, Leuven, Belgium

Chun Xia, chun.xia@ynu.edu.cn Yunnan University, Kunming, China Xiaozhou Zhao, zhaoxz@pmo.ac.cn

Purple Mountain Observatory, Chinese Academy of Sciences, Leuven, Belgium Weiqun Gan, wqgan@pmo.ac.cn

Purple Mountain Observatory, Nanjing, China

We report on thermodynamically consistent magnetohydrodynamic simulations from chromosphere to corona, where an erupting flux rope gets formed by photospheric converging motions. Our model shows how chromospheric material can get levitated into the flux rope and form a filament. The flux rope-filament system transits from quasi-equilibrium stages to an accelerated eruption, and this transition coincides with a changeover in the reconnection occurring in the current sheet underneath the flux rope. A slow Sweet-Parker stage transforms to an unsteady bursty reconnection regime with multiple islands. The largest of these islands are seen to merge with the chromospheric fields below to produce flare arcade loops. Our simulation unifies a variety of processes, from small-scale reconnection structures up to full-scale embedded filaments in a coronal mass ejection.

D2.2-0032-18 FILAMENT DISINTEGRATION IN RELATION TO QUASI-SEPARATRIX LAYERS

Rui Liu, rliu@ustc.edu.cn

University of Science and Technology of China, Hefei, China

The disintegration of solar filaments via mass drainage is frequently observed during a variety of dynamic phenomena, ranging from tornado-like activities, failed eruptions, to partial eruptions. It is generally considered that the draining of dense filament material is directed by both gravity and magnetic field, yet what causes the draining remains elusive. To shed new light into this question, we compared the impact sites of the draining mass with the footprints of large-scale quasi-separatrix layers in a partial eruption, and found a reasonable match between them. Hence we conclude that it is the interactions of the filament field with the overlying QSLs that result in the splitting and disintegration of the filament.

D2.2-0033-18 PLASMA PHYSICAL PARAMETERS OF A PROMINENCE EMBEDDED IN THE CORE OF A CORONAL MASS EJECTION

Max Planck Institute for Astrophysics, Garching, Germany

We determine the plasma physical parameters of an erupting prominence embedded in the core of a CME, combininging visible light coronagraphic images from SOHO/LASCO with UV spectra acquired by SOHO/UVCS. Strong UV emissions were detected in the hydrogen Lyman α and Lyman β lines and C III line. Visible light and UV intensities have been used to estimate the projected thickness and velocity of the prominence, together with the effective plasma temperature, microturbolent velocity, and column density. These parameters have been used to constrain 1D NLTE modeling of the erupting plasma, taking into account the effects of large flow velocities (Doppler dimming). Roughly one-half of considered points in the prominence body show a non-negligible Lyman α optical thickness. Comparison between the calculated and the measured intensities of the two Lyman lines was also used to derive the geometrical filling factor. Results show that the erupting prominence plasma is relatively hot, with a low electron density, a wide range of effective thicknesses, a rather narrow range of radial flow velocities, and a microturbulence of about 25 km/s. This analysis provides a basis for future diagnostics of prominences using the METIS coronagraph on board the Solar Orbiter mission.

D2.2-0034-18 EVIDENCE OF COOL PROMINENCE MATERIAL EMBEDDED IN CMES FROM POLARIZATION MEASUREMENTS

Philippe Lamy, philippe.lamy@lam.fr

Laboratoire d'Astrophysique de Marseille, Marseille, France Olivier Floyd, olivier.floyd

Laboratoire d'Astrophysique de Marseille, Marseille, France Serge Koutchmy, koutchmy@iap.fr

Institut d'Astrophysique de Paris, Paris, France

In white-light coronagraph images, cool prominence material is sometimes observed as bright substructures or plasmoids in coronal mass ejections (CMEs). Based on observations of a CME with the SECCHI/STEREO coronagraphs on 31 August 2007, Mierla et al. (2011) have shown that the emission from such bright patches is characterized by very low polarization and was due to H-alpha radiation from cool prominence material. We have examined several polarization images of CMEs obtained with the LASCO-C2 coronagraph with its orange filter. This filter is approximately centered on the HeI D3 line. This low excitation line emission is superior to the H-alpha emission of HI because its FIP is much higher. In several cases, we observe very low-polarization components embedded in CMEs characterized by a much larger polarization resulting from the Thomson scattering. They most likely present evidence of cool prominence material carried by the CMEs.

D2.2-0035-18 AN ANALYSIS OF SIMULTANEOUS OBSERVATIONS OF A CME-ASSOCIATED ERUPTIVE PROMINENCE WITH IRIS, AIA/SDO, EUVI/STEREO AND KCOR

Ping Zhang, ping.zhang@ias.u-psud.fr

Institut d'Astrophysique Spatiale, Orsay, France Eric Buchlin, eric.buchlin@ias.u-psud.fr

IAS, CNRS / Univ. Paris Sud XI, Orsay, France Jean-Claude Vial, jean-claude.vial@ias.u-psud.fr Institut d'astrophysique spatiale, Orsay, France

We present the simultaneous observations of a CME-associated eruptive prominence which have been made by the Interface Region Imaging Spectrograph (IRIS), Atmospheric Imaging Assembly (AIA) of SDO, EUVI of STEREO and the ground-based K-COR coronagraph. IRIS observations started on 2014 May 28 at 11:25 UT, lasted for about 4.5 hours. With the aim of deriving the velocity vector, we first combined an optical flow method on the AIA 304 observations to compute the POS velocities in the prominence and a Doppler technique with the IRIS observations to compute the LOS velocities. Then we characterized the Mg h and k profiles (time and space-dependent) and compared with the signatures of various (1000) prominence models through NLTE radiative transfer computations (I.A.S. PROM7 code). We paid much attention to the exact incident radiation in various lines and continua. The model parameters include pressure, temperature, height, thickness, radial and turbulence velocities. Having selected the best (fitting) models, we were able to derive the total (hydrogen) density and compute the mass flows. We also used the STEREO observations to derive the 3D geometry of the prominence and K-COR to derive the density later on in the process of eruption. Applying this method to more prominences observed by IRIS could help to reduce the large range of thermodynamic parameters in eruptive prominences and to improve their MHD modeling.

D2.2-0036-18 INTERACTION BETWEEN COOL MATERIAL FROM SUN-GRAZING COMETS AND THE LOW CORONA

Yingdong Jia, yingdong@ucla.edu

University of California, Los Angeles, Los Angles, California, United States Wei Liu, weiliu@lmsal.com

Bay Area Environmental Research Institute / Lockheed Martin Solar and Astrophysics Laboratory, Moffett Field, California, United States

William Pesnell, william.d.pesnell@nasa.gov

Goddard Space Flight Center, Greenbelt, Maryland, United States Cooper Downs, cdowns@predsci.com

Predictive Science, Inc., San Diego, California, United States Paul Bryans, pbryans@ucar.edu

NCAR, Boulder, Colorado, United States

Sun-grazing comets dive into altitudes lower than 1 solar radius from the chromosphere. Cool materials of temperature lower than 103K explode from the comet into the 106 K corona. These materials undergone various stages of rapid chemical reactions in scales of seconds to minutes. Such reactions Structures in such images of various wavelengths indicate strong variation in ambient conditions of the corona. We combine three numerical models: low corona model, particle transportation model, and cometary plasma interaction model into one framework to model the interaction of Sun-grazing comets in the low corona. In our framework, cometary vapor are ionized via multiple channels, and then detained by the coronal magnetic field. In seconds, these ions are further ionized into their highest charge state, which is revealed by certain emission lines. Constrained by coronal graphs and cometary interaction images, we apply our framework to trace back to the local condition of the ambient corona, and its spatial/time variation. Our frame work is able to resolve structures of sub-million meters to tens of million meters. Once trained by multiple stages of the comet's journey in the low corona, this framework can identify the fine spatial variations in plasma density and magnetic field intensity, which may be visible to future close-up observations.

D2.2-0037-18 MAGNETIC DIAGNOSTICS OF CORONAL RAIN USING THE DKIST

Thomas Schad, schad@nso.edu

National Solar Observatory, Pukalani, Hawaii, United States

The routine production of coronal rain in the outer solar atmosphere provides one of the finest probes we have of the coronal plasma environment and its apparent structuring. Despite the range of phenomena discovered with imaging observations, the magnetic environment hosting and marshaling rain production remains poorly constrained by observations. With the dawn of the DKIST and its advanced suite of five facility instruments, this is primed to change. The large DKIST aperture (4 meter) provides a collecting area capable of combining rapid exposure imaging diagnostics and spectroscopic observations of coronal rain with meaningful spectropolarimetric observations, which to date have been rarely achieved for coronal rain. The brightness of coronal rain in key chromospheric diagnostics (as compared to hot infrared coronal lines) offers a very significant photon advantage for conducting "cool" coronal magnetometry. This talk will discuss the building blocks for an observational framework to study coronal rain at DKIST, including how to coordinate VBI imaging, VISP spectropolarimetry, VTF 2D spectro-imaging, and DL-NIRSP IFU-based spectropolarimetry. This discussion will be guided by recent observations of neutral helium production within coronal rain that allow us to much better predict DKIST capabilities for coronal rain polarimetry. In addition, automated analysis techniques based on the Rolling Hough Transform have been developed that assist with these techniques. Coronal rain is a critical use case for early science at DKIST when it becomes operational in 2020.

D2.2-0038-18 PERSPECTIVE OF DIAGNOSING COOL MATERIALS WITH THE LYMANALPHA SOLAR TELESCOPE

Hui Li, nj.lihui@pmo.ac.cn

Purple Mountain Observatory, Chinese Academy of Sciences, Nanjing, China

The Lyman-alpha Solar Telescope (LST) is one of the three payloads proposed for the Advanced Space-based Solar Observatory (ASO-S) mission, which has already been approved by the Chinese Academy of Sciences (CAS). The LST payload consists of three instruments and is aiming at observing the Sun from disk center up to 2.5 solar radii in both the Lyman-alpha line and white-light with high tempo-spatial resolution. The LST payload selects the Lyman-alpha line as one of its observation wavebands due to the unique advantages of the line in observing the Sun: as the most intensive line in Ultraviolet (UV) solar spectrum, its larger relative brightness with respect to the visible waveband in the corona leads to less stringent requirement for the stray light suppression and make it suitable to detect faint features. Meanwhile, the wide temperature coverage of the line allows us to access both lowand high-temperature features on the Sun, such as prominences (filaments), jets, loops, coronal holes, coronal mass ejections (CMEs), flares, etc. In this talk, I will review solar observations in this line done by various satellites and sounding rockets, such as OSO, TRACE, SOHO, IRIS, VAULT, etc. Meanwhile, I will outline the perspectives of the Lyman-alpha line in future solar observations with the ASO-S mission

D2.2-0039-18 CHEMICAL FRACTIONATION IN SOLAR PROMINENCES

Susanna Parenti, susanna.parenti@ias.u-psud.fr Institut d'astrophysique spatiale, Orsay, France Giulio Del Zanna, gdelzanna@spd.aas.org

University of Cambridge, Cambridge, United Kingdom Jean-Claude Vial, jean-claude.vial@ias.u-psud.fr Institut d'astrophysique spatiale, Orsay, France

The First Ionization Potential (FIP) fractionation of elemental abundances in the solar atmosphere and solar wind is a known process which appears to vary depending on the magnetic field property and the dynamic nature of the environment. It is generally identified by an increase of the low FIP elements (with FIP energy below 10 eV) compared to the high FIP elements (with respect to the photospheric values). For instance, the low FIP element abundance is enhanced within active regions by about a factor of 3-4, with respect to photospheric values. A similar property is measured in the slow solar wind. This is one of the reasons why the FIP fractionation is used as a proxy for identifying the solar wind source regions on the Sun, a topic of particular relevance for the upcoming Solar Orbiter mission. Cool, low-state ionized plasma and its composition have been measured in-situ within interplanetary Coronal Mass Ejections (ICMEs) in only a few cases. This cool plasma has been associated to remnants of erupting prominences. However, this association is not confirmed, because the measurement of the composition within prominence plasma is very difficult and poorly known. The scope of this paper is to provide a reliable measurement of elements composition and FIP fractionation in a prominence using the available SOHO/SUMER dataset of the prominence atlas presented in Parenti et. al 2005. Our investigation will consider ions formed in the prominence-corona transition region, taking into account possible density and opacity effects in the formation of the spectral lines.

D2.2-0040-18 RECONNECTION MICROJETS IN THE SOLAR CORONA

Patrick Antolin, patrick.antolin@st-andrews.ac.uk University of St Andrews, St Andrews, United Kingdom Paolo Pagano, pp25@st-andrews.ac.uk

University of St Andrews, St Andrews, United Kingdom Ineke De Moortel, ineke.demoortel@st-andrews.ac.uk University of St Andrews, St Andrews, United Kingdom

Coronal rain is one of the highest resolution tracers of the coronal magnetic field. In this work the dynamics of a prominence/coronal rain complex are analysed based on spectroscopic and imaging observations with IRIS, Hinode/SOT and SDO/AIA. The loop-like magnetic field arcade hosting the rain is observed to slowly expand in height. Prior and especially during this movement, several (100) small (1 arcsec) and short (<20 sec) bursts of plasma perpendicular to the loop arcade are captured in the Si IV and Mg II lines. The line profiles are broad and asymmetric with long tails above 100 km/s. These microjets are accompanied with strong intensity enhancements co-spatially and along the loop in most of the AIA channels, indicating significant energy release increasing the temperature to several MK. Some events generate transverse MHD waves and the strongest events are accompanied by ejection of plasmoidlike structures. We interpret these microjets as magnetic reconnection outflows, produced by component reconnection in a strong guide field. The originally cold conditions of the rain allows, in this case, a unique high resolution glance into the reconnection dynamics in low beta plasmas, and marks the X-target in the Sun for next-generation telescopes.

D2.2-0041-18 PROPERTIES OF PROMINENCES IN 13-24 CYCLES OF ACTIVITY

Kseniya Tlatova, k.tlatova@mail.ru

Pulkovo Astronomical Observatory of the Russian Academy of Sciences, St. Petersburg, Russia Andrey Tlatov, tlatov@mail.ru

Pulkovo Astronomical Observatory, Kislovodsk, Russia Valeria Vasilieva, xyzlera@rambler.ru

Pulkovo Astronomical Observatory of the Russian Academy of Sciences, Russia

Digitization of solar prominences Kodaikanal Observatory (India) on photographic plates in the CaIIK line for the period 1907-1960 was performed. These data were supplemented by data such as daily observations of prominences Kislovodsk Observatory (1957-2017), digitization of prominence sketches by the spectrohelioscopes network (1922-1934) and prominences on synoptic charts (1887-1898, 1904-1915). Comparative analysis of the velocity drift of highlatitude prominences to the poles in activity cycles are performed. Connection between the velocity drift and the power of the activity cycle has been established. Analysis of the height prominences distribution are performed. The maximum of the heights distribution is about 30 Mm. Also there is a second maximum for a height of 60 Mm.

D2.2-0042-18 ON THE NATURE OF FUNNEL PROMINENCES

It has been proposed that prominences are manifestations of a magneto-thermal convection process that involves ever-present dynamic descents of cool material threads and upflows of hot bubbles and plumes (Berger et al. 2011 Nature). On global scales, prominences may play an important role as the return flows of the chromosphere-corona mass cycle. A critical step in this cycle is the condensation of million-degree coronal plasma into T<10,000 K prominence material by radiative cooling instability. Direct observational evidence has been lacking for decades, a situation that has recently changed, especially with the advent of the SDO mission. We present here SDO/AIA observations of runaway cooling in coronal loops leading to condensation at magnetic dips and formation of funnel-shaped prominences (e.g., Liu et al. 2012, 2014; Berger et al. 2012 ApJL). We find that a macroscopically quiescent prominence is microscopically dynamic, involving the passage (through condensation and drainage) of a significant mass of typically 1015 gram/day (comparable to the mass of a typical CME). This picture is further supported by the theoretical development on spontaneous formation of current sheets and condensations (Low et al. 2012a, b, ApJ). Such funnel prominences, usually small in size, can constitute a new type of prominences. We suggest that similar processes could produce elementary building blocks of large-scale quiescent prominences in filament channels.

D2.2-0043-18 ARE “SOLAR TORNADOES” REALLY ROTATING?

Wei Liu, weiliu@sun.stanford.edu

Bay Area Environmental Research Institute / Lockheed Martin Solar and Astrophysics Laboratory, Palo Alto, California, United States

Thomas Berger, thomas.berger@colorado.edu

National Astronomical Observatory of Japan, Mitaka, Japan Boon Chye Low, low@ucar.edu

National Center for Atmospheric Research, High Altitude Observatory, Boulder, United States

Solar “tornadoes” have been proposed to explain certain vertical structures in prominences that exhibit apparent rotations. Yet, it remains highly controversial whether such motions are real rotations or transverse oscillations. We present a statistical study of IRIS observations that reveal no clear evidence of systematic or coherent rotations, which would otherwise result in opposite Doppler shifts, i.e., blueshifts on the one side of the vertical structure and redshifts on the other, which were not found in our sample of “tornadoes”. In addition, we find in one particular case observed by SDO/AIA that the “tornado” disappeared upon the impact of an eruption that pushed its mass away along a primarily horizontal trajectory (presumably along magnetic field lines). This “tornado” shortly reformed with the replenishment of material from the return flow of some of the displaced mass back to its original location, at the dips of local magnetic field lines, followed by back and forth transverse oscillations around the dips. Such observations from both IRIS and AIA suggest that, at least for the cases being analyzed here, the apparent oscillatory motions of “tornadoes” are a result of longitudinal oscillations (like a pendulum) of dense and heavy prominence material about the local minimum of gravitational potential at the magnetic dips, an interpretation proposed and supported by a number of authors.

D2.2-0044-18 COOL MATERIAL IN THE HOT SOLAR CORONA AND THE CHROMOSPHERECORONA MASS CYCLE

In the million-degree hot and tenuous solar corona, under favorable conditions, some mass can undergo a radiative cooling instability and condense into material of 100 times cooler in two distinct forms - prominences and coronal rain. Being at similar temperatures, they exhibit contrasting morphologies and behaviors: a quiescent prominence usually consists of numerous long-lasting, filamentary downflow threads, while coronal rain consists of transient mass blobs falling at comparably higher speeds along well-defined, curved paths (e.g., guided by coronal loops). We report recent imaging and spectroscopic observations from SDO/AIA and IRIS of a hybrid prominence-coronal rain complex structure that suggest different magnetic environments being responsible for such distinctions. We also present an ensemble of observations of the so-called funnel prominences that reside near the dips of magnetic funnels. Regardless of their morphological and behavioral differences, a large fraction of prominence and coronal rain material eventually falls back to the chromosphere and serves as the return flow of the socalled chromosphere-corona mass cycle (the other half of this cycle is the upward transport of heated mass from the chromosphere to the corona). We estimate the downflow mass fluxes in prominences and coronal rain, and compare them with the coronal mass budget in this cycle and with the mass loss to the solar wind and coronal mass ejections (CMEs). We will discuss the broad physical implications of these observations for fundamental questions, such as coronal heating and beyond.

D2.2-0045-18 SOLAR CORONA OBSERVATIONS IN ACTIVITY CYCLES 17-24

Andrey Tlatov, tlatov@mail.ru

Pulkovo Astronomical Observatory, Kislovodsk, Russia

The results of the work of the global observation network are considered, and a comparative analysis of the data of various coronal observatories is performed. The coronal activity index has been reconstructed for the period 1939-2016 based on the data of various observatories in Kislovodsk system. For this purpose, the corona daily intensity maps from the Sacramento Peak and Lomnicky Štit observatories according to the Solar-Geophysical Data journal have been digitized; they supplement the data of other observatories. The homogeneity and continuity of the corona observations at the Kislovodsk station, including activity cycle 24, is confirmed. Unfortunately, the only observatory at present that continues observation of the spectral corona in Fe XIV5303A and Fe XIV6374A lines is the Kislovodsk astronomical station Mountain Astronomical Station (MAS) of the Central Astronomical Observatory, Russian Academy of Sciences (Pulkovo). The data on the combined corona in 5303 A line are analyzed. It is shown that there is a high correlation of the intensity index of green corona with solar radiation measurements in the vacuum UV region. Data on the beginning of the new 25th activity cycle in the corona at high latitudes are presented.

D2.2-0046-18 PRACTICAL REALIZATION OF THE FORCE-FREE MAGNETIC FIELD MODELS

In the solar atmosphere, jets are ubiquitous at various spatial-temporal scales. They are important for understanding the energy and mass transports in the solar atmosphere. According to recent observational studies, the high-speed network jets are likely to be intermittent but continual sources of mass and energy for the solar wind. Here, we conduct a magnetohydrodynamics simulation to investigate the mechanism of these network jets. A combination of magnetic flux emergence and horizontal advection is used to drive the magnetic reconnection in the transition region between a strong magnetic loop and a background open flux. The simulation results show that not only a fast warm jet, much similar to the network jets, is found, but also an adjacent slow cool jet, mostly like classical spicules, is launched. Differing from the fast warm jet as driven by magnetic reconnection, the slow cool jet is mainly accelerated by gradients of both thermal pressure and magnetic pressure near the outer border of the massconcentrated region compressed by the emerging loop. These results provide a new perspective on our understanding of the formation of both the slow cool jets from the solar chromosphere and the fast warm jets from the solar transition region.

SPACE PLASMAS IN THE SOLAR SYSTEM, INCLUDING PLANETARY MAGNETOSPHERES (D)

SOLAR TRANSIENTS: FROM SOLAR ORIGIN TO EARTH IMPACT AND THE OUTER HELIOSHERE (D2.3)

D2.3-0001-18 CMES AND SHOCKS EVOLUTION IN THE INTERPLANETARY SPACE. OBSERVATIONS OF CME EVOLUTION FROM THE SUN TO THE EARTH AND BEYOND

Alessandro Bemporad, bemporad@oato.inaf.it

INAF - Torino Astronomical Observatory, Pino Torinese (TO), Italy

Thanks to remote sensing instruments from space-based observatories it is possible to study in details the early propagation of solar eruptions (or Coronal Mass Ejections - CMEs). The early detection of CMEs with remote sensing instruments (e.g. EUV imagers and spectrometers, visible light coronagraphs, radio spectrometers on-board SOHO, STEREO, SDO, etc.) allows to identify the events propagating towards the Earth, and derive in advance information that are crucial for Space Weather forecasting applications. Higher up, the propagation of Interplanetary CMEs has been followed many times with Heliospheric imagers (e.g. SMEI on-board the Coriolis satellite, and HI1 - HI2 on-board the twin STEREO spacecraft), providing information on ICME drag forces, deflections, CME-CME interactions, preconditioning, and other phenomena affecting their propagation to 1 AU and beyond. These data have proven to be very useful also to derive early information on shock waves associated with major eruptions, believed to be very important accelerators of Solar Energetic Particles. Upcoming solar missions (Solar Orbiter, Parker Solar Probe, PROBA-3, etc.) will provide a new view of CMEs, hopefully helping us to answer some of the major open questions on these events.

D2.3-0002-18 CONSTRUCTING A GENERIC ICME FROM THE SUN TO EARTH FROM STATISTICAL STUDIES OF IN SITU DATA

Miho Janvier, mjanvier@ias.u-psud.fr

Institut d'Astrophysique Spatiale, Orsay Cedex, France Pascal Demoulin, pascal.demoulin@obspm.fr Observatoire de Paris, Meudon, France

Sergio Dasso, sdasso@iafe.uba.ar

Instituto de Astronomía y Física del Espacio (IAFE), Buenos Aires, Argentina

Interplanetary Coronal Mass Ejections (ICMEs) are detected in situ by instruments measuring the magnetic field and plasma properties of the ambient solar wind. In particular, a subset of ICMEs, referred to as Magnetic Clouds (MCs), is well defined by the presence of a rotating magnetic field, indicative of a twisted magnetic structure. Shocks, on the other hand, are also well defined in the interplanetary medium as sharp discontinuities in the plasma and magnetic properties. Both structures then allow defining the presence of a sheath region between the shock and the MC.

Over the past years, we have proposed and refined new statistical methods aiming at analyzing ICME properties, so as to assess the existence of a generic shape and a generic internal profile of ICMEs at different distances from the Sun. These methods rely on the computation from the data of the distribution of the shock normal and the flux-rope axis directions. From these analysis, we were able to constrain an analytical shape that describes best these observed distributions. Another method is a superposed epoch analysis so as to obtain typical profiles of ICME substructures at different distances from the Sun.

Next, we compare such generic features of ICMEs to numerical simulations and heliospheric images of CMEs. We will discuss the commonalities, then the discrepancies that need to be further understood between the models and the constraints given by the in situ data. This is important in completing the scenario of the evolution of solar eruptive flares, from their start in the Sun's atmosphere to their evolution in the solar wind.

D2.3-0003-18 NUMERICAL STUDY OF EROSION, HEATING, AND ACCELERATION OF THE MAGNETIC CLOUD AS IMPACTED BY FAST SHOCK

Jiansen He, jshept@pku.edu.cn Peking University, Beijing, China Shoudi Mao, jshept@pku.edu.cn Peking University, Beijing, China

National Space Science Center, CAS, Beijing, China Linghua Wang, wanglhwang@gmail.com

Peking University, Beijing, China

The impact of an overtaking fast shock on a magnetic cloud (MC) is a pivotal process in CME-CME (CME: coronal mass ejection) interactions and CME-SIR (SIR: stream interaction region) interactions. MC with a strong and rotating magnetic field is usually deemed a crucial part of CMEs. To study the impact of a fast shock on an MC, we perform a multi-dimensional numerical magnetohydrodynamic simulation. Two cases are run in this study: without and with impact by fast shock. In the former case, the MC expands gradually from its initial state and drives a relatively slow magnetic reconnection with the ambient magnetic field. Analyses of forces near the core of the MC as a whole body indicates that the solar gravity is quite small compared to the Lorentz force and the pressure gradient force. In the second run, a fast shock propagates, relative to the background plasma, at a speed twice that of the perpendicular fast magnetosonic speed, catches up with and takes over the MC. Due to the penetration of the fast shock, the MC is highly compressed and heated, with the temperature growth rate enhanced by a factor of about 10 and the velocity increased to about half of the shock speed. The magnetic reconnection with ambient magnetic field is also sped up by a factor of two to four in reconnection rate as a result of the enhanced density of the current sheet, which is squeezed by the forward motion of the shocked MC.

D2.3-0004-18 MODELING THE INTERNAL STATE OF CORONAL MASS EJECTIONS (CMES) USING THEIR KINEMATICS

Wageesh Mishra, wageesh@ustc.edu.cn

University of Science and Technology of China, Hefei, China Yuming Wang, ymwang@ustc.edu.cn

University of Science and Technology of China, Anhui, China

Coronal Mass Ejections (CMEs) have been studied extensively for decades using remote sensing or in-situ observations. Earlier studies have estimated the internal properties of CME plasma; however such estimations were limited to a certain position or at a certain time. The evolution of internal state of CME during their continuous heliospheric propagation is not properly understood. As it is well accepted that most of the CMEs have a flux rope-like structure, in our study, we propose a self-similar flux rope model. The model is used to probe the internal state of CME in order to understand the thermodynamic process. We implement the model to a CME erupted on 12 December 2008. Using this model in conjunction with propagation and expansion speeds profile of the CME, several thermodynamic parameters and their variations with heliocentric distance is determined. Most importantly, we infer the polytropic index of the CME plasma, Lorentz force and the thermal pressure forces inside the CMEs. Based on our results, we explain the flows direction of heat and internal driver of CME expansion. We also calculate the rate of change of entropy and absorbed heat for the CMEs. The limitations of the model and approximations made in the study would also be discussed.

I will present a new series of solar wind simulations of the solar wind from the surface of the Sun to 1 AU (and beyond). We used a new solar wind model, called MULTI-VP, which takes a coronal magnetic field map as input (past data or forecast) and calculates the dynamical and thermal properties of a large collection of solar wind streams the chromosphere up to about 30 Rsun in quasi-real time (while keeping a good description the plasma heating and cooling mechanisms, and taking into account the full magnetic flux-tube geometry). MULTI-VP supplies the full set of physical inner boundary conditions required to initiate the model ENLIL. The two models were used to calculate the properties of the wind flow (speed, density, temperature, magnetic field) from 1 Rsun to 1AU during Carrington rotations spanning the STEREO epoch (CRs 2055 to 2149; see https://stormsweb.irap.omp.eu/doku.php?id=windmaptable, http://www.helcatsfp7.eu/). These were calibrated against in-situ measurements of different spacecraft, white-light J-Maps and coronal/heliospheric imagery in order to provide better predictions than the classical methods. The CIR's identified in the HELCATS CIRCAT catalogue were traced back to the low corona, and their positions were verified to correlated well with the interfaces of fast and slow wind streams simulated. These solar wind simulations were performed in the scope of the HELCATS FP7 project and are included in the SIMCAT catalogue. I will discuss the predictive capabilities of this modeling stategy in terms of the arrival times, amplitudes and fine structure of fast wind streams at 1 AU. I will also address the benefits of multi-point observations and in-situ measurements and the use of synchronic magnetograms.

Solar Energetic Particles (SEPs) constitute an important component of space weather in terms of the radiation hazard to humans and electronic equipment, as well as the ionization of the Earth’s atmosphere. In this work, two real-time prediction tools developed in the framework of the HESPERIA HORIZON 2020 project i.e. HESPERIA UMASEP-500 and HESPERIA REleASE, providing > 500 MeV and 30-50 MeV proton predictions, respectively, will be presented. Both forecasting tools are operational under the HESPERIA server maintained at the National Observatory of Athens (http://www.hesperia.astro.noa.gr). Two main mechanisms of particle acceleration are usually employed to explain SEP events at 1 AU: (i) magnetic reconnectiondriven processes during solar flares and (ii) diffusive shock acceleration at fast Coronal Mass Ejection-driven shock waves. Despite the existence of these main sources of accelerated particles, turbulence and associated coherent structures may be responsible for heating and particle energization throughout the heliosphere. Recent observations of energetic particle enhancements in turbulent wakes of interplanetary shocks, near reconnecting current sheets and within magnetic cavities filled with magnetic islands strongly support theoretical expectations of particle energization in the presence of coherent structures in the solar wind. A new paradigm has recently emerged of particle acceleration to keV/MeV energies which occurs both far from 1 AU as well as locally in the solar wind, due to a combination of these classical mechanisms and small-scale magnetic island reconnection-related processes in magnetic cavities of various origins. Examples of such Atypical Energetic Particle Enhancements (AEPEs) in the heliosphere will be presented and discussed in this work.

Acknowledgements: This work has been partly supported by the International Space Science Institute (ISSI) in the framework of International Team 405 entitled: ’Current Sheets, Turbulence, Structures and Particle Acceleration in the Heliosphere’. This project has received funding from the European Union’s Horizon 2020 research and innovation programme under grant agreement No 637324.

In modeling the transport process of solar energetic particles (SEPs) in the inner heliosphere, previous simulation works often simplify the solar wind velocity as radial and constant, and treat the magnetic field as Parker spiral. In order to fully understand the effect of solar wind velocity and interplanetary magnetic field on the particles' transport process, a realistic background solar wind and magnetic field is required. In this work, we use the focused transport model to investigate the transport of SEPs in the solar wind velocity and magnetic field, which are generated by the 3D high-resolution MHD model with a six-component grid. We find that in the uncompressed solar wind, the time intensity profiles of energetic particles show similar trend in both the MHD background and the Parker magnetic field assumption. However, the simulated SEP flux displays an enhancement as much as a factor of two in the decay phase when a compression region sweeps through the local observer. Our results indicate that the magnetic focusing effect is responsible for the intensity enhancement. This suggests that the magnetic focusing effect has an important influence on the transport of SEPs. Besides, we suggest that the magnetic focusing could be more effective in large heliocentric distances rather than local magnetic focusing at 1 AU and a realistic 3D background solar wind should be included in such simulations.

Using observations from MESSENGER at Mercury, in conjunction with spacecraft at 1 AU and at Mars, we investigate how interplanetary coronal mass ejections (ICMEs) evolve and modulate galactic cosmic rays (GCRs) as they propagate through the inner heliosphere. MESSENGER, the first spacecraft since the 1980s to make in-situ measurements at distances < 0.5 AU, presents a unique opportunity for observing the innermost heliosphere and allows us to make testable predictions for the upcoming Parker Solar Probe and Solar Orbiter missions. We have cataloged shock-driving ICMEs at MESSENGER between 2011 and 2015; through statistical analyses and case studies, we investigate key ICME property changes during propagation as well as changes with heliocentric distance in GCR modulation by ICMEs. We showcase specific case studies of ICMEs observed in longitudinal conjunction in the inner heliosphere to illustrate changes in ICMEs during propagation. Based on these studies, we hypothesize that: 1) ICMEs are less complex closer to the Sun, 2) ICME-driven GCR modulation is significantly stronger in the near solar environment than near 1 AU, 3) the size of Forbush decreases (Fds) diminishes

exponentially with heliocentric distance in the inner solar system, and 4) 2-step Fds are more common closer to the Sun. The results from our studies give both a direct and indirect view of how ICMEs evolve during propagation as well as a glimpse of the inner heliosphere environment about to be explored by the Parker Solar Probe and Solar Orbiter missions.

D2.3-0009-18 SHOCK LOCATION AND CME 3-D RECONSTRUCTION OF A SOLAR TYPE II RADIO BURST WITH LOFAR.

Pietro Zucca, zucca@astron.nl ASTRON, Dwingeloo, Netherlands LOFAR Solar KSP

P. Zucca, D. E. Morosan, A. Rouillard, R. Fallows, P. T. Gallagheg, J. Magdalenic, K-L. Klein,

G. Mann, C. Vocks, E. P. Carley, M. M. Bisi, E. P. Kontar, H. Rothkaehl, B. Dabrowski, A. Krankowski

Type II radio bursts are evidence of shocks in the solar atmosphere and inner heliosphere emitting radio waves ranging from sub-meter to kilometer lengths. These shocks may be associated with coronal mass ejections (CMEs) reaching speeds higher than the local magneto-sonic speed. Radio imaging of decameter wavelengths (20-90 MHz) is now possible with the Low Frequency Array (LOFAR), opening a new radio window to study coronal shocks which leave the inner solar corona and enter the interplanetary medium and to understand their association with CMEs. To this end we study a coronal shock associated with a CME and type II radio burst to determine the locations where the radio emission is generated and investigate the origin of the band-splitting phenomenon. The type II shock source-positions and spectra were obtained using 91 simultaneous tied-array beams of LOFAR while the CME was observed by the Large Angle and Spectrometric Coronagraph (LASCO) on board the Solar and Heliospheric Observatory (SOHO) and by the COR2A coronagraph of the SECCHI instruments onboard the Solar Terrestrial Relation Observatory (STEREO). The 3D structure was inferred using triangulation of the coronographic observations. Coronal magnetic fields were obtained from a 3-D MHD polytropic model using the photospheric fields measured by the heliospheric imager (HMI) onboard the Solar Dynamic Observatory (SDO) as lower boundary. The type II radio source of the coronal shock observed between 50 and 70 MHz was found to be located at the expanding flank of the CME, where the shock geometry is quasi-perpendicular with Bn 70. The type II radio burst showed first and second harmonic emission, the second harmonic source was cospatial with the first harmonic source to within the observational uncertainty. This suggests that radio wave propagation does not alter the apparent location of the harmonic source. The sources of the two split bands were also found to be cospatial within the observational uncertainty, in agreement with the interpretation that split bands are simultaneous radio emission from upstream and downstream of the shock front. The fast magneto-sonic Mach number derived from this interpretation was found in the range 1.3-1.5. The fast magneto-sonic Mach numbers derived from the modelling of the CME and the coronal magnetic field around the type II source were found in the range 1.4-1.6.

D2.3-0010-18 GRAD-SHAFRANOV RECONSTRUCTION OF A MAGNETIC CLOUD AND ITS EFFECT ON THE COSMIC RAY INTENSITY AT ENERGIES ABOVE 70 MEV AS OBSERVED BY LISA PATHFINDER

Monica Laurenza, monica.laurenza@iaps.inaf.it IAPS/INAF, Roma, Italy

Giuseppe Consolini, giuseppe.consolini@iaps.inaf.it Istituto Nazionale di Astrofisica, Rome, Italy

The passage of an interplanetary counterpart of a Coronal Mass Ejection (ICME) was observed at L1 Lagrangian point between 2016 August 2 at 14.00 UT and August 3 at 3.00 UT. The transit of shock, sheath and magnetic cloud (MC) regions are identified and MC characteristics and topology are studied through the Grad-Shafranov reconstruction technique. Moreover, a classical Forbush decrease (FD) in the galactic cosmic ray (GCR) intensity was observed by the world-wide neutron monitor network and by instruments aboard LISA Pathfinder (PF) after 12.00 UT on 2016 August 2. In particular, the particle detector aboard LISA PF allowed for the monitoring of the GCR intensity at energies above 70 MeV n−1 with a statistical uncertainty of 1% on one-hour binned data. These variations are analyzed as well as the energy dependence of the fractional decrease of the GCR intensity at the dip of the event. Finally, the relationship between the ICME passage and the features of the observed FD are discussed in detail.

D2.3-0011-18 SIGNATURE OF FLUX ROPES BEFORE AND AFTER ERUPTIONS: ELECTRIC CURRENTS IN ACTIVE REGIONS

Solar observations, nonlinear force-free field extrapolations relying on these observations, and three-dimensional magnetohydrodynamic (MHD) models indicate the presence of electric currents in the pre-eruption state and in the course of eruptions of solar magnetic structures which are interpreted as flux ropes (sigmoids, filaments, cavities). The MHD models are able to explain the net currents in active regions by the existence of strong magnetic shear along the polarity inversion lines, thus confirming previous observations. The models have also captured the essence of the behavior of electric currents in active regions during solar eruptions, predicting current-density increases and decreases inside flare ribbons and in the interior of expanding flux ropes, respectively. The observed photospheric current-density maps, inferred from vector magnetic field observations, exhibit whirling ribbon patterns similar to the MHD model results, which are interpreted as the signatures of flux ropes and of quasi-separatrix layers (QSLs) between the magnetic systems in active regions. We will show how observations can confirm enhancement of the total current in these QSLs during the eruptions, and how these observations can be used to investigate whether current density decrease can be seen at the footpoints of erupting flux ropes

D2.3-0012-18 INITIATION AND ACCELERATION OF CORONAL MASS EJECTIONS

Xin Cheng, xincheng@nju.edu.cn Nanjing University, Nanjing, China

Coronal mass ejections (CMEs) are the large-scale and most energetic eruptive phenomena in our solar system and are able to seriously affect the safety of human high-tech activities in outer space. An efficient forecast of CMEs requires a clear understanding of some fundamental but elusive processes, in particular the early evolution and acceleration of CMEs. In this talk, we will first present the evolution characteristics of the pre-eruptive configurations (filaments and magnetic flux ropes) of CMEs and discuss the initiation process of CMEs. In the second part, we will focus on the acceleration process of CMEs and reveal the specific process of magnetic reconnection.

D2.3-0013-18 ERUPTIVE FLARE INITIATION AND THE CME MAGNETIC FIELD

Manolis K. Georgoulis, manolis.georgoulis@academyofathens.gr Academy of Athens, Athens, Greece

Spiros Patsourakos, spatsourakos@gmail.com

University of Ioannina, Dept of Physics, Ioannina, Greece Ioannis Kontogiannis, jkonto@noa.gr

Academy of Athens, Athens, Greece

We recount very recent results on the correlation between photospheric characteristics of eruptive solar active regions and coronal mass ejection (CME) occurrence / characteristics. In particular, we argue that one of the most relevant parameters for CME occurrence is the non-neutralized electric currents appearing exclusively along intense, shear-ridden magnetic polarity-inversion lines (PILs) in the photosphere of eruptive active regions. These currents are simply lacking in the absence of strong PILs and shear. While the physics underlying nonneutralized currents is rich and shows far-reaching ramifications, we will focus on the injection of magnetic helicity due to non-neutralized currents in the pre-eruption phase, that will then be bodily transported via the CME. For a conductive plasma of high magnetic Reynolds number, such as that of the solar corona, we show how the fundamental helicity conservation principle can lead to estimates of, first, the CME's axial magnetic field strength and, second, the anticipated magnetic field strength of the interplanetary CME (ICME) on the verge of geospace. We discuss how this analysis can be viewed as a meaningful initial or boundary condition for more elaborate inner-heliospheric propagation models that further consider the orientation of the ICME magnetic field, thus leading to an improved understanding and prediction of ICME geoeffectiveness.

Part of this work has been supported by the EU Horizon-2020 FLARECAST project (grant agreement no. 640216).

D2.3-0014-18 WHICH FACTORS OF AN ACTIVE REGION DETERMINE WHETHER A FLARE WILL BE ERUPTIVE OR CONFINED?

Astrid Veronig, astrid.veronig@uni-graz.at University of Graz, Graz, Austria

Christian Baumgartner, christian.baumgartner@edu.uni-graz.at University of Graz, Graz, Austria

Julia K. Thalmann, julia.thalmann@uni-graz.at University of Graz, Graz, Austria

We study how the magnetic field determines whether a strong flare launched from an active region (AR) will be eruptive or confined. To this aim, we analyzed 44 flares above GOES class M5.0 that occurred during 2011–2015. We used 3D potential magnetic field models to study their location within the host AR (using the flare distance from the flux-weighted AR center, dFC) and the strength of the overlying coronal field (via decay index n). We also present a first systematic study of the orientation of the coronal magnetic field changing with height, using the orientation ϕ of the flare-relevant polarity inversion line as a measure. We analyzed all quantities with respect to the size of the underlying active-region dipole field, characterized by the distance between the flux-weighted opposite-polarity centers, dPC. We find that flares originating from the periphery of an active-region dipole field (dFC/dPC > 0.5) are predominantly eruptive. Flares originating from underneath the AR dipole field (dFC/dPC < 0.5) tend to be eruptive when they are launched from a compact AR (dPC 60 Mm) and confined when launched from an extended AR. In confined events the flare-relevant field adjusts its orientation quickly to that of the underlying dipole field with height (Δϕ 40° between the surface and the apex of the active-region dipole field), in contrast to eruptive events where it changes more slowly with height. The critical height for torus instability, hcrit = h (n = 1.5), discriminates best between confined (hcrit 40 Mm) and eruptive flares (hcrit 40 Mm). It discriminates better than Δϕ, implying that the decay of the confining field plays a stronger role than its orientation at different heights.

D2.3-0016-18 ASSESSING THE GEO-EFFECTIVENESS OF CMES: WHERE DO WE STAND AT THE END OF SOLAR CYCLE 24

Angelos Vourlidas, angelos.vourlidas@jhuapl.edu

Applied Physics Laboratory, Laurel, Maryland, United States

As the minimum of Cycle 24 nears, the database of CME observations from the LASCO coronagraphs will encompass two full solar cycles. This unprecedented coverage of the eruptive sun is complemented by 10+ years of stereoscopic observations from STEREO, sub-minute imaging of the EUV corona from SDO/AIA, and a plethora of high-resolution spectroscopic observations in many atmospheric layers from Hinode and IRIS. So, what have we learned from these missions about the geo-effective potential of CMEs and their sources?

In this talk, I will discuss that current status, identify some of the gaps and offer strategies for improving our understanding of geo-effective CMEs in the future.

D2.3-0017-18 SOLAR ERUPTIONS INITIATED IN SIGMOIDAL ACTIVE REGIONS

Antonia Savcheva, asavcheva@cfa.harvard.edu

Harvard-Smithsonian Center for Astrophysics, Cambridge, Massachusetts, United States

Coronal sigmoids, generally observed in X-rays and EUV, are S-shaped active regions that have been shown to possess high probability for eruption. They present a direct evidence of the existence of flux ropes in the corona prior to the impulsive phase of eruptions. In order to gain insight into their eruptive behavior and how they get destabilized we need to know their 3D magnetic field structure. First, we review some recent observations and modeling of sigmoidal active regions as the primary hosts of solar eruptions, which can also be used as useful laboratories for studying these phenomena. Then, we concentrate on the analysis of observations and highly data-constrained non-linear force-free field (NLFFF) models over the lifetime of several sigmoidal active regions, where we have captured their magnetic field structure around the times of major flares. We present the topology analysis of a couple of sigmoidal regions pointing us to the probable sites of reconnection. A scenario for eruption is put forward by this analysis. We demonstrate the use of this topology analysis to reconcile the observed eruption features with the standard flare model. Finally, we show a glimpse of how such a NLFFF models of an erupting region can be used to initiate a CMEs in MHD simulations with an unprecedented realistic manner. Such simulations can show the effects of solar transients on the near-Earth environment and solar system space weather.

D2.3-0018-18 PROBING THE EVOLUTION OF A CORONAL CAVITY WITHIN A SOLAR CORONAL MASS EJECTION.

On the 10 September 2017, an X-class solar flare erupted at the solar limb. The associated coronal mass ejection (CME) had the classic three part structure with a bright core surrounded by a dark cavity. This event was captured perfectly by the Hinode EUV imaging spectrometer (EIS). The EIS instrument captured spectroscopically the flaring loops, the current sheet and the cavity for the first time. In the 'standard flare model', magnetic reconnection of coronal loops occurs following the eruption of a magnetic flux rope. The flux rope is a key element of the flare process and eruption but is inherently difficult to observe. Dark cavities observed within a CME are assumed to be flux ropes. The observations we describe here, provide an insight into the characteristics of a cavity, and how the rapid injection of energy from the flare underneath forces the rapid expansion of the flux rope resulting in the eruption. Doppler shifts of over 200 km/s are measured at either end of the cavity. There is mixed temperature plasma - cool material in the centre that also has strong flows, and hot FeXXIV emission being observed. SDO Atmospheric Imaging Assembly (AIA) data shows that the cavity erupts rapidly, and is being driven by the non-thermal energy input from the flare below as measured from Fermi data.

D2.3-0019-18 WHAT CAN WE LEARN FROM CORONAL DIMMINGS ABOUT THE EARLY EVOLUTION OF EARTH-DIRECTED CMES?

Karin Dissauer, karin.dissauer@uni-graz.at University of Graz, Graz, Austria

Astrid Veronig, astrid.veronig@uni-graz.at University of Graz, Graz, Austria

Manuela Temmer, manuela.temmer@uni-graz.at Institute of Physics, UNI Graz, Austria, Graz, Austria Tatiana Podladchikova, t.podladchikova@skoltech.ru

The Skolkovo Institute of Science and Technology, Skolkovo, Russia Kamalam Vanninathan, kamalam.vanninathan@uni-graz.at University of Graz, Graz, Austria

Earth-directed coronal mass ejections (CMEs) are the main drivers for severe space weather events affecting the near-Earth environment. However, they allow the least accurate measurements of their properties due to strong projection effects and especially their early evolution is not well observed with traditional coronagraphs. The most distinct phenomena associated with CMEs are coronal dimmings, i.e. localized regions of reduced emission in the extreme-ultraviolet (EUV) and soft X-rays low in the corona. They are interpreted as density depletions due to mass loss or rapid expansion of the overlying corona during the CME lift off. We extract characteristic parameters describing the dynamics, morphology, magnetic properties and the brightness evolution of coronal dimming regions in order to obtain additional information on the initiation and early evolution of Earth-directed CMEs. To this aim, we developed an automatic dimming detection algorithm (based on logarithmic base-ratio images) that allows us also to distinguish between core and secondary dimming regions.

Using this newly developed method, we extract the physical properties of 76 coronal dimming events in optimized multi-point observations and compare them with characteristic parameters describing their corresponding CMEs. The on-disk dimming evolution is studied using the high-cadence, multi-wavelengths data of SDO/AIA and the line-of-sight (LOS) magnetograms of SDO/HMI, while STEREO/EUVI, COR1 and COR2 data is used to measure the associated CME close to the limb with low projection effects.

The impulsive phase of the dimming (i.e. main expansion phase of its area) starts co-temporal with the onset of the CME and the associated flare and the overall dimming region expands around locations that are identified as core dimming regions. On average this main evacuation phase lasts for about 50 minutes. For the majority of events, the total unsigned magnetic flux involved in the dimming regions is balanced and for selected events up to 30% of this flux results from the localized core dimming regions covering only 10% of the total dimming area. The size of the total dimming region, the total unsigned magnetic flux, as well as its intensity decrease are strongly correlated with the CME mass. Events where high-cadence observations from STEREO are available show in addition also a moderate correlations between the growth rate of the dimming and the maximum speed of the CME.

D2.3-0021-18 ERUPTING SOLAR MAGNETIC FLUX ROPES AND THE BZ CHALLENGE: UNDERSTANDING DETAILS OF CME PROPAGATION IN THE INTERPLANETARY MEDIA

Vasyl Yurchyshyn, vayur@bbso.njit.edu

New Jersey Institute of Technology, Big Bear City, California, United States

Understanding the connection between magnetic topologies of a coronal mass ejection (CME) as observed closer to the Sun and in the interplanetary medium close to the Earth is vital for successful predictions of geomagnetic storms. Recent solar and magnetospheric data convincingly demonstrate that fast CME originating from near the solar disk center are the major cause of extreme space weather events. Moreover, topology and helicity of the ejected fields tends to be mainly preserved as the ejecta propagates and evolves in the interplanetary space. The interplanetary CME that is often observed near the Earth as a well organized helical structure called a magnetic cloud (MC) is the result of expansion of the original ejecta and its interaction with the heliospheric plasma and magnetic fields that may cause the ejecta to alter its shape, rotate and shed its magnetic flux. Therefore the probability of a strong geomagnetic storm to occur as well as its intensity depend on both initial properties of the erupted structure and the further interactions that the ejecta may be subjected to as it expands into the heliosphere. Detailed understanding of this interaction may shed light on the problems related to connecting solar surface phenomena to their interplanetary counterparts. In this talk I will briefly review current progress on the CME evolution in the heliosphere.

D2.3-0022-18 BZ DETERMINATIONS AND FORECASTS USING UCSD ANALYSIS TECHNIQUES

Bernard Jackson, bvjackson@ucsd.edu

University of California, San Diego, La Jolla, California, United States Hsiu-Shan Yu, hsyu@ucsd.edu

University of California, San Diego, La Jolla, California, United States

P. Hick, pphick@ucsd.edu

University of California, San Diego, La Jolla, California, United States Andrew Buffington, abuffington@ucsd.edu

University of California, San Diego, La Jolla, California, United States Gary Zhao, garyzhao63@gmail.com

University of California, San Diego, La Jolla, California, United States

Since the middle of the last decade, UCSD has incorporated magnetic field data in its ISEE IPS tomographic analysis. These data are extrapolated upward from the solar surface using the Current Sheet Source Surface (CSSS) model (Zhao Hoeksema, 1995) provide predictions of the interplanetary field in RTN coordinates. When extrapolated to Earth, these fields can be displayed in a variety of ways, including GSM fields in Bx, By, and Bz coordinates. The Bz GSM field component gives a fair correlation with in-situ derived fields near Earth of a few nano-Tesla variation that maximizes in spring and fall as Russell and McPherron (1973) have shown, but even more significantly its daily variation is shown to be correlated with geomagnetic Kp and Dst indices. UCSD currently operates a website that predicts these transient low-resolution GSM Bz field component variations several days in advance. More challenging to predict are large, short-lived magnetic field components that can be north-south in RTN coordinates, and whose southward GSM Bz can provide the most extreme geomagnetic effects. Here, the record for success is not as clear, but there have been some inroads to these predictions from this analysis that will be discussed.

D2.3-0023-18 THE CORONAL MAGNETIC FIELD DERIVED BY VECTOR TOMOGRAPHY FROM IR AND UV MEASUREMENTS

Maxim Kramar, maxim.kramar@gmail.com University of Hawaii, Pukalani, Hawaii, United States Haosheng Lin, lin@ifa.hawaii.edu

Institute for Astronomy, Pukalani, Hawaii, United States Steven Tomczyk, tomczyk@ucar.edu

High Altitude Observatory, NCAR, Boulder, United States

One of the major problems in solar physics is to measure the coronal magnetic fields before and during the coronal transients events. Spectropolarimetric coronal observations of magnetically sensitive spectral lines provide an information about the magnetic field. However, inversion of the magnetic field from such types of measurements is not straightforward due to the nature of the line formation mechanisms and the fact that the coronal is optically thin. Because of the latter it is generally not possible to spatially resolve the coronal field over the line of sight (LOS). Tomography, i.e. observations form multiple LOSe, is required.

We applied the vector tomography technique to measurements of the Fe XIII 10747 A Hanle effect linear polarization obtained by the Coronal Multichannel Polarimeter (CoMP). The photospheric observations and divergenceless of the field were used as additional constraints in the tomographic inversion. The inversion method also requires to know the 3D distribution of the coronal electron density and temperature which have been reconstructed by scalar field tomography based on STEREO/EUVI data.

The obtained 3D coronal magnetic field has been validated by relating its structures (streamers, pseudostreamers, coronal holes) to the STEREO/EUVI images and to the global 3D coronal electron density obtained by tomography based on STEREO/COR1 data.

Also, we explore how the inclusion of circular polarization IR measurements of the coronal Zeeman effect (together with the linear polarization measurements of the Hanle effect) into the inversion will affect the quality of the magnetic field reconstruction.

D2.3-0024-18 MODELING CORONAL MASS EJECTIONS WITH EUHFORIA: A PARAMETER STUDY OF A MAGNETIZED FLUX ROPE MODEL

Christine Verbeke, cgjmverbeke@gmail.com Catholic University of Leuven, Leuven, Belgium Camilla Scolini, camilla.scolini@kuleuven.be Catholic University of Leuven, Leuven, Belgium Jens Pomoell, jens.pomoell@gmail.com University of Helsinki, Helsinki, Finland Stefaan Poedts, stefaan.poedts@wis.kuleuven.be

Centre for Plasma Astrophysics - KU Leuven, Leuven, Belgium

Coronal Mass Ejections (CMEs) are one of the big influencers on the coronal and interplanetary dynamics. Understanding their origin and evolution from the Sun to the Earth is crucial in order to determine the impact on our Earth and society. One of the key parameters that determine the geo-effectiveness of the coronal mass ejection is its internal magnetic configuration. We present a detailed parameter study of our implemented magnetized flux rope model where we focus on changes in the input parameters and how these changes affect the characteristics of the CME at Earth and their evolution in the heliosphere.

Recently, we have implemented a magnetized flux rope model into the inner heliosphere model EUHFORIA ('EUropean Heliospheric FORecasting Information Asset'). EUHFORIA is a magnetohydrodynamical forecasting model of large-scale dynamics from 0.1 AU up to 2 AU. Coronagraph observations can be used to constrain the kinematics and morphology of the flux rope. One of the key parameters, the magnetic field, is difficult to determine directly from observations. In this work, we approach the problem by conducting a parameter study in which flux ropes with varying magnetic configurations are simulated. We have studied the effect of latitude, longitude, toroidal flux and CME speed in a previous study. Now we also focus on density, half-width and tilt of the CME and determine the sensitivity of the CME propagation to those parameters. These parameters are all closely related and will have an effect on the propagation in multiple ways. We try to disentangle the various effects.

D2.3-0026-18 THE ROLE OF EMERGING MAGNETIC FLUX IN THE INITIATION OF SOLAR ERUPTIONS

The eruption of solar magnetic fields, generating flares and coronal mass ejections, and accelerating energetic particles, can have significant effects on the Earth's space environment. The source of these eruptions is ultimately the magnetic field which emerges from the solar interior into the solar atmosphere to energize the coronal magnetic field. We will review theoretical and observational evidence for the generation of eruptions by flux emergence. We will then report on a series of numerical experiments exploring how dynamic flux emergence into either potential or pre-energized coronal fields can lead to eruptions.

This work was supported by the NASA Living with a Star program.

D2.3-0027-18 SOLAR ERUPTIONS DURING MAGNETIC FLUX EMERGENCE FROM THE CONVECTION ZONE TO THE CORONA

Feng Chen, feng.chen@lasp.colorado.edu

Laboratory for Atmospheric and Space Physics, Boulder, Colorado, United States Matthias Rempel, rempel@ucar.edu

National Center for Atmospheric Research, Boulder, Colorado, United States Kenzie Nimmo, 2082859n@student.gla.ac.uk

University of Glasgow, Glasgow, United Kingdom

We present a realistic numerical model of magnetic flux emergence from the convection zone to the corona. The magnetic and velocity fields from a solar convective dynamo simulation are used as a time-dependent bottom boundary to drive the radiation magnetohydrodynamic simulations. The sophisticated treatments on the radiation and thermal conduction in the simulation allow a direct comparison between model synthesized observables and real observations. The main results are: (1) The quiet Sun corona is heated to over 1 MK by the energy flux provided by the small-scale magnetic field that is maintained by a local dynamo. (2) Emerging flux bundles create several active regions in a 200 Mm wide domain. The coronal temperature is significantly increased as active regions are forming at the photosphere. (3) Synthetic EUV images show coronal loops with various lengths and temperature. (4) More than 100 flares, with 1/3 reaching C class and above, occur in the simulation. The magnetic energy is mostly release through the work done by the Lorentz force, which is quickly thermalized by the viscosity. Moreover, the energy released during the flares and soft X-ray flux, i.e., the flare class nicely reproduce the relationship derived from observations. (5) The biggest flare reaches M2.5 and releases about 5e31 ergs magnetic energy. Plasma in cusp-shaped post-flare loops is heated to several tens MK. The flare is accompanied by the ejection of a giant flux rope that originates from highly sheared magnetic field at the polarity inversion line of a sunspot pair.

Coronal mass ejections (CMEs) are the main driver of space-weather disturbances in the terrestrial magnetosphere. Predicting the impact of CMEs before they arrive at Earth is one of the main challenges of solar and heliospheric physics. A candidate tool for this purpose are numerical simulations. State-of-the-art MHD simulations are now capable of modeling CMEs all the way from Sun to Earth, but they are computationally still too demanding to be used for realtime modeling. At present, only a simplified model (ENLIL), which does not include the corona and simulates CMEs as velocity perturbations, is used for operational space-weather forecast. However, given the continuous increase of computing power, more sophisticated simulations may become available for this purpose in the near future, and first attempts are currently made to prepare for operational use. A specific task at hand is to evaluate the accuracy of these simulations in reproducing in-situ measurements at Earth. I this presentation, we will briefly review state-of-the-art CME simulations and discuss their predictive capabilities and limitations. As an example, we will present a recent Sun-to-Earth simulation of the well-known 14 July 2000 "Bastille-Day" event, which produced a very strong geomagnetic storm.

D2.3-0029-18 DO THE SUNSPOT UMBRA MAGNETIC FIELD CHARACTERISTICS VARY DURING FLARES AND CORONAL MASS EJECTIONS?

Iuliia Zagainova, yuliazag@izmiran.ru IZMIRAN, Moscow, Russia

Victor Fainshtein, vfain@iszf.irk.ru

Institute of Solar-Terrestrial Physics SB RAS, Irkutsk, Russia George Rudenko, rud@iszf.irk.ru

Institute of Solar-Terrestrial Physics SB RAS, Irkutsk, Russia Vladimir Obridko, obridko@izmiran.ru

Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation of the Russian Academy of Sciences (IZMIRAN), Troitsk, Moscow Region, Russia

We found variations in the sunspot umbra magnetic field characteristics within active regions (ARs), where eruptive events (solar flares, coronal mass ejections (CMEs)) originated. The behavior of the maximum of the module of magnetic induction Bmax, the minimum inclination of the magnetic field lines to the normal αmin and their averages values (Bmean and αmean) within umbrae were analyzed. A change of behavior of the magnetic field parameters after flare beginning is observed. Thus, for example, during 3 hours before a solar flare/eruption the min angle in umbrae of the sunspots closely located to the "feet" of an eruptive rope is increasing to a larger values (4° through 10°). Later a strong decreasing over 1 3 hours after the flare onset to small values (1°) is observed. At the same time the αmean angle varies essentially more weakly. This implies that the magnetic tube from the umbra of such sunspots after the flare onset deflects from the initial position almost as a whole, i.e. without essential transformation in the distribution of the magnetic field lines inside the tube.

D2.3-0030-18 PASSAGE OF ICMES, THEIR ASSOCIATED SHOCK STRUCTURES AND RESULTING DISTURBANCES IN THE GEO-MAGNETOSPHERE

Anand Kumar, akumar4462@gmail.com

M.V. M. (Main) Agra Road, Aligarh, Aligarh, India

B. Badruddin, badr.physamu@gmail.com Aligarh Muslim University, Aligarh, India

Coronal mass ejections (CMEs) from the Sun propagate into interplanetary space and evolve to form a large-scale structure. This structure, in many cases, when observed in near-Earth space consists of the CME ejecta and an extended shock region. Thus, while headed towards the Earth, the extended structure may hit the magnetosphere from its near-central, intermediate, or near-end location. Thus, the magnetic environment of the Earth may encounter the solar plasma and field regimes of different strength, topology, and duration in the three situations. Consequently, resulting amplitudes and nature of geomagnetic disturbances may not be similar. In this work, we analyze two geomagnetic indices (Dst and AE) and solar plasma/field parameters (plasma velocity, plasma beta, dynamic pressure, interplanetary magnetic field, its north-south component, and interplanetary electric field) in three different situations when the shock/ICME structure crosses the magnetosphere from central, intermediate, and the near-end portions of its extended structure. We find significant differences in geomagnetic and plasma/field parameters in three situations. These differences are analyzed. We study the behavior of geomagnetic disturbances in relation to simultaneous variations in different plasma/field parameters in these three situations. We study the observed differences not only during the main phase of the geomagnetic disturbances but also their recovery characteristics. Implications of these results are discussed.

D2.3-0031-18 RECENT PROGRESS IN UNDERSTANDING EARTH-AFFECTING SOLAR ERUPTIVE EVENTS

Nariaki Nitta, nitta@lmsal.com

Lockheed Martin Solar and Astrophysics Laboratory, Palo Alto, California, United States David Webb, david.webb@bc.edu

ISR, Boston College, Chestnut Hill, Massachusetts, United States

We report on our effort of the Campaign Events Working Group of ISEST ("International Study of Earth-affecting Solar Transients"), which is one of the four elements of the SCOSTEP/VarSITI program. Our main task is to integrate theory, simulations and observations to better understand the chain of cause-effect activities from the Sun to Earth for a handful of carefully selected events. The events in our list show varied degrees of difficulty to understand the link between the solar origin and the heliospheric consequence. At one end of the spectrum, there are "textbook" events in which we can unambiguously associate the solar eruption with the interplanetary CME (ICME). At another end of the spectrum, there are "problem" events in which it is extremely difficult to find the progenitor of the ICME at 1 AU, either as a CME close to the Sun or as an eruption that is expected to leave low coronal signatures (LCSs). In this talk, using representative examples, we summarize recent progress in understanding the LCS-ICME link, and re-forecasting the shock/CME arrival time and the magnitude of the geomagnetic storm. We show how the progress has been made by coordinated analysis of new data (especially from SDO and STEREO) and advanced numerical modeling.

D2.3-0032-18 ON THE STATE OF THE ART IN PREDICTING SOLAR CORONAL MASS EJECTIONS AND THEIR PLANETARY IMPACTS

Christian Moestl, christian.moestl@oeaw.ac.at

Space Research Institute, Austrian Academy of Sciences, Graz, Austria

Predicting when and how a solar coronal mass ejection will arrive at a given heliospheric location is currently a matter of large international efforts. This is of interest for many different human endeavours, such as aurora tourism, air travel, human spaceflight, scientists studying (exo)planetary atmospheric erosion, and given the possibility of a solar superstorm impacting Earth once in about 100 years, even wealth preservation. Ever more sophisticated tools are being developed, based on numerical, analytical or empirical methods, and they all rely on certain observational inputs. I will review some of the "campaign events", where several groups add different types of modeling to gain a broader picture of the involved physics. However, recently modeling efforts have emerged to cover an entire solar cycle, including on the order of 1000 CMEs.

The difficulty in forecasting a CME arrival hit or miss, its arrival time, speed and magnetic field is caused by several factors. Near the Sun, mechanisms for creating the flux rope inside the CME need to be better understood. Additionally, CMEs can be channeled out of the corona to take on a different trajectory as suggested by its source region. In interplanetary space, the shape and structure of this flux rope as it heavily expands is not well known, and interaction between CMEs and the background wind including high speed streams modulates arrival times as well as CME magnetic fields and speeds. The most important unsolved problem is the prediction of the southward interplanetary magnetic field, which should be possible given that for causing the strongest geomagnetic storms, this field component needs to be strong and steady and thus coherent.

In the near future, the missions Parker Solar Probe and Solar Orbiter may make it possible to greatly enhance our knowledge about CMEs in those key areas. But besides large-scale scientific missions, soon interplanetary space could be populated with small satellites, measuring key parameters of the solar wind at multiple locations.

D2.3-0033-18 SURPRISE GEOEFFECTIVENESS OF STEALTHY CORONAL MASS EJECTIONS FROM THE SUN TO 1 AU

Tamitha Skov, tamitha.skov@aero.org

Aerospace Corporation, Los Angeles, California, United States
Nariaki Nitta, nitta@lmsal.com

Lockheed Martin Solar and Astrophysics Laboratory, Palo Alto, California, United States

One of the underlying problems in the investigation of CME genesis and evolution is relating remotesensing observations of coronal mass ejections (CMEs) to in-situ observations of interplanetary CMEs (ICMEs). Typically, remote-sensing observations of an eruption are first observed in the low corona, followed by coronagraph observations of the global structure of the CME projected onto the plane of the sky, and then finally local, highly-quantitative measurements of an ICME are made in situ along a spacecraft trajectory. However, the dramatic change in solar activity in recent years has raised awareness of "stealth" CMEs, which are CMEs observed in coronagraph data but not in coronal images, especially in disk view. Largely identified during the deep minimum of cycle 23/24, stealth CMEs appear to be on the rise. Since solar cycle 25 brings with it the possibility of yet another low activity cycle, it is very likely that the number of stealth CMEs will remain a significant fraction of ejecta. We investigate the properties of stealth CMEs during the rise of solar cycle 24 through solar maximum, paying special attention to their proximity to coronal holes. We investigate the existence of mismatched polarity reversals in the magnetic field and electron strahl measured in situ within ICMEs associated with stealth CMEs. We discuss the plausibility of interaction with solar wind emanating from coronal holes as a key element of stealth CME eruption as evidenced by expanding coronal hole boundaries during eruption and how continued interaction with the fast solar wind emanating from these coronal holes during interplanetary transit influences the geoeffectivness of the corresponding ICMEs at 1AU.

Geomagnetic storms and other adverse space weather phenomena are known to be mostly caused by energetic eruptions from the Sun, resulting in coronal mass ejections (CMEs) as observed near the Sun, and upon arriving at the Earth, appearing as Interplanetary ICMEs (ICMEs) from in-situ solar wind plasma, magnetic field and particle observations. However, there exist one set of ICMEs that have unambiguous signatures in in-situ observations, but lack of apparent progenitor CMEs; A progenitor CME is often shown as a full halo (angular width of 360 deg) or partial halo (angular width larger than 120 deg) CME in the coronagraphs situated along the Sun-Earth line, such as LASOC onboard SOHO at the L1 point. In particular, we report a detailed study of a geoeffective stealth ICME that occurred on 2011 May 28 and whose progenitor CMEs could not be identified in LASCO images. However, fortunately, candidate progenitor CMEs were captured by the Sun-Earth-Connection-Coronal-andHeliospheric Investigation (SECCHI) onboard the Solar TErrestrial RElations Observatory (STEREO) spacecraft in the quadrature configuration, i.e., on the ecliptic orbit and nearly perpendicular to the SunEarth line. We find that there are two progenitor CMEs launching from the Sun in succession of eight hours. We apply the Graduated Cylindrical Shell (GCS) model to reconstruct the 3D geometry, propagating direction, velocity and brightness of the two CMEs. We find that the main cause of the invisibility of the first CME (CME-1) in SOHO/LASCO is due to its low mass, that is, when the CME emerges above the occulter, its brightness is as faint as the noise. The main cause of the second CME (CME-2) is due to its small size, including narrow angular width and small cross section of the magnetic flux rope. Although propagating toward the Earth, CME-2 appeared as a narrow CME, instead of halo or partial halo CME in the LASCO field of view. We also show that CME-2 propagates faster than CME-1, and they might have interacted in the interplanetary space.

D2.3-0035-18 THREE-DIMENSIONAL SHAPE RECONSTRUCTION AND PROPAGATION OF THE CME OF 22 OCTOBER 2003 FROM LASCO IMAGES

Philippe Lamy, philippe.lamy@lam.fr

Laboratoire d'Astrophysique de Marseille, Marseille, France

The determination of the three-dimensional morphology and propagation of coronal mass ejections (CMEs) in coronagraphic white-light images has been a major question of coronal physics, and a challenge to the observers. The STEREO mission has so far provided the required two view points for stereoscopic reconstruction but that capability has ended with the loss of one of the S/C. Two-dimensional images as provided by the LASCO-C2 and C3 coronagraphs are generally insufficient to provide anything more than an idea of the global and internal structures of a CME. There are however favorable cases where the relatively simple morphology of a CME and the geometry of the observations allow perceiving its global shape. In those cases, forward modeling based on an a-priori shape model can be attempted, and the resulting synthetic images are compared and fitted to the observations. We present the case of the CME detected and tracked by LASCO on 22 October 2003 which is amenable to such an approach. The global shape of this CME on the images however requires the introduction of an elaborated shape model, an asymmetric plasma cloud. The images are first processed in order to remove most of the background or foreground coronal structures (essentially streamers) which are superimposed on the CME. Using the cloud model, we generate synthetic images that are fitted to the observed images. The resulting parameters allow a detailed characterization of the 3D shape and propagation of the CME.

D2.3-0036-18 THE CRITICAL CONDITIONS FOR THE ONSET OF SOLAR FLARES AND CORONAL MASS EJECTIONS

Solar flares and coronal mass ejections (CMEs) are believed to be the explosive liberation of magnetic energy in the solar corona. However, the critical condition for their onset is not yet well understood, and thus the accurate prediction of their onset is still difficult. Which kind of instability determines the critical condition is a key question of this problem, because magnetohydrodynamic (MHD) instabilities, e.g., the kink and torus modes of instabilities, may cause the explosive energy liberation in the solar corona. Recently, Ishiguro and Kusano (2017) proposed that a new instability called double-arc instability (DAI) may work as the initial driver of solar flares and it can trigger the onset of the solar eruption by destabilizing the torus instability. In this paper, we analyze the spatiotemporal evolution of three-dimensional magnetic field structure which is reconstructed by the nonlinear force-free field (NLFFF) extrapolation technique for the solar active regions NOAA 11158 and 12673. The result suggests that the critical condition for the DAI well explains the onset of the major flares occurred in these active regions. Finally, we discuss the applicability of the critical condition to the prediction of flares and CMEs based on the statistical analysis of three hundred active regions.

D2.3-0037-18 NOAA SWPC'S OPERATIONAL GEOSPACE MODEL PERFORMANCE DURING EARTH-AFFECTING EVENTS

University of Michigan, Ann Arbor, Michigan, United States

The Geospace model was first transitioned into real-time operations at the NOAA Space Weather Prediction Center (SWPC) in October 2016 and has been upgraded once since going operational. The Geospace model is a part of the Space Weather Modeling Framework (SWMF) developed at the University of Michigan, and the model simulates the full time-dependent 3D Geospace environment (Earth's magnetosphere, ring current and ionosphere) and predicts global and local space weather parameters such as induced magnetic perturbations in space and on Earth's surface. The current version of the Geospace model uses three coupled components of SWMF: the BATS-R-US global magnetosphere model, the Rice Convection Model (RCM) of the inner magnetosphere, and the Ridley Ionosphere electrodynamics Model (RIM). In the operational mode, SWMF/Geospace runs continually using real-time solar wind data from a satellite at L1, either DSCOVR or ACE. We present an analysis of the overall performance of the Geospace model during the Earth-affecting events that occurred since the Geospace model went operational. We also use past large Earth-affecting events to evaluate how well the current operational version of the model would have performed during enhanced storm periods.

D2.3-0038-18 CME ACCELERATION AND EUV WAVE KINEMATICS FOR SEPTEMBER 10TH 2017 EVENT

University of Colorado at Boulder, Boulder, Colorado, United States

On September 10th 2017 a large solar eruption, accompanied by an X8.2 solar flare, from NOAA active region 12673 was observed on the Sun's western limb by the new Solar Ultraviolet Imager (SUVI) on the GOES-16 spacecraft. We present a method to identify the CME bubble shape and to determine its radial and lateral acceleration. The large field of view of SUVI allows us to study the early impulsive CME acceleration up to 2 solar radii. The CME bubble reveals a fast evolution and strong overexpansion. The radial propagation of the CME revealed a peak value of the acceleration of about 4.8 km/s2, whereas the lateral expansion reached a peak value of 8.9 km/s2. The EUV wave associated with this eruption was observed by SUVI and STEREO-A, which had a separation angle with Earth of 128°, and the common field of view of both spacecraft was 52°. SUVI images above the solar limb reveal the initiation of the EUV wave by the accelerating flanks of the CME bubble, followed by detachment and propagation of the wave with a speed of 1100 km/s. Above the limb, the wave front can be observed as high as 0.7 solar radii. The EUV wave shows a global propagation over the full SUVI disk as well as into the STEREO-A field-of-view, and can be followed up to distances of about 1727 Mm from the source region. We study the propagation and kinematics of the direct as well as the various reflected and refracted EUV wave components on the solar sphere, finding speeds in the range from 370 to 1010 km/s. Finally, we note that this EUV wave is also distinct as it reveals propagation and transmission through a polar coronal hole.

During the declining phase of the current solar cycle, heliospheric activity has suddenly and drastically increased starting from a simple sunspot in Active Region (AR) 2673, which transformed into a complex region with three X-class flares accompanied by several Earth-directed Coronal Mass Ejections (CME) from 4th to 6th of September.

Only a few days later, on 10th September, the same AR 2673 produced solar energetic particles (SEPs) which were registered as a ground level enhancement (GLE) at Earth and the biggest GLE on the surface of Mars as observed by the Radiation Assessment Detector (RAD) since the landing of the Curiosity rover in August 2012. Both Earth and Mars saw an impulsive and intense enhancement of the accelerated protons with energies larger than hundreds of MeV whereas STEREO-A, despite being at the back side of the event, detected gradually increasing fluxes of particles transported there across the heliospheric magnetic field. These high energy particles were mainly accelerated by the flares and shocks which were associated with three consecutive CMEs launched on 9th and 10th of September. Based on STEREO-A and SOHO coronograph images, we identified the initial three-dimensional kinematics of the three CMEs using the Graduated Cylindrical Shell (GCS) model. The first two CMEs had moderate launch speeds while the last one was extremely fast (larger than 2500 km/s at 20 solar radii). These three CMEs interacted as they propagated outwards into the heliosphere and the resulting complex interplanetary CME (ICME) together with its associated shock was highly likely related to the effective acceleration of particles at such high energies causing GLE at both Earth and Mars. The arrival of the ICME at Mars caused a very significant Forbush decrease seen by the Radiation Assessment Detector (RAD) on the surface of Mars and the arrival time is only a few hours later than that at Earth which is about 0.5 AU closer to the Sun than Mars. We investigated the interaction of three CMEs and propagation of the consequent ICME using the Drag Based Model (DBM) as well as the WSA-ENLIL plus cone model and the simulated results are compared with in-situ measurements at both Earth and Mars. The comparison shows that in order to better predict the ICME arrival and its potential space weather impact at Earth and other heliospheric locations, it is essential to 1) analyze the evolution of the ICME kinematics, especially during interactions of different CMEs and better understand the spatially and temporally varying interplanetary conditions of the heliosphere.

D2.3-0040-18 SOLAR ENERGETIC PROTON ACCESS TO THE MAGNETOSPHERE DURING THE SEPTEMBER 2017 PARTICLE EVENT

Paul O'Brien, paul.obrien@aero.org

The Aerospace Corporation, Houson, Texas, United States Joseph Mazur, joseph.mazur@aero.org

The Aerospace Corporation, Chantilly, United States Mark Looper, mark.d.looper@aero.org

Aerospace Corporation, Los Angeles, California, United States

We analyze access of energetic protons (>60 MeV) to the magnetosphere during the solar particle event of September 10, 2018. We rely primarily on measurements from the Relativistic Proton Spectrometer on board NASA's Van Allen Probes. We investigate proton access as a function of location, direction, and energy. We compare observed proton access to established geomagnetic cutoff models with the aim of assessing their utility for high altitude satellite anomaly investigations.

D2.3-0041-18 OPERATIONAL SPACE WEATHER FORECASTING AT THE UK MET OFFICE

Suzy Bingham, suzy.bingham@metoffice.gov.uk UK Met Office, Exeter, United Kingdom David Jackson, david.jackson@metoffice.gov.uk UK Met Office, Exeter, United Kingdom

Siegfried Gonzi, siegfried.gonzi@metoffice.gov.uk UK Met Office, Exeter, United Kingdom

The Met Office Space Weather Operations Centre (MOSWOC) has been monitoring solar transients and resulting impacts on geospace and at Earth, 24/7, since its official opening in 2014. MOSWOC produces twice daily space weather forecasts, and issues real-time alerts and warnings. Forecasts issued include CME arrival times at Earth, and 4 day probabilistic predictions of solar flares, geomagnetic storms, high energy electron events and high energy proton events.

It is essential for forecasters to have access to reliable data from models which are well-supported and implemented on a robust infrastructure. To provide this, the Met Office space weather research group transitions research models to operations. Collaboration with national and international partners is key to the Met Office identifying and implementing suitable models, tools and prediction techniques to forecast solar transient impacts.

Enlil, the solar wind prediction model, is one of several models implemented operationally at the Met Office. The SWPC CME analysis tool is employed to estimate CME parameters such as origin and speed, which are used as input into Enlil. It is crucial for forecasters to understand the strengths and limitations of such models and tools in order to optimise accuracy and to communicate confidence to users. For example, using a CME analysis tool is subjective and introduces errors into predictions of CME arrival time at Earth; error in CME arrival time is

+/-9 hours.

Initial verification of space weather forecasts has been undertaken. This provides an understanding of forecaster added value and of forecast performance compared with climatology and persistence models.

This presentation will examine the operational space weather prediction techniques and models used at the Met Office. Also discussed will be accuracy of these techniques, strengths and limitations, and verification results.

D2.3-0042-18 OPERATIONAL SIMULATION OF HELIOSPHERIC SPACE WEATHER: IMPROVEMENTS OF THE WSA-ENLIL-CONE MODELING SYSTEM

Dusan Odstrcil, dusan.odstrcil@gmail.com

George Mason University and NASA/GSFC, Fairfax, Virginia, United States

The ENLIL-based heliospheric modeling system enables faster-than real-time simulations of corotating and transient disturbances. This hybrid system does not simulate origin of coro- nal mass ejections (CMEs) but uses appearance in coronagraphs, its geometric and kinematic parameters, and launches a CME-like hydrodynamic structure into the solar wind computed using the Wang-Sheeley-Arge (WSA) coronal model. Propagation and interaction in the heliosphere is then solved by a 3-D magnetohydrodynamic (MHD) code. This modeling system is operationally used at NOAA/SWPC, NASA/CCMC, UK/MetOffice, and Korea/KSWPC. In this presentation, we introduce the recent improvements that support modeling of the evolving background solar wind, launching of CME-like transients with embedded magnetic structure, and further facilitate comparison with in-situ and remote observations. Further, we introduce the project testbed system (http://helioweather.net) that has helped us to monitor the model development, verify robustness of new model features, and evaluate the prediction accuracy. Finally, we present results of the verification and validation studies, show improvements over the currently-used version, and illustrate broader applications of the new ENLIL version to support various heliospheric missions.

The drag-based model (DBM) for heliospheric propagation of ICMEs is a widely used simple analytical model which can predict ICME arrival time and speed at a given heliospheric distance (Vršnak et al., 2013, SolPhys). It is based on the assumption that the heliospheric propagation of ICMEs, is solely under the influence of MHD drag, where ICME propagation is determined based on CME properties as well as the properties of the ambient solar wind. The current version of the DBM is operational as part of ESA's SSA programme (http://swe.ssa.esa.int/web/guest/graz-dbm-federated). The DBM takes into account the ICME geometry to track the whole leading edge of an ICME, it can estimate whether or not an ICME will reach the observer and calculate the transit time and impact speed. To estimate the uncertainty for a single event, Drag-Based Ensemble Model (DBEM) was developed (Dumbovic et al., 2018, ApJ) which utilizes an ensemble of the observation-based CME input and synthetic values of the ambient solar wind speed and drag parameter. Using multiple runs with different input parameters, distributions of predicted arrival times and speeds are obtained allowing to forecast the confidence in the likelihood of the ICME arrival. The DBEM was further developed to an on-line application to provide the real-time CME forecast, which is currently in a test phase, and will soon be a part of ESA-SSA Heliospheric Weather Expert Service Group (http://swe.ssa.esa.int/heliospheric-weather). We test the model and the on-line application using observations and compare the performance with other CME propagation models.

D2.3-0044-18 PREDICTING A CME ARRIVAL AS OBSERVED FROM L1 BY HELIOSPHERIC IMAGERS USING ELEVOHI

The Lagrangian point L5 is expected to be an ideal location for a future operational space weather observatory, already indicated by The Solar TErrestrial RElations Observatory (STEREO). STEREO has improved our understanding on the interplanetary (IP) evolution of coronal mass ejections (CMEs). Especially the wide-angle heliospheric imagers (HI) facilitated the development of a variety of methods for analyzing the evolution of CMEs through IP space. In this study, we present an ensemble forecast based on 339 model runs using the HI-based CME prediction tool ELEvoHI and test if an HI observer located at L1 may be an appropriate alternative (or supplement) to an L5 HI observatory. ELEvoHI, the ELlipse Evolution model (ELEvo) based on HI observations uses the benefits of different methods and observations. It provides the possibility to adjust the CME frontal shape (angular width, ellipse aspect ratio) and the direction of motion for each CME event individually. This information can be gained from Graduated Cylindrical Shell (GCS) flux-rope fitting within coronagraph images. Using the ELlipse Conversion (ELCon) method, the observed HI elongation angle is converted into a unit of distance, which reveals the kinematics (including the initial time, distance and speed) of the event. After fitting the time-distance profile of the CME using the drag-based equation of motion, where real-time in situ solar wind speed from 1 AU is used as additional input, we obtain all input parameters needed to run a forecast using the ELEvo model and to predict arrival times and speeds at any target of interest in IP space. Here, we present a test on a slow CME event of 3 November 2010, in situ detected by the lined-up spacecraft MESSENGER and STEREO-B and remotely observed by STEREO-B/HI, i.e. it was a halo CME for

STEREO-B. These conditions simulate an Earth-directed CME observed by HI located at L1. Our study suggests that L1 may provide a sufficient vantage point for an Earth-directed CME, when observed by HI, and that ensemble modeling could be a feasible approach to use ELEvoHI operationally.

D2.3-0045-18 DEVELOPMENT OF ADAPTIVE KALMAN FILTER FOR SOLAR WIND FORECAST

Tatiana Podladchikova, t.podladchikova@skoltech.ru

The Skolkovo Institute of Science and Technology, Skolkovo, Russia
Astrid Veronig, astrid.veronig@uni-graz.at

University of Graz, Graz, Austria

Manuela Temmer, manuela.temmer@uni-graz.at Institute of Physics, UNI Graz, Austria, Graz, Austria Stefan Hofmeister, stefan.hofmeister@uni-graz.at University of Graz, Graz, Austria

Accurate solar wind modeling is important for predicting the arrival and geomagnetic response of high-speed solar wind streams as well as for modeling the transit of coronal mass ejections in interplanetary space and their impact at Earth. Data assimilation techniques combining the strength of models and observations provide a very useful tool for accurate solar wind forecasts. We develop a method to predict the solar wind speed at Earth 1-day ahead by using coronal hole areas derived from SDO AIA images in combination with in situ solar wind plasma and field data (speed, density, and magnetic field magnitude) from ACE and Wind spacecraft. To forecast the solar wind speed, we form a multidimensional linear regression model relating the solar wind speed one day ahead with the fractional coronal hole area observed three days before the current moment, as well as proton density, magnetic field magnitude, and solar wind speed at the current moment. One of the major concerns with such data assimilation scheme is that the regression coefficients do not remain constant and are time-varying. To avoid the fitting of regression coefficients to a particular situation, that can be changed in future, we develop an adaptive Kalman filter to create a dynamic linear regression for the 1-day ahead prediction of the solar wind speed. Testing the developed forecasting technique for the period 2010-2017, we obtain a correlation coefficient between the predicted and observed solar wind speed of 0.93, with an RMS error of prediction of 33 km/s. These results demonstrate that the proposed adaptive Kalman filter method significantly improves the quality of the solar wind forecasts and can be applied for reliable real-time warnings of the space weather conditions in the near-Earth environment.

D2.3-0046-18 INTERPLANETARY SCINTILLATION OBSERVATIONS TO STUDY SOLAR WIND TRANSIENTS. A TOOL FOR SPACE WEATHER FORECASTING

Americo Gonzalez-Esparza, americo@igeofisica.unam.mx

Universidad Nacional Autónoma de México-Instituto de Geofísica, Morelia, Mexico Ernesto Aguilar-Rodriguez, ernesto@geofisica.unam.mx

UNAM, MORELIA, Mexico

Julio-Cesar Mejia-Ambriz, julio@ifm.umich.mx

Universidad Nacional Autónoma de México-Instituto de Geofísica, Morelia, Mexico Pedro Corona-Romero, pdrocr@yahoo.com.mx

Universidad Nacional Autonoma de Mexico, Morelia, Mexico

The study of solar transients and their evolution in the interplanetary medium requires the combination of different instruments. The Interplanetary Scintillation (IPS) technique is a remote sensing measurement that uses radio observations of extragalactic sources to infer solar wind properties along the line of sights. If there is a good number of radio sources around the sun detected by the radio telescope, then it is possible to infer solar wind speeds and changes in solar wind density along their lines of sight. This pixel information can help us to map the interplanetary space to infer solar wind streams and solar transients. The Mexican Array Radio Telescope (MEXART) is a plane array of 4096 dipoles dedicated to study solar wind properties applying the IPS technique. The MEXART is a transit instrument with an operation frequency of 140 MHz. The instrument is currently upgrading to digitalize its backend. This upgrade will allow us to perform daily scanning of the whole sky and to detect a few dozens of extragalactic radio sources. The MEXART is part of a global effort to combine different IPS stations located at distint longitudes under the name of Worldwide Interplanetary Scintillation Stations (WIPSS). Combining data from different WIPSS instruments in real time, potentially would allow us to track the evolution of solar wind transients in the interplanetary medium. This remote sensing of solar wind characteristics obtained from stations at different longitudes could make the IPS technique in a useful tool for space weather.

D2.3-0047-18 PREDICTION TECHNIQUES IN OPERATIONAL SPACE WEATHER FORECASTING

Andrei Zhukov, andrei.zhukov@sidc.be

Royal Observatory of Belgium, Brussels, Belgium

The importance of forecasting space weather conditions is steadily increasing as our society is becoming more and more dependent on advanced technologies that may be affected by disturbed space weather. Operational space weather forecasting is still a difficult task that requires the real-time availability of input data and specific prediction techniques that are reviewed in this presentation, with an emphasis on solar and interplanetary weather. Key observations that are essential for operational space weather forecasting are listed. Predictions made on the base of empirical and statistical methods, as well as physical models, are described. Their validation, accuracy, and limitations are discussed in the context of operational forecasting. Several important problems in the scientific basis of predicting space weather are described, and possible ways to overcome them are discussed, including novel space-borne observations that could be available in future.

D2.3-0048-18 APPLIED ARTIFICIAL INTELLIGENCE FOR SPACE WEATHER RESEARCH

Madhulika Guhathakurta, madhulika.guhathakurta@nasa.gov NASA ARC/HQ, Washington, District of Columbia, United States

The recent advances in Artificial Intelligence (AI) capabilities are particularly relevant to NASA Heliophysics because there is growing evidence that AI techniques can improve our ability to model, understand and predict solar activity using the petabytes of space weather data already within NASA archives. This represents a strategic opportunity, since the need to improve our understanding of space weather is not only mandated by directives such as the National Space Weather Action Plan and the Presidential Executive Order for Coordinating Efforts to Prepare the Nation for Space Weather Events, but also because space weather is a critical consideration for astronaut safety as NASA moves forward with the Space Policy Directive to leave LEO and return to the Moon.

The Frontier Development Lab (FDL) is an AI research accelerator that was established in 2016 to apply emerging AI technologies to space science challenges which are central to NASA's mission priorities. FDL is a partnership between NASA Ames Research Center and the SETI Institute, with corporate sponsors that include IBM, Intel, NVidia, Google, Lockheed, Autodesk, Xprize, Space Resources Luxembourg, as well as USC and other organizations. The goal of FDL is to apply leading edge Artificial Intelligence and Machine Learning (AI/ML) tools to space challenges that impact space exploration and development, and even humanity.

The applied AI projects for space weather that are being undertaken by the Frontier Development Lab (FDL) represent an ideal opportunity for utilization of vast amount of NASA and other data to leverage the public-private partnerships of the FDL program in a manner that is highly complementary to ongoing efforts in space weather research. In this talk I will summarize the findings from two space weather topics, "Solar flare forecasting" and "A tool for exploring variability of Solar-Terrestrial interactions" that were part of FDL 2017 summer program.

D2.3-0049-18 REAL-TIME SOLAR FLARE PREDICTION WITH DEEP NEURAL NETWORK USING VECTOR MAGNETOGRAM AND CHROMOSPHERIC BRIGHTENING

Naoto Nishizuka, nishizuka.naoto@nict.go.jp

National Institute of Information and Communications Technology, Tokyo, Japan Komei Sugiura, komei.sugiura@nict.go.jp

National Institute of Information and Communications Technology, Tokyo, Japan Yuki Kubo, kubo@nict.go.jp

National Institute of Information and Communications Technology, Tokyo, Japan Mitsue Den, den@nict.go.jp

National Institute of Information and Communications Technology, Koganei, Japan Mamoru Ishii, mishii@nict.go.jp

National Institute of Information and Communications Technology, Koganei, Japan

Solar flares are the largest explosive phenomena in the Heliosphere. They affect the earth by X-ray and UV emissions, high energy particles, and magnetic storms, causing troubles of satellites and blackout in a large area. To avoid these problems, it is important to predict flares. The mechanism of solar flares is a long-standing puzzle. The energy storage and triggering processes of flares have been intensely studied. In particular, the amount of solar observation data available in the near real time has remarkably increased. However, it is still difficult to predict flares occurring in the following 24 hr. Here we focused on a new approach to predict flares using deep neural network (DNN). DNN has an advantage to deal with the huge amount of data, from which accurate empirical rules are derived. We expect that DNN models automatically predict flares in the near real-time, and that a new physics can be found from the huge amount of data.

We developed a DNN model to predict flares occurring in the following 24 hr, named Deep Flare Net (DeFN). We used observation data taken by SDO and GOES during 2010-2015:

(1) the line-of-sight and vector magnetograms by HMI/SDO, (2) the lower chromospheric and coronal brightening by 1600 and 131 A filters of AIA/SDO, and (3) the soft X-ray emission by GOES. During 2010-2015, 26 X-class, 383 M-class and 4054 C-class flares were observed on disk. First, we detected active regions from magnetogram images in 1 hr cadence. Second, we extracted features for each region, i.e., the maximum magnetic field strength, the number and the maximum length of magnetic neutral lines, the time variations of magnetic field configurations, the histories of X, M and C-class flares, the background X-ray emission, the activity in the lower chromosphere, and the histories of X-ray and 131 A emissions 1 and 2 hr before an image. Third, we applied a DNN algorithm, which consists of 8 layers, skip connections and batch normalization. We separated the database into training and testing datasets with a chronological split, i.e. in an operational setting. We evaluated the prediction result with a skill score, named the true skill statistic (TSS), and we achieved TSS=0.80 for >=M-class flares and TSS=0.63 for >=C-class flares. These are higher than those for human forecasts. Note that in usual DNN models, the prediction process is a black box. However, in the DeFN model, the features are manually selected, and it is possible to analyze which features are effective for prediction.

In this talk, we would like to introduce our DeFN model and to discuss the flare triggering mechanisms by the comparison of the extracted solar features.

D2.3-0050-18 AUTOMATED DETECTION OF SOLAR WIND HIGH-SPEED STREAMS FROM OMNI DATA AND PROPERTIES DURING CYCLES 23 AND 24

Maxime Grandin, maxime.grandin@helsinki.fi University of Helsinki, Helsinki, Finland Anita Aikio, anita.aikio@oulu.fi

University of Oulu, Oulu, Finland

Alexander Kozlovsky, alexander.kozlovsky@sgo.fi

Solar wind high-speed streams (HSSs) emanating from coronal holes are known to be responsible for geomagnetic disturbances, especially during the declining phase of the solar cycle. When the fast solar wind accumulates behind the preceding slower wind, this creates a compression region characterised by strong interplanetary magnetic field (IMF) magnitude, high solar wind density and high pressure, called corotating interaction region (CIR). Defining criteria to automatically identify such solar wind structures in long time series of data is of particular interest in order to make statistical studies of their effect on planetary environments. We present an automated HSS detection method which exclusively relies on solar wind data measured at 1 AU. The algorithm uses three criteria applied to the IMF magnitude and to the solar wind speed. This method is applied to the solar wind data gathered from 1995 to 2017, which leads to the detection of 640 HSS events from coronal holes for which the solar wind velocity exceeds 500 km/s. In addition to these, some coronal mass ejections (CMEs) are identified as HSSs by the algorithm, and these are removed by comparing with existing CME lists. Using the compiled HSS event catalogue, the statistical behaviour of several solar wind parameters (IMF magnitude, solar wind velocity, density, Akasofu epsilon parameter) and geomagnetic indices (AE and SYM-H) is studied using the superposed epoch analysis method. We discuss the characteristics of HSS events during solar cycles 23 and 24 and their different properties at 1 AU during the rising, maximum, early and late declining phases of a solar cycle.

D2.3-0051-18 PERSISTENCE IN SOLAR ACTIVITY PARAMETERS AND PREDICTION FOR SOLAR CYCLE 25TH

Ashok Singh, aksphys@gmail.com

Lucknow University Lucknow, Lucknow, India Asheesh Bhargawa, asheeshbhargawa@gmail.com Lucknow University Lucknow, Lucknow, India

The analysis of long memory processes in solar activity, space weather and other geophysical phenomena has beena major issue even after the enough available data. We have examined data of three major solar parameters namely the sunspot numbers, 10.7cm index and the Lyman alpha index for the period 1976 - 2017. We have examined the statistical test for persistence in solar activity based on the value of Hurst exponent (H) which is one of the most classical applied methods known as rescaled range analysis. The efficiency of this methodology is further improved on the basis of Hodrick Prescott filter (detrending of time series) applied on observed data for solar cycle 21st to 24th. Further, the Hurst exponent analysis has been used to investigate the persistence of above mentioned solar activity parameters. After calculation we have found H = 0.902, 0.949 and 0.965 for sunspot number, 10.7cm radio flux and Lyman alpha index respectively that supported the strong sense of persistence in time series of considered parameters. Further simplex projection analysis has been used to predict the ascension time and the maximum number of counts for 25th solar cycle. The maximum number of counts for sunspot numbers, F10.7cm index and Lyman alpha has been calculated as 102.8±24.6, 137.25±8.9 and 4.52±1.6 respectively. On basis of above findings we have predicted about the solar cycle 25th and also have forecasted that the next solar cycle will start in the year 2021 (around January) and would last up to the year 2031 (around September) with its maxima in June 2024.

D2.3-0052-18 PREPARING FOR PARKER SOLAR PROBE: SYNTHETIC WHITE-LIGHT IMAGERY AND ANALYSIS FOR THE WIDE-FIELD IMAGER (WISPR)

Paulett Liewer, paulett.liewer@jpl.nasa.gov JPL, Pasadena, California, United States Paulo Penteado, paulo.penteado@jpl.nasa.gov

Russell Howard, russ.howard@nrl.navy.mil

Naval Research Laboratory, Washington, District of Columbia, United States

The Parker Solar Probe (PSP) trajectory, approaching within 10 solar radii, will allow the white light imager, WISPR, to view the inner corona with unprecedented spatial resolution. WISPR, with a field of view extending from 13.5° to 108° elongation angle from the Sun, will image the fine-scale coronal structure with arcminute resolution. The dependency of the Thomson scattering on the imaging geometry (distance and angle from the Sun) dictates that WISPR will be very sensitive to the emission from plasma close to the spacecraft, in contrast to the situation for imaging from 1 AU. Thus, WISPR will be the first 'local' imager providing a crucial link between the large-scale corona and PSP's in-situ measurements. To prepare for this unprecedented viewing of the structures in the inner corona, we are creating synthetic white light images and animations, viewed from the PSP trajectory, using the white-light raytracing package developed at NRL (available through SolarSoft). We will present results for small flux ropes moving outward through the corona as well as fly-throughs of finely structured coronal streamers. Using the synthetic images, analysis techniques similar to traditional white light "jmaps" are used to find the "track" of a flux rope's elongation versus time. The "track" is compared with predictions using simple geometric expressions to gain information on the 3D trajectory of the flux rope. Additional analysis techniques, such as re-projections of the images, will also be discussed.

Interplanetary corotating interaction regions (CIRs) and coronal mass ejections (CMEs) can be remotely imaged in white light (WL), as demonstrated by the in-flight performance of the Coriolis/SMEI and STEREO/HI instruments. Because of the in-ecliptic locations of both the STEREO and Coriolis spacecraft, the longitudinal dimension of interplanetary CIRs and CMEs has, up to now, always been integrated in WL imagery. To synthesize the WL radiance patterns of CIRs and CMEs from an out-of-ecliptic (OOE) vantage point, we perform forward magnetohydrodynamic (MHD) modeling of the background solar wind flow at solar maximum and a halo CME at solar minimum. We assert that a panoramic OOE view in WL would be highly beneficially in revealing the morphology and kinematics of CIRs and CMEs in the hitherto unresolved longitudinal dimension, and hence for monitoring the propagation and evolution of in-ecliptic CMEs for space weather operations.

D2.3-0054-18 MODELLING AND PROTECTION FROM SOLAR FLARES THROUGH CONSTELLATION OF SATELLITES AT LAGRANGIAN POINT 1

University of Petroleum & Energy Studies, Dehradun, India Vishal Singh, singhvishal0103@outlook.com

University of Petroleum & Energy Studies, Dehradun, India Siddharth Jain, siddharthjain18@gmail.com

University of Petroleum & Energy Studies, Dehradun, India

The Sun is the star at the center of the Solar System. It is by far the most important source of energy for life on Earth. The Sun is a boon for now but will be a bane in few million years. Till then, Solar Flares are the greatest problem that the Sun imposes on the Earth. A solar flare is a sudden flash of increased Sun's brightness. Flares are often, but not always, accompanied by a coronal mass ejection. The flare ejects clouds of electrons, ions, and atoms along with the electromagnetic waves through the Sun's corona into the outer space. It takes usually a day or two for these clouds to reach Earth. This paper presents a theoretical way to prevent blackouts on Earth caused by solar flares. A constellation of 5 satellites will be placed strategically at L1. The arms of the satellites join together and an origami protective sheet unfolds itself. The structure then forms a solar windscreen. A three-dimensional, time-dependent solar wind flow from 0 to 2 astronomical units will be simulated where the solar wind is assumed to be supersonic. Comprehensive tables and graphs will be given, which will depict the amount of time that will pass at each stage of the mission and more importantly some idea on the cost in terms of energy, as well as money, will be discussed within today's context. Even though the possibility of such a mission is probably nonexistent for this decade, it is essential to do these exercises increase the chances of human survivability. In addition, this paper hopes to establish some general guidelines for such a protective mission.

D2.3-0055-18 THE NON-FOURIER IMAGE RECONSTRUCTION METHOD FOR THE STIX INSTRUMENT.

Tomasz Mrozek, mrozek@astro.uni.wroc.pl

Space Research Centre, Polish Academy of Sciences, Wroclaw, Poland Marek Siarkowski, ms@cbk.pan.wroc.pl

Space Research Centre of the Polish Academy of Sciences, Wroclaw, Poland

The STIX is an X-ray imaging spectrometer operating in the 4-150 keV range. It will be launched on board the Solar Orbiter in the beginning of 2020. The STIX is equipped with 30 pairs of grids with pixelized Caliste-SO detectors which allow for registering the Fourier components of solar flare HXR emission distribution. In our method we abandon the Fourier's approach to image reconstruction. We use only the number of counts recorded by each of detectors, and reconstruct image on the basis of the classical Maximum Likelihood method. With a knowledge of the instrument detailed geometry we are able to calculate detectors response for point source. For our purpose the point source is a 1x1 arcsec pixel on the Sun. Having calculated point source response on the grid covering entire solar disc, we can iteratively combine point responses with varying weights until the best match between reconstructed and observed detector responses is achieved. Preliminary tests revealed that the developed algorithm reproduce reliable images of simulated solar HXR sources. In particular, it is very robust for some specific configurations which are problematic for other existing algorithms.

D2.3-0056-18 DESIGN AND PRIMARY RESULT OF SOLAR X-RAY MONITOR FOR CHINA SEISMO-ELECTROMAGNETISM SATELLITE

Institute of High Energy Physics, CAS, China, Beijing, China Yanbing Xu, xuyb@ihep.ac.cn

Institute of High Energy Physics, CAS, China, Beijing, China

China Seismo-Electromagnetism Satellite(CSES) is a scientific satellite, which is used to explore the precursory information of earthquakes, space environment monitoring and geoscience. High Energy Particle Package(HEPP) is one of the eight payloads, and its main scientific objective is to measure the variation of the space high energy particles by two sub-detectors, the High-energy payload(HEPP-H), and the Low-energy payload(HEPP-L). Combining with electromagnetic and ionospheric measurement, HEPP can look for the possible relations between the flux, energy, direction or distribution of high energy particles and the electromagnetic radiation caused by earthquake. Most charged particle in the earth is captured from the high-energy particles of the solar, and the Earth space environment is strongly influenced by solar activity, HEPP include the third sub-detector, the solar X-ray monitor(HEPP-X), which is aimed to monitor the activities of solar by the X-ray generated from the interaction of high-energy particles and the Earth's space environment. In addition, by the X-ray observations, we can predict the activities of solar energetic particles in advance. In this paper, we describe the details of HEPP-X about composition, calibration and primary results on orbit.

D2.3-0057-18 LARGE-SCALE SOLAR WIND PHENOMENA: A CATALOG FOR 1976-2016.

Yuri Yermolaev, yermol@iki.rssi.ru

Space Research Institute, Moscow, Russia Irina Lodkina, irina-priem@mail.ru

Space Research Institute, Moscow, Russia Michael Yermolaev, michaely2@yandex.ru Space Research Institute, Moscow, Russia

To obtain reliable conclusions on solar-terrestrial physics, it is very important to correctly identify large-scale phenomena of the solar wind [Yermolaev et al., 2017]. To solve these problems, we create a catalog of large-scale solar wind phenomena for the entire space era on the basis of OMNI database of in situ interplanetary measurements (see website ftp://ftp.iki.rssi.ru/pub/omni/ and paper [Yermolaev et al., 2009]) and now it includes data for 41 years (1976 - 2016). Our catalog identifies reliably 3 types of quasi-stationary streams of the solar wind (heliospheric current sheet (HCS), high speed streams from the coronal holes (HSS), and slow streams from the coronal streamers), and 5 disturbed types (compression regions before fast streams HSS (CIR), and interplanetary manifestations of coronal mass ejections (ICME) that can include magnetic clouds (MC) and Ejecta with the compression region Sheath (SHEMC and SHEEj) preceding them) as well as the interplanetary shock (IS). In particularly our analysis shows that number of disturbed types of solar wind during solar cycle 24 is lower than during previous cycles, but most average interplanetary parameters are insignificantly (within the statistical error) lower. This work was supported by Russian Science Foundation, project no. 16-12-10062.

Forbush decreases (FDs) can be used as one of the "signatures" of an ICME passage. An analytical diffusion-expansion FD model (ForbMod) was developed that is based on the widely used approach of an initially empty, closed magnetic structure (i.e. flux rope) that fills up slowly with particles by diffusion perpendicular to the magnetic field of the flux rope. In our approach the FD amplitude is not only determined by the diffusion process but also by the expansion of the flux rope. While the first process leads to a smaller amplitude the second one leads again to a larger effect. Remote CME observations and 3D reconstruction is used to constrain initial and boundary conditions. CME evolutionary properties are taken into account by incorporating the flux rope expansion. Several options of flux rope expansion are regarded as competing mechanism to diffusion, which can lead to different FD characteristics, and forward modelling is used to analyse flux rope expansion and further constrain the model. In testing the model, a number of spacecraft and planetary observation is utilised, including those by the Radiation Assessment Detector aboard the Mars Rover Curiosity. This project has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 745782.

D2.3-0059-18 STATISTICAL STUDY OF INTERPLANETARY SOLAR RADIO EMISSIONS

Vratislav Krupar, vratislav.krupar@nasa.gov

NASA Goddard Space Flight Center - USRA, Greenbelt, Maryland, United States Adam Szabo, adam.szabo-1@nasa.gov

NASA GSFC, Greenbelt, Maryland, United States Robert Macdowall, robert.macdowall@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, United States

Type II and type III radio bursts are produced by beams of suprathermal electrons accelerated at shock waves in front of coronal mass ejections, and at reconnection sites of solar flares, respectively. While these emissions originating in the solar corona are frequently measured by ground-based instruments, dedicated instruments in space are needed to observe radio sources generated in the solar wind due to the ionospheric cutoff. We performed a statistical analysis of 50 type II and 152 type III radio bursts observed by Solar TErrestrial RElations Observatory (STEREO)/Waves instruments (125 kHz – 16 MHz) between May 2007 and February 2013. We have found that type II radio bursts are preferably observed at higher frequencies, when compared to type III radio bursts in this frequency range. The flux density of type II bursts is statistically frequency independent, while the flux density of type III bursts is larger for the lower frequencies. We derived empirical relations of exponential rise and decay times of type III radio bursts. Finally, we discuss a role of solar radio emissions in space weather forecasting.

D2.3-0060-18 LOW CARBON CHARGE PLASMAS IN ICMES MEASURED BETWEEN YEAR 1998 AND 2011

It is a statistical work investigating the cold materials in 219 ICMEs measured by both ACE and WIND satellites between year 1998 and 2011. A data combination of the ion charge distribution, the proton moments, the alpha particle moments, the magnetic field vectors, and the solar observations are applied. We use a new criterion to identify the cold material that the mean carbon ion charge in the ICME is lower than that of the 24 hours solar wind prior to the ICME by three standard deviations. The cold materials are identified in 71 ICMEs. The cold materials tend to have the speed around 400 to 500 kms-1, the duration between 2 to 6 hours, and the occurrence rate as once or twice per ICME. In all the 71 ICMEs containing the cold materials, we identify two extreme cases that one has all the mean charge of O, Mg, Si, and Fe ions lower than that in the solar wind named as type A, the other has the mean charge of these ions higher than that in the solar wind named as type B. The type A cold materials have the higher proton temperature than the ICME mean value, but the type B have the opposite trend. In all 71 ICMEs, there are 55 ICMEs related to the CMEs approaching to the earth, and 19 of them could be related to the prominence eruptions. The type B materials related to the filament indicate either a heating process appearing beyond 1.2 solar radius when the CMEs erupted, or the filaments being combination of the condensed coronal plasmas and the evaporated chromospheric plasmas. The type B cold materials not related to the filaments are similar to the slow solar wind depletion phenomenon. The nature of the type A materials is not quite clear. In type A materials, there is no heating changing the ion charge distributions under 5 solar radii, but the protons are heated.

D2.3-0061-18 A STUDY ON EFFECT OF SOLAR WIND PLASMA PARAMETERS

Balveer Singh Rathore, balveer_singhra@yahoo.co.in

SMS Govt. Model Science College, Gwalior, India, Gwalior, India

Today's challenge for space weather research is to quantitatively predict the dynamics of the magnetosphere from measured solar wind and interplanetary magnetic field (IMF) conditions. Correlative studies between geomagnetic storms (GMSs) and the various interplanetary (IP) field/plasma parameters have been performed to search for the causes of geomagnetic activity and develop models for predicting the occurrence of GMSs, which are important for space weather predictions. We find a possible relation between GMSs and solar wind and IMF parameters in three different situations and also derived the linear relation for all parameters in three situations. On the basis of the present statistical study, we develop an empirical model. With the help of this model, we can predict all categories of GMSs. This model is based on the following fact: the total IMF Btotal can be used to trigger an alarm for GMSs, when sudden changes in total magnetic field Btotal occur. This is the first alarm condition for a storm's arrival. It is observed in the present study that the southward Bz component of the IMF is an important factor for describing GMSs. A result of the paper is that the magnitude of Bz is maximum neither during the initial phase (at the instant of the IP shock) nor during the main phase (at the instant of Disturbance storm time (Dst) minimum). It is seen in this study that there is a time delay between the maximum value of southward Bz and the Dst minimum, and this time delay can be used in the prediction of the intensity of a magnetic storm two-three hours before the main phase of a GMS. A linear relation has been derived between the maximum value of the southward component of Bz and the Dst, which is Dst = (0:06)+(7:65)Bz +t. Some auxiliary conditions should be fulfilled with this, for example the speed of the solar wind should, on average, be 350 km s¡1 to 750 km s¡1, plasma - should be low and, most importantly, plasma temperature should be low for intense storms. If the plasma temperature is less than 0:5 X 106 K then the Dst value will be greater than the predicted value of Dst or if temperature is greater than 0:5 X 106 K then the Dst value will be less (some nT).

D2.3-0062-18 STUDY ON QUANTITATIVE TECHNOLOGY OF MAGNETIC FIELD CHARACTERS IN SOLAR ACTIVE REGION

Yang Xiaohua, yxhua3@163.com

National Space Science Center, Chinese Academy of Sciences, BeiJing, China

In order to resolve the problem of quantitative techniques of magnetic field characters of solar active region, all SOHO Michelson Doppler Interferometer (MDI) magnetograms from 1996 to 2011 have been segmented from 45oNsim 45oS and 45oEsim 45oW, the causes that lead to projective area distortion of magnetograms have been studied, the Consine area correction factor has been established, and all segmented solar active regions area have been corrected. Quantitative index system of magnetic field characters have been established and improved, include magnetic field properties of active region and polarity separation line magnetic field properties of active region, in all, there are 18 characteristic parameters, the equations of all characters have been defined. The quantitative results have been analyzed by the PCA, and magnetic field of active region10486 erupting X17.2 flare has been qualitative analysis, the results showing: The characteristic parameters of the polarity separation line(WL*sg, WLsg, R,t,i, P hiPSL, PSL,t,i, Lsg, P himax,) can well illustrate the changes of the magnetic field structure during flare bursts. The changes of these parameters may cause magnetic field shear or magnetic field distortion, and play a leading role in the magnetic field structure during flare bursts. The characteristic parameters of the magnetic field fluxes (P hiuns, P hitot) can well illustrate the changes of the magnetic field flux in the active region during flare bursts. When these parameters change, maybe new magnetic field fluxes emerge in the active region, so they have a direct impact on the flux changes during the flare bursts. P hiPSL, and P himax are proposed in this study. 9 characteristic parameters are used together to effectively monitor the changes of the magnetic field structure and magnetic field fluxes in the active region before and after flare bursts. The research results can be directly used for flare, proton event monitoring and used to forecasting models. Enrich the means of monitoring and warning of solar activity, and improve the ability of solar activity monitoring and early warning.

D2.3-0063-18 PHOTOSPHERIC AND CHROMOSPHERIC OBSERVATIONS WITH SOLAR TELESCOPE AT HVAR OBSERVATORY

Jaša Čalogović, jcalogovic@geof.hr

Faculty of Geodesy, University of Zagreb, Zagreb, Croatia Mateja Dumbovic, mateja.dumbovic@uni-graz.at University of Graz, Graz, Austria

Bojan Vrsnak, bvrsnak@geof.hr

Faculty of Geodesy, University of Zagreb, Zagreb, Croatia Roman Brajsa, romanb@geof.hr

Faculty of Geodesy, University of Zagreb, Croatia Ivica Skokic, iskokic@geof.hr

Faculty of Geodesy, University of Zagreb, Zagreb, Croatia

The double solar telescope at the Hvar Observatory consists of two Carl Zeiss refractors, one with 217 mm objective diameter used for photospheric observations and the second one with 130 mm objective used for chromospheric observations. Hvar solar telescope aims to produce the high-resolution and high-cadence imaging of active regions on the Sun using a field of view of about 11 arcmin for the photosphere and 7 arcmin for the chromosphere. The modern Pulnix TM-4200GE 12-bit 4 megapixel CCD cameras recording seven frames per second together with the software that automatically selects the sharpest frames allow to study the rapid changes on the Sun in great detail. High-cadence ground-based observations are an important tool to identify and study solar flares, filaments and other solar phenomena that are associated with coronal mass ejections and their propagation to the Earth. Aiming to improve the space weather forecasts using ground-based observations, we compiled the catalogue of Hvar solar telescope observations in the solar cycle 24. In addition, expansion of this catalogue in future will be used for comparison with ALMA-SSALMON observations. This work has been supported by the Croatian Science Foundation project 6212 “Solar and Stellar Variability” (SOLSTEL).

D2.3-0064-18 OBSERVATION OF HELICITY WITH VECTOR FIELD ON PHOTOSPHERE AND SUBSURFACE

Yu Gao, gy@bao.ac.cn

National Astronomical Observatories, Chinese Academy of Sciences, Beijing, China

Some observational results on current helicity and subsurface kinetic helicity will be presented. The current helicity was derived from vector magnetograms observed by Solar Magnetic Field Telescope installed at Huairou Solar Observing Station. The subsurface kinetic helicity was derived from time-distance helioseismology data-analysis pipeline of Solar Dynamics Observatory/Helioseismic and Magnetic Imager.

D2.3-0065-18 IMPULSIVE PHASE CHROMOSPHERIC FLARE EMISSION, STRUCTURE AND ENERGY BALANCE.

Marcos E. Machado, machado@conae.gov.ar CONAE, Buenos Aires, Argentina

Ryan Milligan, ryan.milligan@glasgow.ac.uk University of Glasgow, Glasgow, United Kingdom Paulo Simões, paulo.simoes@glasgow.ac.uk

SUPA - School of Physics and Astronomy, U. Glasgow, Glasgow, United Kingdom

Using semiempirical modelling results and the analysis of EUV flare data from the SDO spacecraft, we empirically determine the structure of the top of the chromosphere and/or base of the transition zone, during the onset and development of the impulsive phase of several solar flares. Implications of the general results are discussed, in terms of various modes of energy transport that may dominate as a function of time. These finding are contrasted with purely theoretical models, revealing needs for their improvement. In this study we have used in particular the temporal behavior of the intensity and characteristic parameters such as color temperature of the observed Lyman continuum (LyC) emission, we find that besides accelerated particles, heating by heat conduction must play an important role in defining the characteristics of the chromosphere-transition zone structure, while other mechanisms such as radiative backwarming do not play a substantial role at these atmospheric layers.

D2.3-0066-18 THE CORONAL HOLE INFLUENCE PARAMETER (CHIP) AS AN IMPORTANT PARAMETER FOR DEVELOPING THE GEOMAGNETIC STORM PREDICTION MODELS

Amaal Mohamed, amaal.mohamed@nriag.sci.eg

National Research Institute of Astronomy and Geophysics (NRIAG), Cairo, Egypt

It is well demonstrated that fast and wide halo coronal mass ejections (CMEs) can produce geomagnetic storms. Several attempts to predict well in advance the geomagnetic storms have been carried out. Moon et al. [2005], and Kim et al. [2008, 2010] reported on an important geoeffective parameter named direction parameter (D); defined as the ratio of the shortest to the longest distance measured from the solar disk center to the CME front. Such parameter quantifies the asymmetry degree of the CME shape to indicate how much CME propagation can be directed to Earth. They also developed an empirical model for predicting geomagnetic storms; their occurrence and strength as well. Their model is based on the CME parameters such as CME speed (V), CME longitude (L), magnetic eld orientation (M), and the direction parameter (D). They showed that Dst index is best correlated with D. Here, we define another empirical model relying on the coronal hole inuence parameter (CHIP) which was introduced by Gopalswamy et al. [2009] as another CME parameter that can decide the CME propagation towards to or away from the Sun-Earth line. This is important for developing the empirical prediction models. The results show that D can be successfully replaced by the CHIP in the storm prediction model and pertain similar predicted Dst values with an accuracy 56 % for both parameters. In this paper, we also investigate the correlation between the Dst index versus CME speed, sheath speed, and ICME speed for a sample of 19 disc-center MCs and 13 disc-center non-MCs. The correlation is found to be the strongest for MCs (CC=-0.69, -0.82, and-0.84, respectively) and the smallest for non-MCs (CC=-0.20, -0.33, -0.49, respectively). We also investigate the best set of parameters which depend on CME-ICME properties and can decide the most important parameter for Dst prediction. The results show that ICME speed is better correlated with Dst than CME speed (CC=-0.77, and -0.61, respectively) but due to its short forewarning time (30 minutes), we use the CME speed in our empirical model.

D2.3-0067-18 TWO-STEP MAGNETIC RECONNECTION IN A SOLAR FLARE

University of Science and Technology of China, Hefei, China

We report observations of an eruptive X2.8 flare on 2013 May 13, which shows two distinct episodes of energy release in the impulsive phase. The first episode is characterized by the eruption of a magnetic flux rope, similar to the energy-release process in most standard eruptive flares. The second episode, which is stronger than the first normal one and shows enhanced high-energy X-ray and even -ray emissions, is closely associated with magnetic reconnection of a large-scale loop in the aftermath of the eruption. The reconnection inflow of the loop leg is observed in the Solar Dynamics Observatory (SDO)/Atmospheric Imaging Assembly (AIA) 304 A passband and accelerates toward the reconnection region to speeds as high as 130 km/s. Simultaneously, the corresponding outflow jets are observed in the AIA hot passbands with speeds of 740 km/s and a mean temperature of 14 MK. RHESSI observations show a strong burst of hard X-ray (HXR) and -ray emissions with hard electron spectra of δ 3, exhibiting a soft-hard-harder behavior. A distinct altitude decrease of the HXR loop-top source coincides with the inward swing of the loop leg observed in the AIA 304 A passband, which is suggested to be related to the coronal implosion. This fast inflow of magnetic flux contained in the loop leg greatly enhances the reconnection rate and results in very efficient particle acceleration in the second-step reconnection, which also helps to achieve a second higher temperature peak up to T~30 MK.

D2.3-0068-18 OPERATIONAL FLARE FORECASTING BENCHMARKS AND INITIAL PERFORMANCE COMPARISONS

We present here select preliminary results from a recent workshop, "Benchmarks for Operational Solar Flare Forecasts" held at the Institute for Sun-Earth Environmental Research (ISEE) in Nagoya, Japan, in late 2017. Numerous methods were tested in a head-to-head operational forecasting performance exercise. Results are quantified using standard validation metrics, with a preference for metrics based on the probabilistic forecasts (rather than categorical results which are impacted by probability thresholds). We present here a preliminary analysis of the performance impacts of general method attributes, addressing questions centered on "which approaches demonstrate improvement in operational performance, and which approaches do not?"

When coronal mass ejections (CMEs) depart the corona, they leave behind a transient void. Such a region evacuated of plasma is known as a coronal dimming and it contains information about the kinetics of the CME that produced it. The dimming can be so great in the extreme ultraviolet (EUV) that it reduces the overall energy output of the sun in particular emission lines, i.e., dimming is observable in spectral irradiance. This should be generally true for magnetically active stars. The Solar Dynamics Observatory (SDO) EUV Variability Experiment (EVE) data provide an excellent opportunity to search for and parameterize dimming. We focus our search on the 39 extracted emission lines data product. We search these light curves for dimming around all of the >8,500 C1 solar flares observed by the Geostationary Operational Environmental Satellite (GOES) X-ray Sensor (XRS) in the SDO era. In prior work, we have found that it is important to remove the gradual flare phase from dimming light curves in order to obtain slopes and magnitudes that are consistent with what can be obtained by spatially isolating flaring loops in spectral image data. To do this, we peak-match and subtract two different emission line light curves. In this exhaustive search and characterization of dimming, we therefore consider every permutation of the 39 emission lines as well as the "uncorrected" light curves, resulting in 1,521 light curves for every C1 solar flare. Thus, we come to a total of 13 million light curves in which to search for dimming. We parameterize each light curve in terms of magnitude, slope, and duration and correlate these with CME speed and mass. Thus, we obtain a robust relationship between irradiance coronal dimming and CME kinetics.

Here, we briefly describe the feature detection and characterization algorithms developed and applied to the 13 million EUV irradiance light curves. Machine learning techniques have been used for both this backend processing pipeline and to analyze the results. All of the code is open source python available on GitHub (https://github.com/jmason86/James-s-EVEDimming-Index-JEDI). We

then provide preliminary results on the comparison between our new catalog and the established Coordinated Data Analysis Workshops' CME Catalog.

D2.3-0070-18 NEW GLE EVENT ON SEPTEMBER 10, 2017

Polar Geophysical Institute, Apatity, Russia

New ground level enhancement (GLE) was detected by the worldwide network of neutron monitors. This is the second GLE event in the 24th solar cycle. The active "Beta-Gamma-Delta" region 2673 produced it. During September 2017 the region produced a series of strong flares (up to X class). The flare which produced the GLE was of X8.2 magnitude with coordinates S08W83 and started at 15:35 UT. GLE amplitude on neutron monitors did not exceed 6% for 5-min data reduced to the sea level, a lot of stations registered it. Fort Smith (Canada) was the first station detected the solar cosmic rays in 16:10 UT. At the nearest station Inuvik the increase began about half hour later. This is an evidence of a strong anisotropy on the first phase. We have analyzed the GLE event: energy spectra and pitch-angle distribution were derived using a methodics developed by our group. It includes calculation of asymptotic cone for each station using a modern magnetosphere model and solution of the inverse problem. This methodics was already used to calculate many GLE events. Differential energy spectra during the event are derived with a 5-min step. The spectra are not purely power-law forms, but average slope is about $\gamma = -4$. This is hard (rigid) spectrum of solar cosmic rays. The results were compared with GOES spacecraft measurements on adjacent energy range. There is an acceptable agreement.

D2.3-0071-18 CORONAL MASS EJECTIONS' KINEMATICS IN 3D USING OBSERVATIONS FROM STEREO

We have implemented a method to track coronal mass ejections (CME) events in three dimensions by combining triangulation and tie-pointing analysis with a supervised computer vision algorithm. This novel approach does not rely on any geometric constraint, and eliminates the need for visual identification of the CME boundaries. We applied our method to CME events observed simultaneously by the twin Solar Terrestrial Relations Observatory (STEREO) COR2 coronagraph imagers from 2008 to 2011 in order to obtain their 3D kinematical characterization (i.e., the velocity vector) along with their morphological properties. Some of these events have already been analyzed using other methodologies. In these cases, a comparison of results was carried out. We found that, in spite of both the different nature of the methodologies, and the different spatial coverage of the other studies with respect to ours, the majority of the results agree. On the other had, some events exhibited discrepancies in the magnitude of the velocity vector, in the longitudinal direction of propagation, and in latitude. The discrepancies appeared mainly in those cases where quasi-simultaneous, quasi-co-located events were observed in the coronagraphs' fields of view. (G.S. gratefully acknowledges the support of NASA.)

In order to forecast the arrival times of Coronal Mass Ejections (CMEs) at 1 AU for Space Weather purposes, many different pipelines and tools are actually under development by different groups. The solar physics group in Turin Observatory is currently developing new routines to derive from the analysis of remote sensing data different information needed for CME forecasting. These include the determination of ambient Parker spiral conditions, the early detection of CMEs from coronagraphic images, and their propagation in the interplanetary medium taking into account magnetic drag forces. First results on thse activities will be reviewd here.

As a coronal mass ejection (CME) passes, the flank and wake regions are typically strongly disturbed. Various instruments, including the Large Angle and Spectroscopic Coronagraph (LASCO), the Atmospheric Imaging Assembly (AIA), and the Coronal Multi-channel Polarimeter (CoMP), observed a CME close to the east limb on 26 October 2013. A hot (10 MK) rising blob was detected on the east limb, with an initial ejection flow speed of 330 km/s. The magnetic structures on both sides and in the wake of the CME were strongly distorted, showing initiation of turbulent motions with Doppler-shift oscillations enhanced from ±3 km/s to

±15 km/s and effective thermal velocities from 30 km/s to 60 km/s, according to the CoMP observations at the Fe XIII line. The CoMP Doppler-shift maps suggest that the turbulence behaved differently at various heights; it showed clear wave-like torsional oscillations at lower altitudes, which are interpreted as the anti-phase oscillation of an alternating red/blue Doppler shift across the strands at the flank. The turbulence seems to appear differently in the channels of different temperatures. Its turnover time was 1000 seconds for the Fe 171 Å channel, while it was 500 seconds for the Fe 193 Å channel. Mainly horizontal swaying rotations were observed in the Fe 171 Å channel, while more vertical vortices were seen in the Fe 193 Å channel. The differential-emission-measure profiles in the flank and wake regions have two components that evolve differently: the cool component decreased over time, evidently indicating a drop-out of cool materials due to ejection, while the hot component increased dramatically, probably because of the heating process, which is suspected to be a result of magnetic reconnection and turbulence dissipation. These results suggest a new turbulence-heating scenario of the solar corona and solar wind.

D2.3-0074-18 STUDY OF SOLAR TRANSIENTS CAUSING GMSS WITH DST -100NT DURING THE PERIOD 1999-2010

Rajiv Kumar, captainrajiv@live.com

Department Of Physics Govt. College Parasia, Chhindwara, India

The effect of solar features on geospheric conditions leading to geomagnetic storms(GMSs)with Dst index Dst -100nT has been investigated using interplanetary magnetic field(IMF),solar wind data(SWP) and solar geophysical data with CMEs that erupted between 1999 and 2010, we considered all 51 events .The study investigated the relationship coronal mass ejection (CME) and their influence on Earth's geomagnetic field, i.e. storms and sub storms .The study is performed mainly considering intense geomagnetic storms that occurred during Solar Cycle 23 and ascending phase of 24 Solar Cycle. It has been analysed and estimated by cross correlation method that there is a delay of 17 to 96 hours in happening GMSs on the Earth after the happening of the CME on the sun. Keywords: Coronal mass ejections; Solar Wind; Interplanetary Magnetic Field; Geomagnetic Storms.

D2.3-0075-18 COMPARING FEATURES OF GENERATION OF CORONAL MASS EJECTIONS WITH DIFFERENT VELOCITIES IN FIELD OF VIEW OF LASCO CORONAGRAPHS

Iuliia Zagainova, yuliazag@izmiran.ru IZMIRAN, Moscow, Russia

Victor Fainshtein, vfain@iszf.irk.ru

Institute of Solar-Terrestrial Physics SB RAS, Irkutsk, Russia

The question of what determines maximum velocity of a coronal mass ejection (CME) in coronagraph's field of view (FOV) is still pending. This paper compares features of generating CMEs with the smallest, intermediate and the highest velocities in LASCO C2 and C3 FOV, as detected based on analysis of multi-wave data with high temporal and spatial resolution. From data of magnetic field vector measurements, we compared dynamics of the field parameters in umbra of active regions' spots, where CMEs with various velocities occur.

D2.3-0076-18 SPORADIC MICROWAVE RADIATION ASSOCIATED WITH THE FORMATION AND INITIAL EXPANSION OF CMES, AS A TOOL FOR ASSESSING THEIR POTENTIAL GEOEFFECTIVENESS

Olga Sheiner, rfj@nirfi.unn.ru

Radiophysical Research Institute Nizhny Novgorod State University, Nizhny Novgorod, Russia Vladimir Fridman, vladfr42@gmail.com

Radiophysical Research Institute Nizhny Novgorod State University, Nizhny Novgorod, Russia

The issues of studying of geoeffectiveness of coronal mass ejections and their influence on the parameters of the near-Earth space involve analysis of and allowance for the types of the coronal mass ejections, their interaction with the near-Earth space, and the characteristics of their geoeffective manifestations. In this work, we have studied the features of the sporadic solar microwave emission which precedes recording of the geoeffective coronal mass ejections on the basis of the broadband patrol observations of the Sun in the radio range, which cover the centimeter-, decimeter-, and meter-wave ranges in some periods of the XXIst-XXIIIrd solar-activity cycles. It has been shown that a significant number of coronal mass ejections in a two-hour interval before their recording by coronagraphs are preceded by sporadic radio emission that can be defined as radio precursors of coronal mass ejections. The following regular features of the existence of radio precursors of such coronal mass ejections whose effect on the near-Earth space is accompanied by variations in the geomagnetic indices (Kp and Dst) have been established on the basis of statistical consideration: the presence of the broadband radio emission of radio precursors of coronal ejections at least in one wavelength range, centimeter or decimeter; radio-precursor duration exceeds 10 min. It is confirmed that halo and partial halo coronal mass ejections, the most geoeffective coronal mass ejections, are preceded by radio precursors which cover the centimeterand decimeter-wave ranges and have the special features, namely, the radiation component possessing similar temporal behavior at various frequencies of the microwave range with a gradual increase and subsequent decrease in the flux, which simultaneously emerges in the entire microwave range. It is confirmed that in cases where the source of coronal mass ejections is located at the western edge of the solar disk or behind its limb, the broadband radio precursors are absent due to the radiation directivity effect, whereas geoeffective manifestations of the halo and partial halo coronal ejections are possible. In conclusion, it should be emphasized that allowance for the effects in a wide spectrum of electromagnetic waves, including the microwave radiation, in the stage of formation and initial propagation of coronal mass ejections seems a necessary step in the complex approach to considering geoeffectiveness of coronal ejections and their influence on the parameters of the near-Earth space.

D2.3-0077-18 CLUSTERS OF HIGH ENERGY PARTICLES ACCORDING TO HIGH RESOLUTION NEUTRON MONITOR DATA

Yury Balabin, balabin@pgia.ru

Polar Geophysical Institute, Russian Academy of Sciences, Apatity, Russia

Neutron monitors Baksan (Northern Caucasus, 42 N), Apatity (67 N) and Barentsburg (arch. Spitsbergen, 78 N) have an advanced data acquisition system. The system registers each neutron monitors (NM) pulse: which tube produced the pulse and time with one microsecond accuracy. The system is used to study multiplicity events on NM. The multiplicity is characterized by the number of M pulses (neutrons). A multiplicity event is clear distinct: at an average interval between pulses is 22 ms on an NM the intervals between pulses inside an M event are 10-200 mcs and number of events M = 5-200. The multiplicity is two kinds: multiplicity into NM (M = 5-10) and in the atmosphere (M = 10-200). The second kind corresponds to coming in the atmosphere a particle with very high energy from hundreds GeV and more. After upgrading the acquisition system of the monitors are connected to the universal time with accuracy less than 1 mcs. Now three NMs are like one distributed detector. It is found a long sequence of multiplicity events (15-40 events during 20 seconds) after processing the data. An average time profile and spectrum of multiplicity sequence. Time profile shows a gap before and after the sequence with low number of multiplicity events. Frequency of such sequences is two orders more than occasional fluctuation. Further more, a part of the long sequences of multiplicity are simultaneously on two or three NMs. We consider it to be detected by the neutron monitors quick surges (or clusters) of density in the high-energy particle flux. Larmour radius of 1 TeV particle in the interplanetary magnetic field is compatible to heliosphere size. In this case large scale irregularities of the interplanetary magnetic field could produce such surges. Using a wide net of NMs and solving inversed problem one could derive large scale structure of heliosphere.

D2.3-0078-18 MULTI-POINT OBSERVATIONS OF QUASI-PERPENDICULAR INTERPLANETARY SHOCK STRUCTURES

NOAA Space Environment Centre, Boulder, Colorado, United States

We study structures of quasi-perpendicular interplanetary shocks observed by the Wind and DSCOVR spacecraft at L1. The continuous high-time resolution DC-magnetometer measurements (11 vectors/s on Wind and 50 vectors/s on DSCOVR) allow identification of the shock ramp structure and magnetosonic-whistler precursor waves, typically observed at up to several Hz in the spacecraft frame. We analyze the shock structure dependence on the interplanetary shock parameters and on the spacecraft separation. We also identify Wind observed interplanetary shocks without precursors resulting from magnetic field under-sampling to determine the fraction of unresolved precursors.

D2.3-0079-18 STUDY OF HALO CORONAL MASS EJECTIONS USING THE CORSET METHOD

Amanda Lúcia Mesquita, mesquitalamanda@gmail.com

INPE - National Institute for Space Research, São José Dos Campos, Brazil Carlos Roberto Braga, carlos.braga@inpe.br

National Institute for Space Research (INPE), Sao Jose Dos Campos, Brazil Alisson Dal Lago, alisson.dallago@inpe.br

National Institute for Space Research (INPE), Sao Jose Dos Campos, Brazil

Coronal Mass Ejections (CMEs) are large structures constituted of plasma and magnetic field that are expelled by the Sun into the heliosphere. CMEs pointing along the Sun-Earth line, called halo CMEs, are the main cause of geomagnetic storms. We select a set of 31 halo CMEs from April of 2001 until December of 2015. We used a computational algorithm called CORonal Segmentation Technique (CORSET) to track the CME and calculate the kinematic parameters, such as radial and lateral expansion speeds. From the results of the 31 events we obtained an empirical relation between the radial and the lateral expansion speeds, described by the expression Vrad=0.78 Vexp.

D2.3-0080-18 ASHI: AN 'ALL SKY' HELIOSPHERIC IMAGER FOR VIEWING THOMSONSCATTERED LIGHT

Rutherford Appleton Laboratory, Oxford, United Kingdom

We have developed, and are now making a detailed design for an All-Sky Heliospheric Imager (ASHI), to fly on future deep-space missions. ASHI's principal long-term objective is acquisition of a precision photometric map of the inner heliosphere as viewed from deep space. Photometers on the twin Helios spacecraft, the Solar Mass Ejection Imager (SMEI) on the Coriolis satellite, and the Solar-TErrestrial RElations Observatory (STEREO) twin spacecraft Heliospheric Imagers (HIs), all indicate an optimum instrument design for visible-light Thomson-scattering observations. This design views a hemisphere of sky starting a few degrees from the Sun. Two imagers can cover almost all of the whole sky. A key photometric specification for ASHI is 0.1% differential photometry: this enables the three dimensional (3-D) reconstruction of density starting from near the Sun and extending outward. SMEI analyses have demonstrated the success of this technique, and when employed by ASHI, this will provide an order of magnitude better resolution in 3-D density over time. We augment this analysis to include remotely-sensed 2-D velocity, and thus when these imagers are deployed in deep space they can provide comparisons of both imaged density and velocity to those measured in situ. We present recent progress in the instrument design, its expected performance specifications, and the possibilities for its deployment over the next few years.

D2.3-0081-18 CORONAL MASS EJECTION PROPERTIES AT EARTH'S VICINITY

Alisson Dal Lago, alisson.dallago@inpe.br

National Institute for Space Research (INPE), Sao Jose Dos Campos, Brazil Carlos Roberto Braga, carlos.braga@inpe.br

National Institute for Space Research (INPE), Sao Jose Dos Campos, Brazil Amanda Mesquita, amanda.mesquita@inpe.br

National Institute for Space Research, Sao Jose Dos Campos, Brazil

It has been now over 20 years of nearly continuous coverage of solar coronagraphs and interplanetary monitors in the near Earth space. Several studies have addressed the challenge of predicting interplanetary disturbance parameters from solar observations. Special attention has been given to the coronal mass ejections (CMEs) because they are among the main origins of geomagnetic disturbances. They change the properties of the near-earth interplanetary medium, enhancing some key parameters, such as the southward interplanetary magnetic field and the solar wind speed. These quantities are known to be related to the energy transfer from the solar wind to the Earth's magnetosphere via the magnetic reconnection process. Among the several attempts to establish correlations between CMEs and their interplanetary counterpart (ICME) properties, it was found that the average CME propagation speed to 1AU is highly correlated to the ICME peak speed (Dal Lago et al, 2004). In this work, we present an extended study of such correlation, which confirms the results found in our previous study.

D2.3-0082-18 GEOEFFECTIVENESS GENERATED BY THE SIRS AND THE GEOMETRY OF THE SI

Elsa Sanchez-Garcia, elsasg@igeofisica.unam.mx UNAM, Morelia, Mexico

Ernesto Aguilar-Rodriguez, ernesto@geofisica.unam.mx UNAM, MORELIA, Mexico

Americo Gonzalez-Esparza, americo@igeofisica.unam.mx

Universidad Nacional Autónoma de México-Instituto de Geofísica, Morelia, Mexico Esmeralda Romero-Hernández, cefeyda_esm@yahoo.com.mx

UNAM-Institute of Geophysics, Morelia, Mexico

The stream interaction regions (SIRs) are generated in the interplanetary medium when a fast solar wind stream overtakes a slower one. The boundary between fast and slow solar wind flows is known as a stream interface (SI). If these large-scale phenomena interact with the Earth's magnetosphere, they can give rise to geomagnetic storms (GSs). In this study we analyzed the geoeffectiveness of a set of GSs that were generated by SIRs during the cycle 23-24. Their geoeffectivity is measured using magnetic indices at different latitudes: PCN (Polar Cap North) and PCS (Polar Cap South), aa (antipodal amplitude), AE (Auroral Electrojet), Kp (estimated global index) and SYM-H (symmetric disturbance component in H). We analyzed the geoeffective region within the SIRs with respect to the relative position of the SI. In addition, we present an analysis of the geoefectivity generated by the geometry of the SI.

D2.3-0083-18 ELECTROMAGNETIC INDUCTION ASSOCIATED TO SOLAR ERUPTIVE EVENTS AT LOW LATITUDE

Nguessan Kouassi, nguessank23@yahoo.fr

Université Felix Houphouet Boigny d' Abidjan - Cote d'Ivoire, ABIDJAN, Cote D'Ivoire Vafi Doumbia, vafid@yahoo.fr

Université Félix Hophouet Boigny Abidjan Cote D'Ivoire, Abidjan, Cote D'Ivoire Christine Amory, christine.amory@lpp.polytechnique.fr

Laboratoire de Physique des Plasmas / CNRS/UPMC, Saint-Maur-des-Fossés, France Ivory

Nguessan Kouassi Vafi Doumbia Christine Amory

The sun, during its eruption, emits an intense light (solar flare) followed sometimes by the ejection of millions of tons of particles (CME) which crosses the interplanetary medium and causes variation of magnetospheric (ring current) and ionospheric (electrojet) currents. The variation of these currents causes rapid variation of the terrestrial magnetic field which induces, according to Faraday's induction law, an electric field on the surface and in the solid earth. This geoelectric field creates the induced currents, which seeps into the infrastructures, such as transformers, power grids, pipelines, telecommunication cables, etc. . and damage them. These currents have many times caused damage in high latitude regions (Hydro-Québec network) leading to an increased study of GICs in these regions (John G.Kappenman 2005, David Boteler 2014). It is only in these last decades that the effects of these currents are observed in mid-latitudes (in South African's transformers) and low latitudes

D2.3-0084-18 LONG-TERM FLUCTUATIONS OF GEOMAGNETIC FIELD AS PROGNOSTIC PARAMETER OF SOLAR FLARE ACTIVITY

Sergei Snegirev, sneg@nirfi.unn.ru

Radiophysical Research Institute Nizhny Novgorod State University, Nizhny Novgorod, Russia Olga Sheiner, rfj@nirfi.unn.ru

Radiophysical Research Institute Nizhny Novgorod State University, Nizhny Novgorod, Russia Anna Smirnova, alfiyaren@rambler.ru

Radiophysical Research Institute Nizhny Novgorod State University, Nizhny Novgorod, Russia

This paper is devoted to short-term forecasting of powerful solar flares. The opportunity of developing the short-term forecasting technique of geoeffective solar flares is presented in this study. The technique is based on the analysis of the long-period pulsations of the horizontal component of the geomagnetic field. It was shown that there was a period of about 30-60 minutes during the days before the proton solar flares. The analysis of individual events of the powerful solar flares (observed in 1991, 2001, 2005, 2006) and geomagnetic data allowed to develop a prognostic algorithm and short-term forecasting scheme, which is presented in this report. The verification of the proposed method of solar proton flares was carried out for 3 individual events (26.11.11, 07.03.12, 17.05.12). The method enhances the reliability and reduction of the cost of the implementation of short-term forecasting of geoeffective solar flares. The assumptions about the reason of such precursors-fluctuations appearance are made.

The Sun-Earth coupling has significant consequences on several physical systems in the heliosphere, involving significantly different spatial-time scales. A multidisciplinary approach is necessary to understand the full chain of coupled processed. In this work, we carry out a study over the main processes associated to one space weather event, we identify the essential keys from its genesis at Sun to its impact on the terrestrial environment, in particular on the ionosphere, where we evaluate the event response by using multiple instruments, including both in situ and remote measurements. Data acquired by space probes have been used to study the solar origin of the transient, as well as its transport in the interplanetary medium. These data have been combined with the ones acquired in the "Tucumán Low Latitude Observatory for Upper Atmosphere" (26° 51' S, 65° 12' W) to study consequences on the low latitude ionosphere. The main aim of this study is to analyze disturbances in low latitude ionosphere occurred when it is forced by an interaction between solar wind and terrestrial magnetosphere under the presence of a space storm in the geospace. The event we analyze here is associated with a coronal hole, placed near the solar equator, with fast streams of plasma directed towards Earth between 3 and 5 of October, 2015. This event developed an intense geomagnetic storm on October 7th 2015 having a sudden commencement in the early hours that day. The geomagnetic storm reached a Dst index of -124 nT around 23 UTC. Preliminary results showed that, associated with this geomagnetic storm, an ionospheric storm occurred over Tucuman. We observe a negative ionospheric storm followed by a positive ionospheric storm in coincidence with the minimum value of Dst.

D2.3-0086-18 SPEED VECTOR DEFLECTION IN DISTURBED TYPES OF SOLAR WIND.

Yuri Yermolaev, yermol@iki.rssi.ru

Space Research Institute, Moscow, Russia Irina Lodkina, irina-priem@mail.ru

Space Research Institute, Moscow, Russia Michael Yermolaev, michaely2@yandex.ru Space Research Institute, Moscow, Russia Natalia Borodkova, nlbor@yahoo.com

Space Research Institute of RAS, Moscow, Russia

In our recent paper [Yermolaev et al., 2015] we describe the average temporal profiles of interplanetary plasma and field parameters in large-scale solar-wind (SW) streams: corotating interaction regions (CIRs), interplanetary coronal mass ejections (ICMEs including both magnetic clouds (MCs) and Ejecta), and Sheaths as well as interplanetary shocks (ISs). Changes of longitude angle ϕ in CIRs from -2 to +2° agree with earlier observations. Besides we have for the first time analyzed the average temporal profiles of bulk velocity angles in Sheaths and ICMEs and found that the angle ϕ in ICME changes from 2 to -2° while in Sheath it changes from -2 to 2° (similar to change in CIR), i.e., the streams in CIR/Sheath and ICME deflect in the opposite side. When averaging the latitude angle ϑ on all intervals of the chosen SW type, the angle ϑ is almost constant 1°. We made selection SW events with increasing and decreasing angle ϑ and found that average temporal profiles for angle ϑ in selected events have the same "integral-like" shape as for angle ϕ. The difference in average profiles for angles ϕ and ϑ is explained by the fact that most events have increasing profiles for angle in ecliptic plane due to solar rotation while for angle in meridional plane numbers of increasing and decreasing profiles are equal. This work was supported by Russian Science Foundation, project no. 16-12-10062.

SPICE Operations and Scientific Exploitation Team Consortium

F. Auchère, A. Fludra, D. M. Hassler, M. Carlsson, H. Peter, F. Baudin, K. Bocchialini, E. Buchlin, S. Caminade, M. Janvier, C. Mercier, S. Parenti, G. Poulleau, J.-C. Vial, T. Grundy,

Guest, A. Giunta, R. Harrison, S. Sidher, M. Caldwell, S. Matthews, G. Del Zanna, T. Fredvik, V. Hansteen, S. V. Haugan, U. Schuehle, S. Solanki, L. Teriaca, C. DeForest, G. Dunn, J. Hanley, B. Walls, J. Davila, P. Chamberlin, W. Thompson, M. Haberreiter, W. Schmutz, R. Wimmer-Schweingruber, J. Dudik, P. Heinzel

The SPICE spectrometer will address key science goals of the Solar Orbiter mission, including science questions on the origin of CMEs, the acceleration of energetic particles, and the connectivity to the heliosphere.

The SPICE Operations and Scientific Exploitation Team Consortium was selected by ESA in 2016. Support for the operations and scientific exploitation of SPICE is shared between 4 main agencies in Europe (CNES, UKSA, the Norwegian Space Center, and DLR) and NASA in the United States. The lead funding agency is CNES, responsible for providing leadership and coordinating the collective efforts to ensure that the SPICE operations activities are conducted smoothly.

The Consortium will operate SPICE and provide operations support to the Solar Orbiter project to fulfill the mission's science objectives, including:

Planning of SPICE operations, in coordination with other Solar Orbiter instruments.

Providing ESA with a data processing pipeline for low-latency data, and operating a processing pipeline up to calibrated data products.

Maintaining the SPICE instrument, including monitoring and troubleshooting instrument health and safety.

Providing software and support to the scientific community to work with SPICE data.

We will present the tasks to be performed by the consortium, the consortium team structure and responsibilities, as well as an overview of the capabilities of the instrument and its contributions to the Solar Orbiter science goals.

D2.3-0088-18 KINEMATICS OF FAST AND SLOW CORONAL MASS EJECTIONS IN SOLAR CYCLES 23 AND 24

Vaibhav Pant, vaibhavpant55@gmail.com

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States

Coronal mass ejections (CMEs) are the large eruptions of plasma and magnetic field from the solar atmosphere in to the heliosphere. They are the drivers of space weather. We have performed a statistical study of the kinematics of slow and fast CMEs in solar cycles 23 and 24. We have investigated the distribution of the width of slow and fast CMEs using Coordinated Data Analysis Workshops (CDAW) and Computer Aided CME Tracking (CACTus) catalogs. We find that the width distribution of slow and fast CMEs follow different power laws. We study the width distribution of CMEs by isolating the limb CMEs extracted from CDAW catalog and found that results are similar to non limb CMEs. We also study the variation of occurrences of CMEs with solar cycles 23 and 24 using CDAW and CACTus catalogs. We note that while the occurrence rate of fast CMEs follow the sunspot numbers, slow CMEs do not follow this trend, at least in cycle 23. We also find that solar cycle 24 produces more slow and poor CMEs which may be due to the weak polar field of sun and heliospheric field in solar cycle 24.

D2.4-0001-18 SOLAR INFLUENCE ON REGIONAL CLIMATE: WHAT IS THE CURRENT STATUS?

Rémi Thiéblemont, remi.thieblemont@latmos.ipsl.fr

Laboratoire Atmosphères, Milieux, Observations Spatiales, Paris, France

Solar radiation is the primary energy source of the Earth's climate system. It is furthermore firmly established that fluctuations of the solar irradiance, triggered by orbital changes or variations in solar activity, constitute an important driver of climate variability. Beyond the basic consideration of global energy balance and associated changes in the averaged surface temperature, there have been increasing evidences of links between solar variations and regional climate variability at multiple timescales (quasi-decadal, centennial, .). Signatures have for instance been detected in the equatorial Pacific or at high latitudes of both Hemispheres. While the regional solar signals are consistently detected in observational datasets of several kinds (e.g. meteorological reanalysis, historical climate and paleoclimate reconstructions, .), they are not univocally supported by climate model simulations constrained by realistic observed forcings as revealed by the recent analysis of the solar signal in historical simulations of the Coupled Model Intercomparison Project Phase 5 (CMIP5). I will present an overview of recent observational and modeling studies that explored solar influence on climate and describe the mechanisms that are proposed to explain the transfer of the solar signal, i.e. from fluctuations of the solar irradiance and geomagnetic activity to the surface response. These mechanisms involve complex interactions within the atmosphere-ocean coupled system. I will then stress the main scientific issues and discuss ongoing work and future research directions which may help to improve our understanding of solar influences on regional climate.

D2.4-0002-18 UNUSUAL POLAR CONDITIONS OF THE SUN DURING SOLAR CYCLE 24 AND ITS IPLICATIONS FOR CYCLE 25

Kiyoto Shibasaki, shibasaki.kiyoto@md.ccnw.ne.jp Solar Physics Research Inc., Kasugai, Japan

Polar field strength in one solar cycle is known to indicate the strength (e.g., Sunspot number) and phase of the next cycle. In particular the polar field strength (or its proxies such as the polar coronal hole area and microwave polar brightness) during the minimum phase of a given cycle seem to be well correlated with the maximum sunspot number of the next cycle. Polar prominence eruptions and coronal mass ejections have also been found to be indicators of low polar field; their cessation signals the time of polarity reversal. While these indicators are present in the current cycle, significant differences are found regarding the phase lag between the two hemispheres and the duration of polar eruptions. We use data from the Nobeyama Radioheliograph, the Solar Dynamics Observatory, SOLIS, and Wilcox Solar Observatory to highlight these differences. We find that the north polar region of the Sun has near-zero field strength for more than three years. This is unusually long and caused by surges of both polarities heading toward the north pole that prevent the buildup of the polar field. This seems to be due to anti-Hale active regions that appeared around the 2012 peak sunspot activity in the northern hemisphere. The unusual condition is consistent with (i) the continued high-latitude prominence eruption, (ii) the extended period of high tilt angle of the heliospheric current sheet, the weak microwave polar brightness, and (iv) the lack of north polar coronal hole. On the other hand, the south polar field has started building up and the coronal hole has appeared in early 2015 because of large active regions of the correct tilt in the southern hemisphere during the 2014 peak of sunspot activity. The extended period of near-zero field in the north polar region should result in very weak and delayed sunspot activity in the northern hemisphere in cycle 25. On the other hand the south polar field has already increased significantly, suggesting that the activity in the southern hemisphere should start early; the amplitude will depend on how the south polar fields will evolve in the declining phase of cycle 24.

D2.4-0003-18 LONG-TERM EVOLUTION OF SOLAR WIND ELEMENTAL AND CHARGE STATE COMPOSITION

Rudolf Von Steiger, vsteiger@issibern.ch

International Space Science Institute, and University of Bern, Bern, Switzerland Jason A. Gilbert, jagi@umich.edu

University of Michigan, Ann Arbor, Michigan, United States

Before the 1990s observations of heavy elements in the solar wind (A > 4) were limited to a small number of brief periods with favorable conditions. This has changed with the launch of the Ulysses mission in October 1990 and the ACE mission in August 1997, whose SWICS sister instruments are providing us with composition data covering all charge states of C, N, O, Ne, N, Mg, Si, S, and Fe. The nearly uninterrupted data sets combined now cover almost three full decades: Ulysses was operating until June 2009 and ACE continues to operate until today, although with some limitations of SWICS since August 2011. We will present an overview of these unique data sets and the interpretation of the elemental and charge state composition therein.

D2.4-0004-18 STRUCTURE OF THE PHOTOSPHERIC MAGNETIC FIELD DURING SECTOR CROSSINGS OF THE HELIOSPHERIC MAGNETIC FIELD

Tibebu Getachew, tibebu.ayalew@oulu.fi University of Oulu, Oulu, Finland

Ilpo Virtanen, ilpo.virtanen@oulu.fi University of Oulu, Oulu, Finland Kalevi Mursula, kalevi.mursula@oulu.fi University of Oulu, Oulu, Finland

The photospheric magnetic field is the source of the coronal and heliospheric magnetic fields (HMF), but their mutual correspondence is non-trivial and depends on the phase of the solar cycle. The photospheric field during the HMF sector crossings observed at 1 AU has been found to contain enhanced field intensities and definite polarity ordering, forming regions called Hale boundaries. Here we separately study the structure of the photospheric field during the HMF sector crossings during Solar Cycles 21-24 for the four phases of each solar cycle. We use a refined version of Svalgaard's list of major HMF sector crossings, mapped to the Sun using the solar wind speed observed at Earth, and the daily level-3 magnetograms of the photospheric field measured at the Wilcox Solar Observatory in 1976-2016. We find that the structure of the photospheric field corresponding to the HMF sector crossings and the existence and properties of the corresponding Hale bipolar regions varies significantly with solar cycle, solar cycle phase, and hemisphere. The Hale boundaries in more than half of the ascending, maximum, and declining phases are clear and statistically significant. The clearest Hale boundaries are found during the (+,) HMF crossings in the northern hemisphere of odd Cycles 21 and 23, but less systematical during the (+,) crossings in the southern hemisphere of even Cycles 22 and 24. No similar difference between odd and even cycles is found for the (,+) crossings. This shows that the northern hemisphere has a more organized Hale pattern overall. The photospheric field distribution also depicts a larger area for the field of the northern hemisphere during the declining and minimum phases, in a good agreement with the bashful ballerina phenomenon.

Getachew, T., I. Virtanen, and K. Mursula, Structure of the photospheric magnetic field during sector crossings of the heliospheric magnetic field, Solar Physics, 292, 174, 2017.

D2.4-0005-18 THE SUNSPOT NUMBER REVISION AND RECALIBRATION: AN ONGOING EFFORT

Laure Lefevre, laure.lefevre@oma.be

Royal Observatory of Belgium, Brussels, Belgium Fr Clette, frederic.clette@oma.be

Royal Observatory of Belgium / Solar Terrestrial Center of Excellence, Brussels, Belgium

We will present the effort that has been undertaken by the solar community to achieve the revision of the Sunspot Numbers (Sunspot and Group numbers). The well-known Sunspot Number, for example, had never been revised extensively since its creation by Rudolf Wolf in 1849.

We will focus on the different methods that are applied and envisioned for future versions of the two series.

Some corrections rely entirely on base sunspot data, using original and newly recovered historical sunspot records. A critical data selection was applied for the 17th and 18th century and an updated database is now available.

Over the 19th century, the k scaling coefficients of individual observers were recomputed using statistical methodologies developed recently, like the "backbone" method resting on a chain of long-duration observers. After identifying major changes in the observing methods, two major inhomogeneities were corrected in 1884 in the Group Number (40% upward drift) and in 1947 in the Sunspot Number (17% overestimate).

New methods like the Active Day Fraction method (Usoskin, 2016) were applied to combine different observers and compared with other available methods.

For the most recent 50 years, a full re-computation of the group and sunspot numbers was done, using all original data from the 270 stations archived by the World Data Center - SILSO in Brussels.

The new Sunspot Number series definitely exclude a progressive rise in average solar activity between the Maunder Minimum and an exceptional Grand Maximum in the late 20th century. Residual differences between the Group and Sunspot Numbers over the past 250 years confirm that they reflect different properties of the solar cycle.

We conclude on the implications for solar cycle and Earth climate studies and on important new conventions adopted for the new series.

D2.4-0006-18 ON FORECASTING SEASONAL-TO-DECADAL-TO-MILLENNIAL TIME-SCALE SOLAR MAGNETIC ACTIVITY

Mausumi Dikpati, dikpati@hao.ucar.edu

National Center for Atmospheric Research, Boulder, Colorado, United States

Powerful space weather events caused by solar magnetic activity pose serious risks to human health, safety, economic activity and national security. Currently it is impossible to forecast the solar eruptions that can cause these terrestrial events until they are seen on the Sun, hence leaving only a few days to mitigate their hazardous impact on our technological society. After describing the current status of decadal-scale solar activity predictions, based on all plausible methods, I will demonstrate how we can predict the recently observed "seasons" in space weather, which occur in the form of a quasi-periodic, activity burst, followed by a quiet period, with a periodicity of 6-18 months. Successful predictions of these seasonal variations in solar magnetic activity would build a much firmer ground for decadal and longer time-scale forecasts. I will close by discussing the prospects and issues with both short and long-range forecasts.

D2.4-0007-18 CENTURY-LONG, MULTI-WAVELENGTH SOLAR DATABASE FROM KODAIKANAL SOLAR OBSERVATORY

Dipankar Banerjee, dipu@iiap.res.in

Indian Institute of Astrophysics, Bangalore, India

The Kodaikanal observatory has been obtaining solar images since 1904 in broad band white light, narrow band Ca-K 393.37 nm and H 656.3 nm wavelengths. Many of these observations are still continuing. The historical data which were on photographic plates has been digitized. The calibration of the Ca-K, white light and H images have been completed. The digitized data are available through an online portal. Cross calibration between different data sources as collected from observatory across the globe is underway. Some new results from this multiwavelength database will be presented.

D2.4-0008-18 CURRENT EFFORTS TO PRESERVE MT. WILSON HISTORICAL OBSERVATIONS

Alexander Pevtsov, apevtsov@nmsu.edu

National Solar Observatory, Boulder, Colorado, United States Luca Bertello, lbertello@nso.edu

National Solar Observatory, Tucson, Arizona, United States Alexei Pevtsov, apevtsov@nso.edu

National Solar Observatory, Sunspot, New Mexico, United States Ilpo Virtanen, ilpo.virtanen@oulu.fi

University of Oulu, Oulu, Finland

Mount Wilson Observatory (MWO) located in the San Gabriel Mountains near Pasadena, California, has been taking solar observations since the early 1900s. The earliest of which include the nearly unbroken record of daily sunspot activity from 1917 through the present day. Full disk spectroheliograms in Ca K spectral line were taken from 1915 through 1985. Starting from the 1950s synoptic magnetograms were also taken utilizing the full disk longitudinal magnetograph at MWO. However, working with historical long-term dataset presents unique challenges. To be useful, data from hand drawings needed to be digitized. Furthermore, data server failures in the past have led to a loss of public access to parts of these historical data sets. Over the past several years we have worked to process and extract metadata from MWO sunspot drawings. Recently, a new project on the preservation of historical magnetograms has been started. These efforts have provided insight into dealing with issues presented by historical datasets. In this presentation we provide an overview of current efforts in preserving the historical (solar) datasets from MWO. We discuss some of these issues and the application of these insights with regard to the recovery and processing of early magnetogram data along with the current plans to transfer this data to the public domain.

D2.4-0009-18 SOLAR IRRADIANCE VARIABILITY ON TIME SCALES OF DECADES TO MILLENNIA

Natalie Krivova, natalie@mps.mpg.de

Max Planck Institute for Solar System Research, Göttingen, Germany Chi-Ju Wu, wu@mps.mpg.de

Max Planck Institute for Solar System Research, Göttingen, Germany Sami K. Solanki, solanki-office@mps.mpg.de

Max Planck Institute for Solar System Research, Göttingen, Germany Kok Leng Yeo, yeo@mps.mpg.de

Max-Planck-Institute for Solar System Research, Göttingen, Germany

Reconstructions of past solar irradiance changes over as long periods of time as possible are crucial to our understanding of solar influence on climate. They are only possible with the help of suitable models, based on detailed understanding of the mechanisms of the variability. With the advance of such models, also the past reconstructions are becoming more reliable. Nevertheless, the remaining uncertainties spread out when extrapolating back over long periods of time. They are further amplified by the increasingly poorer amount and quality of the available data that bear information on past solar activity. We will discuss the progress and the uncertainties of irradiance reconstructions on time scales of decades to millennia.

D2.4-0010-18 ESTIMATE OF THE SOLAR LUMINOSITY VARIABILITY FOR CYCLES 23 AND 24

Luis Eduardo Antunes Vieira, luis.vieira@inpe.br

INPE - National Institute for Space Research, São José Dos Campos - SP, Brazil

The effect of the solar activity on the solar luminosity, which is the total electromagnetic solar output, is one of the fundamental questions in solar physics. Changes of the solar luminosity can arise from changes of the energy flux in the convection zone that can also affects other solar parameters such as the surface temperature, the apparent radius and shape, and the symmetry of the radiative field itself. Additionally, understanding the latitudinal distribution of the flux density is needed to compare the solar variability and its stellar analogues. Nevertheless, our observations of the solar flux density are limited to a region near the ecliptic plane, which have provided just a raw estimate of the variability of the solar luminosity. Here we present a reconstruction of the solar flux density and solar luminosity for the solar cycle 23 and ascending phase of cycle 24. The reconstruction is based on a combination of a state-of-art solar surface magnetic flux transport model and a semi-empirical total and spectral irradiance model. The flux transport model is based on assimilation of MDI/SOHO and HMI/SDO magnetograms. The irradiance model's free parameters are estimated by minimizing the difference between the model's output and the PMOD Composite of TSI measurements. We have obtained a good agreement between the model's output and the measurements. The distribution of active regions leads to a clear low latitude brightening during the solar maximum. This brightening results from the balance of the contributions from bright (faculae and network) and dark features (sunspots) located in the solar surface, which peaks near the solar equator. As the effects of dark features are limited to a narrower region, the variability of the flux density at the poles is dominated by the evolution of faculae and network. The preliminary results indicate that the heat flux blocked by sunspots is lower than the flux leaked by bright features. Consequently, an increase of the luminosity through the cycle is observed as previously estimated based on near ecliptic measurements. This work also enables an assessment of the properties of solar variability when viewed from out of the ecliptic, i.e., such as we might be viewing other stars of solar activity level. Finally, the limitations of the model and future strategies to extend the reconstruction of the flux density and solar luminosity will be presented.

D2.4-0011-18 CYCLE 24 VARIABILITY OF THE ULTRAVIOLET SOLAR SPECTRAL IRRADIANCE WITH THE SOLAR/SOLSPEC 9 YEARS OF DATA FROM THE INTERNATIONAL SPACE STATION

Accurate measurements of solar spectral irradiance (SSI) and its temporal variation are of primary interest to better understand solar mechanisms and the links between solar variability and Earth's atmosphere and climate. We present recent Ultra Violet (UV) SSI observations performed by the SOLAR/SOLSPEC spectrometer on board the International Space Station. SOLAR/SOLSPEC observations cover the essential of the solar cycle 24, from April 5, 2008 to February 15, 2017.We provide an evolution of the solar spectral irradiance during Cycle 24 using the SOLAR/SOLSPEC data thanks to revised engineering corrections, improved calibrations, and advanced procedures to account for thermal and aging corrections of the instrument. The SOLAR/SOLSPEC observations are compared with other measurements (SORCE/SOLSTICE, SORCE/SIM, SCIAMACHY) and models (SATIRE-S, NRLSSI).

D2.4-0012-18 MAGNETIC FLUX DENSITY IN THE HELIOSPHERE THROUGH FOUR SOLAR CYCLES

Geza Erdos, erdos.geza@wigner.mta.hu

Wigner Research Centre for Physics, Budapest, Hungary Melinda Dosa, dosa.melinda@wigner.mta.hu

Wigner Research Centre for Physics, Budapest, Hungary

The variations of the heliospheric open magnetic flux with location and time is studied using long-term datasets obtained from magnetometers onboard space probes, including near-earth, off-ecliptic and close to Sun observations. Although the determination of the heliospheric magnetic field seems straightforward from source surface magnetic maps, we argue that deviations from the simple radial, ballistic solar wind propagation should be taken into account for specific reasons. These are the effect of fluctuations of the magnetic field, the compression of the plasma at fast-slow solar wind interfaces, and the non-radial solar wind propagation close to the Sun due to high magnetic pressure. Our study recovers a long time scale, up to four solar cycles when possible, which allows us to identify features recurrent with solar rotations and their variations with solar cycles. It is shown, that long lasting recurrent magnetic sector patterns are present as well as recurrent enhanced magnetic field flux densities. However, the rotation periods tend to be different, as the latter rotates with the equatorial rotation period of the Sun, while the sector patterns has slower recurrent periods. We discuss the consequence of the different rotation period, which cause topological constraints in some cases. Our longterm statistical study of the heliosperic open magnetic flux density may contribute to a better understanding of the global magnetic cycle of the Sun

D2.4-0013-18 RESPONSE OF THE ELECTRON SLOT REGION TO SPACE WEATHER CONDITIONS

Lidia Nikitina, lidia.nikitina@canada.ca Natural Resources Canada, Ottawa, Canada Larisa Trichtchenko, ltrichtc@nrcan.gc.ca Natural Resources Canada, Ottawa, Canada

Enhancements of electrons in the slot region attracts a special interest for planning and operations of space missions due to detrimental effects posed to spacecrafts by energetic particles. The aim of this study is to analyse variability of the radiation environment in the slot region during the period from 1998 to 2008, which covers a vide variety of space weather conditions. Dynamics of electrons with energies >0.6 MeV, >1.5 MeV, and >3 MeV were analysed based on HEO-3 highly elliptical orbit data. The data are provided online by the Aerospace Corporation at http://virbo.org/HEO.

All the cases of electron flux increase in the slot location were analysed together with interplanetary and magnetosphere characteristics associated with these events. Probability of occurrence of a "slot event" and its magnitude were defined for different levels of geomagnetic activity, such as DST index and the hourly range of the magnetic field at high latitudes (Canada), and solar wind parameters.

Long-term variability of electron flux in the slot region related to space weather conditions was studied by analysing of annual statistical distributions of electron flux during the solar cycle (1998 - 2008). While the median values of electron fluxes do not change significantly between years, the annual mean as well as standard deviation can vary dramatically, i.e. increasing 100 times for the mean and 3000 times for the standard deviation from geomagnetically more quiet to more active years. The shape of distribution function changes as well, from almost symmetric distribution around the mean value to long-tailed distributions in active years.

D2.4-0014-18 THE STORY OF THE GRAND MODERN MAXIMUM: EVOLUTION OF SOLAR MAGNETIC FIELDS DURING THE 20TH CENTURY

Kalevi Mursula, kalevi.mursula@oulu.fi University of Oulu, Oulu, Finland Lauri Holappa, lauri.holappa@oulu.fi University of Oulu, Oulu, Finland

The 20th century marks a period of exceptionally high solar activity, now termed the Grand Modern Maximum. Sunspot activity increased from a low level at the beginning of the century to a maximum during the solar cycle 19, then settled to a slightly lower level during cycle 20-23, and reduced to a significantly lower level during the ongoing cycle 24. Solar coronal holes are sources of high-speed solar wind streams, which cause persistent geomagnetic activity especially at high latitudes. One can estimate seasonal solar wind speeds at 1 AU for the last 100 years using high-latitude geomagnetic measurements, and thereby obtain information on the long-term evolution of the most important structures of the solar large-scale magnetic field, in particular on persistent coronal holes. The centennial evolution of solar wind speed at 1 AU is different for equinoxes and solstices, reflecting differences in the evolution of polar coronal hole extensions and isolated low-latitude coronal holes. Equinoctial solar wind speeds had their centennial maximum in 1952, during the declining phase of solar cycle 18, verifying that polar coronal holes had exceptionally persistent extensions just before the peak of the Grand Modern Maximum of solar activity. This verifies the solar dynamo model for the most active period of solar activity. On the other hand, solstice speeds due to large low-latitude coronal holes had their centennial maximum during the declining phase of solar cycle 23. A similar configuration of seasonal speeds (coronal holes) as in cycle 23 was not found earlier, not even during the less active cycles of early 20th century. Therefore, the exceptional occurrence of persistent, isolated low-latitude coronal holes in cycle 23 is not related to the low level of sunspot activity but to the demise of the Grand Modern Maximum. Based on these findings we can reconstruct the main features of the solar magnetic field and the overall coronal structure during the last 100 years.

D2.4-0015-18 ORIGIN AND RECOVERY FROM GRAND SOLAR MINIMA IN A TIME DELAY DYNAMO MODEL WITH MAGNETIC NOISE AS AN ADDITIONAL POLOIDAL SOURCE

Bindesh Tripathi, bindeshtrip@gmail.com

St. Xavier's College, Maitighar, Kathmandu, Kathmandu, Nepal Dibyendu Nandi, dnandi@iiserkol.ac.in

Center of Excellence in Space Sciences India, IISER Kolkata, Mohanpur, India

We explore a reduced Babcock-Leighton (BL) dynamo model based on delay differential equations using numerical bifurcation analysis. This model reveals hysteresis, seen in the recent mean-field dynamo model and the direct numerical simulations of turbulent dynamos. The BL model with 'magnetic noise' as an additional weak-source of the poloidal field recovers the solar cycle every time from grand minima, which BL source alone cannot do. The noise-incorporated model exhibits a bimodal distribution of toroidal field energy confirming two modes of solar activity. It also shows intermittency and reproduces phase space collapse, an experimental signature of the Maunder Minimum. The occurrence statistics of grand minima in our model agree reasonably well with the observed statistics in the reconstructed sunspot number. Finally, we demonstrate that the level of magnetic noise controls the duration of grand minima and even has a handle over its waiting period, suggesting a triggering effect of grand minima by the noise and thus shutting down the global dynamo. Therefore, we conclude that the 'magnetic noise' due to small-scale turbulent dynamo action (or other sources) plays a vital role even in Babcock-Leighton dynamo models and thus should be given a serious concern to understand the space climate.

D2.4-0016-18 EXTREME SOLAR PARTICLE EVENTS: HISTORICAL PROSPECTIVE

Ilya Usoskin, ilya.usoskin@oulu.fi University of Oulu, Oulu, Finland

The era of space-borne or ground-based observations of solar energetic particle events (SPEs) covers several decades, respectively. About 70 strong energetic events (ground-level enhancements, GLEs) have been recorded by ground-based instrumentations, the greatest being GLE No.5 on 23-Feb-1956. However, the statistic is still insufficient to conclude whether the Sun can produce stronger events, how much stronger and what the expected rate of their occurrence can be. Of special importance is the question of the worst-case scenario. In order to answer these questions, one has to exploit data on much longer time scales, covering millennia and millions of years, which can be done only using proxy data of cosmogenic radionuclides. Here we present an brief overview of the present state of the art in the study of extreme SEP events and an assessment of the worst case scenario for the SEP fluence in the vicinity of Earth.

The precision measurements of the monthly proton and helium cosmic ray fluxes for the period from May 2011 to May 2017 with Alpha Magnetic Spectrometer on the International Space Station are presented. This period covers the ascending phase of solar cycle 24 together with the reversal of the Sun's magnetic field polarity through the minimum. The detailed variations with time of the proton and helium fluxes are shown up to rigidities of 60 GV. The time dependence of the proton to helium flux ratio is also presented.

D2.4-0018-18 AN EMPIRICAL MODIFICATION OF THE FORCE FIELD APPROACH TO DESCRIBE THE MODULATION OF GALACTIC COSMIC RAYS CLOSE TO EARTH IN A BROAD RANGE OF RIGIDITIES

Jan Gieseler, gieseler@physik.uni-kiel.de

Christian-Albrechts-Universität zu Kiel, Kiel, Germany Bernd Heber, heber@physik.uni-kiel.de

Christian-Albrechts-Universität zu Kiel, Kiel, Germany Konstantin Herbst, herbst@physik.uni-kiel.de

Christian-Albrechts-Universität zu Kiel, Kiel, Germany

On their way through the heliosphere, galactic cosmic rays (GCRs) are modulated by various effects before they can be detected at Earth. This process can be described by the Parker equation, which calculates the phase space distribution of GCRs depending on the main modulation processes: convection, drifts, diffusion, and adiabatic energy changes. A first-order approximation of this equation is the force field approach, reducing it to a one-parameter dependency, the solar modulation potential ϕ. Utilizing this approach, it is possible to reconstruct ϕ from ground-based and spacecraft measurements. However, it has been shown previously that ϕ depends not only on the local interstellar spectrum (LIS) but also on the energy range of interest. We have investigated this energy dependence further, using published proton intensity spectra obtained by PAMELA and heavier nuclei measurements from IMP-8 and ACE/CRIS. Our results show severe limitations at lower energies including a strong dependence on the solar magnetic epoch. Based on these findings, we will outline a new tool to describe GCR proton spectra in the energy range from a few hundred MeV to tens of GeV over the last solar cycles. In order to show the importance of our modification, we calculate the global production rates of the cosmogenic radionuclide 10Be which is a proxy for the solar activity ranging back thousands of years.

D2.4-0019-18 VARIATION OF THE PSD SLOPES OF COSMIC RAYS IN 1953-2016

Pauli Väisänen, pauli.vaisanen@oulu.fi University of Oulu, Oulu, Finland

Ilya Usoskin, ilya.usoskin@oulu.fi University of Oulu, Oulu, Finland Kalevi Mursula, kalevi.mursula@oulu.fi University of Oulu, Oulu, Finland

The flux of cosmic rays observed at the Earth is modulated by the Sun and the heliosphere. Modulation of the galactic cosmic rays (GCR) is mostly caused by scattering on the inhomogeneities of the heliospheric magnetic field (HMF). Sporadic solar events like coronal mass ejections and merged interaction regions affect the HMF and scatter GCR. Turbulent variations are another source of inhomogeneities of the, causing scattering at different scales. The variability of the cosmic ray flux as measured ground-based neutron monitors (NMs) can serve as a probe for heliospheric turbulence and its scaling. Turbulent phenomena are often characterized by a power-law type power spectral density (PSD) of the measured variable. Using

1-hour resolution data from the global NM network in 1953–2016, we have studied the powerlaw slope in the frequency range between 5.56 10−6 and 2.14 10−6 Hz, corresponding to time scales of 50 and 130 hours. The mean power-law slope was found to be 1.81 0.02. We have studied the temporal variation of this power-law slope and found that the slope values differ for different solar cycles and different cycle phases, with steeper slopes observed usually during the ascending and maximum phases, and less steep slopes during the declining and minimum phases. This implies that the scaling of HMF turbulence varies in the course of the solar cycle, reflecting different physical processes affecting GCR modulation.

D2.4-0020-18 CHARACTERISTICS OF HIGH INTENSITY LONG DURATION CONTINUOUS AURORAL ACTIVITIES (HILDCAAS) AND ESTIMATION OF AKASOFU PARAMETERS ALONG WITH ITS CORRECTION.

Binod Adhikari, binod.adhi@gmail.com St. Xavier's College, Kathmandu, Nepal Binod Adhikari, binod.adhi@gmail.com St. Xavier's College, Kathmandu, Nepal Odim Mendes, odim.mendes@inpe.br INPE, Sao Jose Dos Campos, Brazil

National Institute for Space Research (INPE), Sao Jose Campos, Brazil

High Intensity Long Duration Continuous AE Activities (HILDCAAs) are form of geomagnetic disturbances caused by intermittent magnetic reconnection. By definition of HILDCAAs, which are intense auroral activity characterized by peak AE intensity greater than 1000nT at least for 2 days and within this period the value of AE never drops below 200nT for more than 2 h at a time. In our work, we study the characteristics of HILDCAA events based on auroral electrojet index and component of interplanetary magnetic field (Bz) using continuous wavelet transform and discrete wavelet transform. We also estimate the Akasofu parameters and its corrections during HILDCAAs. We found that during HILDCAAs, there is high fluctuation in IMF-Bz with corresponding peak of AE index. The CWT analysis shows highest intensity power areas from 50 to 300 minutes for both AE and Bz during the HILDCAAs. In DWT analysis, we used higher level of decomposition to identity the common singularities present on AE and Bz. Moreover, we found that different HILDCAA events have different geoeffectiveness based on their interplanetary cause and the amount of the average energy transferred to the magnetospheric/ionospheric system. We also found that second correction in Akasofu parameter gives nearly thrice the amount of energy predicted by Akasofu parameter without correction. This indicates that the solar wind magnetosphere energy coupling efficiency during the main phase of the storm is larger than in the HILDCAA interval.

D2.4-0021-18 SOLAR CYCLE VARIATIONS OF OCCURRENCE OF SOUTHWARD COMPONENT OF INTERPLANETARY MAGNETIC FIELD OBSERVED NEAR 1 AU

Felix Pereira, felix.pereira@pnguot.ac.pg

PNG University of Technology, Lae, Papua New Guinea Girish T.E, tegirish5@yahoo.co.in

University College, Trivandrum, Trivandrum, India Gabriel Anduwan, ganduwan@gmail.com

PNG University of Technology, Lae, Papua New Guinea

Occurrence of southward component of IMF in the GSE system in different IMF sector polarities separately has been studied for the period from 1967 to 2016 covering solar cycles 20 to 24 using satellite data. A systematic helio-latitudinal dependence and sunspot cycle variations were observed for the period of study. The phase of the annual variations of the occurrence of the southward component of IMF in the GSE system near the Earth reverses with the reversal of the polarity of large-scale solar polar magnetic field during the above sunspot cycles. The sunspot cycle-dependence of different magnitude ranges of IMF Bz (GSE) near 1 AU is also studied during the period suggesting some characteristic features.

D2.4-0022-18 VLF IONOSPHERIC EMISSION MONITORED ON THE EQUATOR

Ericson Lopez, ericsonl@hotmail.com

Quito Astronomical Observatory, Quito, Ecuador

Ionospheric electromagnetic phenomena were recorded by the VLF instrument built at the Quito Astronomical Observatory (latitude 0°,12',57 " S; longitude 78°,29',56" W). The observations were made with an electric antenna in the frequency range 0 Hz - 100 kHz. The signal processing is carries out using a computer audio card, so the instrument sensitivity depends on the audio card electronic features. The software Spectrum lab is used for data processing and visualization. Characteristics of the emissions are presented based on the study of the signal phase and amplitude variations corresponding to distinct types of electromagnetic disturbances.

D2.4-0023-18 DYNAMICAL MODELS FOR SPACE WEATHER PREDICTION: A MULTIDISCIPLINARY APPROACH, COMPARATIVE ANALYSIS, AND NUMERICAL RESULTS.

Vitaliy Yatsenko, stcu5240@gmail.com

Space Research Institute of NASU and NSAU, Kyiv, Ukraine

This report focuses on comparative analysis of dynamical models for space weather prediction. SRI researchers utilize a variety of models to better understand the current state of the space weather environment, as well as to predict future events. Many of these models have been developed by Space Research Institute (Ukraine), while other models have been developed by participants in the EU project "Progress" and are shared by the space weather community. This report starts with the physical basis and a brief description of the system identication approach. Following that, several examples illustrate practical issues in temporal and spatiotemporal prediction, NARMAX and bilinear modeling. This report concerns improvement and new development of models based on data driven modelling, such as BILINEAR and NARMAX The following methods and models have been proposed: (a) dynamical-information approach to NARMAX system identication; (b) combination of NARMAX model and Lyapunov dimension; (c) guaranteed prediction; (d) robust models; (e) risk assessment in safety analysis. The Guaranteed NARMAX Model (GNM) also provides predictions. Its main advantage is that it delivers an increased prediction reliability in comparison to earlier SRI models. A novel method of the probabilistic risk assessment of the inuence of the free space environment on space systems is considered. As an example the superlight-weight thermal protection system (TPS) is considered. An approach based on combination of nonlinear dynamical models and Lyapunov dimension are used to analyze measurements of the geomagnetic indexes and solar wind parameters.

D2.4-0024-18 FLEXIBILITY, VALIDITY AND SUSCEPTIBILITY OF CYLINDRICAL LANGMUIR PROBES FOR CUBESAT AND PICO-SATELLITE TO CHARACTERIZE IONOSPHERE AND THERMOSPHERE PLASMA

Shankar Bhattarai, oshobhattarai2@gmail.com Department of Physics, Kathmandu, Nepal

Nobel Laureate Irving Langmuir pioneered the use of electrostatic probes to measure the electron temperature, number density, floating potential, and plasma potential in ionized gases (in the 1920's). Langmuir probe is comprised of an exposed conductor (e.g., wire) immersed within a plasma. The theory of interpreting the data acquired (namely the current drawn from the plasma at a sequence of different bias voltages) from Langmuir probes is well established. Druyvesteyn noted that the second derivative of the probe current with respect to the bias voltage is proportional to the electron energy distribution function. The analysis by Laframboise enabled accurate evaluation of experimental data for cylindrical and spherical probes regardless of sheath size. PEPL makes extensive use of planar and cylindrical Langmuir (single, double, and triple) probes for evaluating plasma properties in the plumes of thrusters and in near electrode regions. The small size of typical Langmuir probes coupled with their relatively simple theory of operation make them an indispensable and widely used plasma diagnostic. We can constructs custom probes sized to each experiment, commercially available systems do exist. This research paper explore the reliability, validity and susceptibility of small dimensional Langmuir Probe in CubeSat and Pico-Satellite for Ionosphere Characterizations. There is no general theory of Langmuir probes which is applicable to all measurement conditions, because it depends on the probe size and geometry, plasma density and temperature, platform velocity, and other factors. The actual design of the probe is usually determined by considering the relationship between the probe dimensions and the Debye length of the plasma. Keywords: Ionospheric Plasma, CubeSat, Langmuir Probe, Plasma Characterization

D2.4-0025-18 STATISTICAL STUDY OF PC4 MAGNETIC PULSATIONS AT LOW LATITUDES IN INDIA AND ITS DEPENDENCE ON SOLAR WIND VELOCITY AND INTERPLANETARY MAGNETIC FIELD

Iqbal Ahmad Ansari, iaaamuphysics@gmail.com Aligarh Muslim University, Aligarh, India

Magnetic Pulsations recorded on the ground are the signatures of the integrated signals from the earth's magnetosphere. Pc4 geomagnetic pulsations are quasi-sinusoidal variations in the earth's magnetic field in the period range 45-150 seconds. The magnitude of these pulsations ranges from fraction of a nano Tesla (nT) to several nT. Although these pulsations can be observed in a number of ways, yet the application of ground-based magnetometer arrays has proven to be the most successful methods of studying the spatial structure of hydromagnetic waves in the earth's magnetosphere. The solar wind provides the energy for the earth's magnetospheric processes. The source of Pc4 magnetic pulsations can either be internal to the magnetosphere (endogenic) or external to it, transmitted through the magnetopause (exogenic). Most of the Pc4 studies undertaken in the past have been confined to middle and high latitudes.

The spatial and temporal variations observed in the Pc4 occurrence are of vital importance because these provide evidence that can be directly related to both endogenic and exogenic wave generation mechanisms. At low latitudes (L< 2), the wave energy predominates in the Pc4 band. However the spatial characteristics of these pulsations have received little attention in the past. The present study is undertaken for describing the dependence of low latitude Pc4 occurrence on the Solar Wind Velocity (VSW) and the Interplanetary Magnetic Field (IMF) over the period range 01 January to 31 December, 2005 employing an array of three low latitude recording stations at Hanley, Nagpur and Pondicherry.

Analysis of the data for the whole year 2005 provided similar patterns of Pc4 occurrence for VSW at all the three stations. Although Pc4 occurrence was reported for VSW ranging from 250 to 1000 Km/s, yet the major Pc4 events occurred for a VSW range of 300-700 Km/sec. The IMF dependence of Pc4 occurrence for the year 2005 has shown that even though at all the three stations, it spread for IMF magnitude of up to 22 nT, yet the majority of Pc4 events occurred for a narrower range of 2-10 nT. However it is important to note that at all the three stations, the peak in the occurrence of Pc4 events was observed for IMF range of 3 to 5 nT. The results suggest that the solar wind controls Pc4 occurrence through a mechanism in which Pc4 wave energy is convected through the magnetosheath and coupled to the standing oscillations of the magnetospheric field lines.

The Heliospheric Data Centre project for Space Weather medium-term and short-term forecast combines remote sensing and in situ open-access data relative to the Sun, the Heliosphere and the Earth's magnetosphere. This is done with the novel big data technologies, to provide scientists with the possibility to design, implement and validate Space Weather algorithms on extensive datasets.

The Heliospheric Data Centre is a joint effort between ALTEC and INAF-OATo, both located in Turin, Italy. The project has two main objectives: 1. Consolidate and evolve the Heliospheric Data Centre, initially set up with the SOHO data coming from the ESA approved SOLAR (SOho Long-term ARchive) archive, in order to manage additional solar archives storing solar coronal and heliospheric data coming from ESA and NASA space programs. 2. Develop a Heliospheric Space Weather Centre to forecast the impacts of solar disturbances on the Heliosphere and the Earth's magnetosphere.

D2.4-0027-18 PHASE RELATIONSHIP BETWEEN SUNSPOT NUMBERS AND F10.7 CM SOLAR RADIO-FLUX USING CROSS-RECURRENCE PLOTS AND WAVELET-TRANSFORM

Ashok Kumar Gwal, ashok.gwal@gmail.com Rabindranath Tagore University, Raisen, India

Abstract The phase relationship between daily and monthly counts of sunspot and solar radioflux at 10.7 cm was investigated during Solar Cycle 23 and the current Cycle 24 (1 January 1996 - - 31 December 2013) to identify essential characteristics of solar cycle maximum. The nonlinear approaches such as cross-recurrence plots and advanced wavelet techniques are used to study the asynchronous behaviors of sunspot numbers with solar radio-flux. The results are in agreement with the past findings that solar activity maxima occur at least twice during a cycle: first, near the end of the increasing activity phase and then in the early beginning years of the declining phase. We also found that the odd and even numbered Solar Cycles 23 and 24 are essentially not in phase and have a phase difference of two months. The sunspot number and solar radio-flux are in phase at the significant period of 27 days, which corresponds to one solar rotation, during the maximum phase of the cycles. Keywords: Sunspot number, Solar radio-flux, Cross-recurrence plots and wavelet transform.

D2.4-0028-18 SOLAR ACTIVITY AND IRRADIANCE RECONSTRUCTION OVER THE HOLOCENE

CNRS, Aixen-Provence, France Edouard Bard, bard@cerege.fr CNRS, Aixen-Provence, France

Direct measurements of the solar irradiance are only available since 1978. To understand the solar influence on Earth's climate, longer records and thus reconstructions of the solar variability in the past are needed. The directly observed sunspot number allows going back to 1610 A.D, although with progressively increasing uncertainty. To assess solar variability at earlier times, one has to rely on indirect proxies of solar activity, such as concentrations of cosmogenic isotopes 10Be and 14C in terrestrial archives. They are produced mostly in the upper atmosphere by impinging galactic cosmic rays (GCRs). The flux of GCRs is modulated by both the heliospheric magnetic field and the geomagnetic field. Therefore, the isotope signals retrieved from various sites around the globe show a very high degree of similarity, reflecting changes in the solar activity. Still, short-and mid-term deviations can be observed due to various systematic effects, such as different geochemical production, atmospheric distribution processes and local climatic conditions. To account for these differences, we have constructed a state-of-the-art consistent multi-isotope composite from one global 14C and six regional 10Be data sets. This composite is then used to reconstruct decadal values of the total and spectral solar irradiance over the Holocene with the semi-empirical SATIRE-M model, while the quasi-11 year solar cycle has been simulated statistically.

D2.4-0029-18 MAGNETIC FIELD EXPERIMENT AT L1 POINT ONBOARD ADITYA-L1 MISSION

The Aditya-L1 mission is first Indian solar mission scheduled to be placed in a halo orbit around the first Lagrangian point (L1) of Sun-Earth system in the year 2019. The scientific payloads onboard Aditya-L1 spacecraft includes a Fluxgate magnetometer (FGM) to measure the local magnetic field which is necessary to supplement the outcome of other scientific experiments onboard. The in-situ vector magnetic field data at L-1 is essential for better understanding of the data provided by the particle and plasma analysis experiments, on board Aditya-L1 mission. Also, the dynamics of Coronal Mass Ejections (CMEs) can be better understood with the help of in-situ magnetic field data at the L1 point region. This data will also serve as crucial input for the short lead-time space weather forecasting models.

The FGM is a dual range 3-axis magnetic sensor sits on a 6 m boom mounted on the EP-01 [Earth viewing Panel] deck and configured to deploy along the negative roll direction of the spacecraft. Two sets of such sensors are to be mountedone at the boom tip (6 m from the spacecraft) and other somewhere in between the boom tip and spacecraft. The main science goals of this instrument is to measure the magnitude and nature of interplanetary magnetic field (IMF) locally and to study the disturbed magnetic conditions and extreme solar events by detecting the CME from Sun as a transient event. The secondary science goals are to study the impact of interplanetary structures and shock solar wind interaction on geo-space environment and to detect plasma waves emanating from the solar corona at L1 point.

This paper gives the detailed scientific goals of this magnetic field experiment and brief technical details of the proposed FGM onboard Aditya-L1 spacecraft.

D2.4-0030-18 THE DECLINING PHASE OF THE SUNSPOT CYCLE 24

H.S. Ahluwalia, hsa@unm.edu

University of New Mexico, Albuquerque, New Mexico, United States

We explore solar activity for the decay phase of the cycle 24 using data for geomagnetic indices aa/Ap and the solar polar magnetic field intensity for shorter time intervals; these indices do not depend on Earth's climate. The baseline of the geomagnetic indices increases monotonically from 1900 to 1986 and declines rapidly afterwards. We speculate that a cycle with a period 172y may exist in aa/Ap. If one assumes that solar wind will exhibit the same periodicity for the rest of the twenty-first century, one should expect the next uptick of the aa/Ap timeline to occur in the seventies. In the meantime, the indices Ap/aa may continue to undergo three-cyclequasi-periodicity to a value lower than in early 1900s, due to a steeper slope during the last few solar cycles compared to that of the period before 1900; it may reach the grand minimum level. Solar polar magnetic field intensity is decreasing systematically for the last three cycles (22-24) as are the sunspot numbers at the cycle peaks. Livingston and Penn (2009) note a long term weakening of maximum sunspot magnetic field since 1992. The North-South asymmetry in the polar field strength is pronounced for the decay phase of cycles 23, 24; itseems to change sign after cycle 21. These trends have great implications for solar physics and future space weather/climate.

D2.4-0031-18 EXTREME SOLAR PARTICLE EVENTS AND SPACE WEATHER BENCHMARKS

National Space Science Center, CAS, Beijing, China

The radiation impacts of solar energetic particles (SEPs) include electronic devices, computers, satellites, communications, power grids and astronauts. The research on the extreme historical solar particle events (SPEs) and the forecast for the future extreme SPEs is significant for the protection of modern infrastructure, civilization, economy and society stability. According to the US research plan and strategy, the benchmarks and the forecast methods and hazard mitigation for the extreme space weather are vital. The space weather benchmarks and forecast methods can be obtained by investigating the extreme SPEs. The benchmarks established using the 1859 SPE only are not complete, more research on the extreme historical SPEs should be carried out. In the comprehensive method for identifying the extreme historical SPEs, the solar proton intensity is derived from the radioactive elements 14C/10Be and NO radicals produced in the Earth's atmosphere and deposited in the rings of trees, corals and ice cores; the related auroras and geomagnetic storms are found from the historical records; the non-solar origin is excluded. This paper introduces briefly the comprehensive method, provides the detail evidence of the 775 SPE and proves it to be the strongest SPE in the past 11400 years, and presents the benchmarks of the proton spectra and radiation for the 775 and 1859 SPEs.

D2.4-0032-18 SIMULATION STUDY OF COSMIC RAY INTERACTIONS WITH EARTH MAGNETOATMOSPHERE: MEASUREMENT OF DIFFERENT PARTICLE FLUXES AT SATELLITE AND BALLOON HEIGHTS

Ritabrata Sarkar, ritabrata.s@gmail.com

Indian Centre for Space Physics, Kolkata, India Abhijit Roy, aviatphysics@gmail.com

Indian Centre for Space Physics, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

We calculated the primary and secondary particles and radiations at the balloon height (35 km) and satellite height (400 km) due to the interaction of the primary cosmic rays and solar energetic particles/radiations with the earth's atmosphere. We consider the solar modulation of the primary cosmic ray fluxes and the geomagnetic field distribution and used Monte Carlo simulation toolkit Geant4 for the full 3D description of the atmospheric and magnetospheric modeling surround earth. We present the component-wise flux distribution of the primary and secondary cosmic rays at the mentioned heights. We also compare the simulated results near the tropical latitude (geomagnetic latitude: 14.50° N) to the measured radiation flux using small balloon-borne low energy X-ray scintillator detector at this region.

D2.4-0033-18 MEASUREMENT OF SECONDARY COSMIC RAYS AT THE PFOTZER MAXIMUM AND ITS CORRELATION WITH SOLAR ACTIVITY NEAR THE TROPIC OF CANCER

Ritabrata Sarkar, ritabrata.s@gmail.com

Indian Centre for Space Physics, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India Debashis Bhowmick, debashisbhowmick@gmail.com

Indian Centre for Space Physics, Kolkata, India Arnab Bhattacharya, arnabseacom@yahoo.com Indian Centre for Space Physics, Kolkata, India

The galactic cosmic rays in the heliosphere is primarily modulated due to solar activity. These primary cosmic rays interact in the atmosphere to produce secondary particles and radiation which again strongly depends on the geomagnetic latitude of the earth due to variation of the geomagnetic field strength. So the secondary radiation flux in turn dictated by the solar activity for various geomagnetic latitudes. At relatively lower heights such as the balloon altitude these variations are more prominent at the higher latitudes, but in the present work we have measured the variation at a relatively lower latitude near the Tropic of Cancer. We used scintillation detectors on board meteorological rubber balloons to measure the cosmic secondary radiation flux (15-140 keV) throughout the atmosphere up to about 40 km from various locations near geomagnetic latitude of about 14.50° N in West Bengal, India. These measurements covering the solar activity transition from the solar maximum of the 24th solar cycle up to the next minimum (2012-2016) shows a strong anti-correlation between the secondary cosmic-ray intensity at the Pfotzer maximum and the solar activity, even at such low geomagnetic latitude.

D2.4-0034-18 THE EFFECTIVE ENERGY FOR NEUTRON MONITORS AND COSMOGENIC ISOTOPES-REDEFINED CONCEPT

Agnieszka Gil, gila@uph.edu.pl Siedlce University, Siedlce, Poland

Eleanna Asvestari, eleanna.asvestari@helsinki.fi University of Helsinki, Helsinki, Finland Gennady A. Kovaltsov, gen.koval@mail.ru

University of Oulu, Oulu, Finland

Cosmic ray variability is often described in terms of the modulation potential (ϕ) changes. Based on measurements of ground-based energy-integrating detectors, such as neutron monitors for the recent decades, and by cosmogenic isotopes stored in natural archives for the millennial timescale, variability of ϕ can be reconstructed. Here we defined the effective energy of an energy-integrating detector as energy at which the cosmic ray flux changeability is straightforward proportional to that of the detector's response. We calculated that the effective energy for the standard sea-level polar neutron monitor is around 11-12 GeV/nucleon, while for cosmic ray reconstruction based on cosmogenic isotopes it is around 6-7 GeV/nucleon and 5.5-6 GeV/nucleon for 14C data and 10Be, respectively. We compared results based on different models of local interstellar spectrum (LIS) of galactic cosmic rays, showing that the effective energy is determined robustly against the particular LIS model.

D2.4-0035-18 ENERGETIC PARTICLES EFFECTS ON THE GLOBAL ATMOSPHERIC ELECTRIC CIRCUIT

Lebedev Physical Institute of Russian Academy of Sciences, Moscow, Russia

Events of Energetic particles are potential candidates to affect the Global Atmospheric Electrical Circuit (GAEC). This is supported by theoretical models proposing that these events can modify the atmospheric conductivity profile above thunderstorms. If very strong events occur, they are able to change the atmospheric conductivity at low altitudes. These effects can be studied through measurements of the atmospheric electric field (AEF) in fair weather regions. In this study, we investigate the AEF daily curve departures from the standard curve during solar proton events and Forbush decrease. The superposed epoch analysis was utilized in order to enhance weak effects. AEF data corresponds to the period between January 2010 - December 2017, and were recorded at Complejo Astronomico El Leoncito (CASLEO) at 2550 masl. The results show possible ionization effects in regions of disturbed and fair weather regions, which alters the GAEC.

D2.4-0036-18 ANALYSIS OF SHORT TERM PERIODIC VARIATION IN SOLAR AND TERRESTRIAL PARAMETERS USING WAVELET BASED TECHNIQUES

Rabindranath Tagore University, Raisen, India

Solar and terrestrial activities reveal periodic variations in large range of time scales. Analysis of periodicities in the Sun and interplanetary medium exhibits various aspects of solar and terrestrial Physics. Periodicities in solar and terrestrial parameters are classified into short, mid and long-term types on the basis of period length. Short term periodicities are attributed to the solar rotation, evolution of active regions and the outflow of solar wind. In this work wavelet transform and global wavelet transform methods are used to identify the short term periodicities of Solar wind plasma parameters (i.e. Solar wind speed, proton density, temperature, plasma pressure), component of interplanetary magnetic field (IMF) (i.e. Bx, By and Bz) and corresponding geomagnetic indices (Dst) during the current solar cycle 24. We detect the short term periodicities of 14 and 27 days with the 90% confidence level for all parameters. These periods have different amplitude for different parameters. In case of Solar wind plasma density, Bz component of IMF and terrestrial geomagnetic indices short term periodicity of 14 day are more significant. This is probably due to fast stream from coronal holes overlaps with mass ejection from or near the active region resulting in a more or less random variation of measured Solar wind speed. It was concluded that the wavelet power spectrum and Global wavelet spectrum have identified the 27 day periodicities (with 14 day being its harmonic) in the dynamic parameter of Solar wind, interplanetary magnetic field. The amplitude of the periodicity depends on the parameter considered and each of them evolves differently.

Keywords: Solar Wind, Geomagnetic activity, wavelet transform, Short term periodicity

D2.4-0037-18 THE POSSIBLE IMPACT OF SOLAR ACTIVITY ON EXTRATROPICAL CYCLONE ACTIVITY

The mechanism based on the global electric circuit (GEC) flowing vertically from the ionosphere to the Earth's surface could potentially provide the link between the solar modulated energetic particles and Earth's weather and climate. Cosmic ray induced atmospheric ionization modulates the vertical current density (Jz) and introduces the changes in GEC that could alter the microphysical properties of the clouds (Tinsley, 2008). Due to the complexity and scale of the GEC and its feedbacks, possible implications and importance of this mechanism are still mostly unknown. One of the possible feedbacks to GEC alteration could be the proces of storm invigoration and occurrence of extratropical cyclones. Using 6-hourly sea level pressure (SLP) fields from the ERA-Interim data, extratropical cyclones are identified by tracking their low-pressure centers. Daily timescale epochsuperpositional (composite) analysis is performed to analyze the occurrence of extratropical cyclones during the biggest Forbush decrease events in the last three solar cycles. Since autocorrelations are the common feature of geophysical data, to test the significance of results we use robust Monte Carlo significance testing. This work has been supported by the Croatian Science Foundation project 6212 "Solar and Stellar Variability" (SOLSTEL).

D2.4-0038-18 ON THE ROLE OF COSMIC-RAY INDUCED IONIZATION IN AEROSOL FORMATION AND CLIMATE: INSIGHTS FROM THE SOUTHERN HEMISPHERE

Phillip L Prinsloo, drageoprinsloo@gmail.com

North-West University, Potchefstroom, South Africa Du Toit Strauss, dutoit.strauss@nwu.ac.za

North-West University, Potchefstroom, South Africa Olakunle Ogunjobi, olakunle.ukzn@gmail.com Federal University Lokoja, Lokoja, Nigeria

It has been proposed that cosmic rays (CRs) can affect cloud cover, and thereby the Earth's climate, by facilitating the growth of cloud-seeding aerosols in the atmosphere through increased ionization. The ion-aerosol clear-air (IACA) mechanism, by which this could occur, suggests that larger atmospheric ion concentrations (e.g. as a result of higher CR incidence) would enhance the nucleation of condensation nuclei from condensable vapours, and that a fraction of these nuclei may grow large enough to contribute to cloud formation. Contradicting findings have emerged from different studies of correlations between CR intensities and cloudiness, and the topic remains controversial. In this study, a preliminary investigation of South African climate responses to the solar activity cycle revealed very weak correlations, and although signals of characteristic 11 and 22-year CR periods were present, they were not statistically significant. Expanding on this, the study aims to assess the relatively pristine aerosol and climate data recorded at and/or near the South African National Antarctic Expedition (SANAE) IV base over different timescales. The Forbush decrease of 16-17 July 2017 is particularly fortuitous: Having occurred during the Antarctic polar night, with no substantial precipitation of energetic particles (from e.g. the radiation belts) reported, it affords the opportunity to study the response of the aerosol nucleation process in the absence of other extraterrestrial sources of ionization and anthropogenic aerosols. The observed response of aerosol properties to the CR variations is evaluated against the IACA mechanism, and the implications for cloud formation and climate is discussed.

D2.4-0039-18 ESTIMATION OF THE IMPACT OF COSMIC-RAY PROTONS DURING GLE ON THE PROCESS OF IONIZATION OF THE EARTH'S ATMOSPHERE

Eugene Maurchev, maurchev@pgia.ru

Polar Geophysical Institute, Russian Academy of Sciences, Apatity, Russia Yury Balabin, balabin@pgia.ru

Polar Geophysical Institute, Russian Academy of Sciences, Apatity, Russia

This work presents the results of calculating the passage of cosmic-ray protons (CR) with spectra corresponding to GLE events through the Earth's atmosphere using the software package RUSCOSMICS based on the GEANT4 software toolkit. Parameterization of the Earth's atmosphere model was obtained through the work of NRLMSISE-00. A standard physics lists for electromagnetic processe, a quark-gluon string model for hadrons with energies above 10 GeV, Bertini cascades for energies below 10 GeV and ENDF / B-VII.1 data for calculating neutron interactions with energies from 10-11 MeV to tens of MeV were used. As a result of modeling, the energy spectra of secondary CR were obtained as a function of altitude, as well as the ionization profiles from ground level to 80 km. The results are compared with the experimental data obtained during the launch of stratospheric balloons with Geiger counters installed on them and have good agreement.

D3.1-0001-18 MAGNETOSPHERIC MULTISCALE (MMS) AT THE MAGNETOPAUSE

C.T. Russell, ctrussell@igpp.ucla.edu

Institute of Geophysics and Planetary Physics, University of California, Los Angeles, California, United States

Advances in science occur when new capabilities arise, such as measurements at higher time resolution, or at smaller scales, or with improved instrumentation. The successful launch of MMS brought us improved temporal resolution, the ability to measure the gradients in three orthogonal directions, improved instrumentation, and a novel data acquisition strategy aimed at returning to Earth only the data with high science value. These data have enabled us to develop new diagnostic techniques to characterize the phenomena and magnetospheric structure encountered. We can examine the curvature of the field lines, the strength and thickness of the currents, pressure balance, the orientation of current sheets and their speeds. We find extensive streaming and counterstreaming electrons along the magnetic field. We see curved fields on scales below the proton gyroradius. We detect planar magnetopause current systems with a constant total (magnetic plus plasma) pressure during the crossings of the magnetopause. We also detect self-balancing ropes with finite dimensions that do not have constant pressure as they cross the spacecraft. Some of these are magnetic flux ropes and some of these are not. The complexities found raise questions about the nature of these features at the magnetopause.

D3.1-0002-18 ON THE ROLE OF THE RCONNECTION ELECTRIC FIELD IN THE ELECTRON DIFFUSION REGION

Space Sciences Laboratory, University of California, Berkeley, California, United States

The structure of the reconnection diffusion region is, to a large degree, determined by the requirement to balance both the current flow and its dissipation processes, and the forces exerted onto the current layer by the inflow magnetic pressure. These balances are critical: without resupply processes, the transport of accelerated and current-carrying particles away from the diffusion region would generate a current density depletion, which, in principle, could lead to a mismatch with the curl of the magnetic field. Similarly, without heating processes, the convection of hot plasma away from the diffusion region would generate a force imbalance with the ambient magnetic field. The fact that neither of these imbalances occur is a consequence of the reconnection electric field, which is therefore not only required to facilitate magnetic flux transport, but also to provide the energization required to maintain balance in the diffusion region. In this presentation, we will use particle-in-cell simulations to analyze these balance conditions. We will furthermore show that nongyrotropic particle dynamics plays a key role both as current dissipation mechanism, and as overall heating mechanism in the diffusion region current layer.

D3.1-0003-18 THIN CURRENT SHEET PROCESSES IN THE MAGNETOSPHERE OBSERVED BY MMS

Rumi Nakamura, rumi.nakamura@oeaw.ac.at

Space Research Institute, Austrian Academy of Sciences, Graz, Austria Kevin Genestreti, kevin.genestreti@oeaw.ac.at 1 Space Research Institute, Austrian Academy of Sciences, Graz, Austria, Graz, Austria Takuma Nakamura, takuma.tkm.nakamura@gmail.com 1 Space Research Institute, Austrian Academy of Sciences, Graz, Austria, Graz, Austria Ferdinand Plaschke, ferdinand.plaschke@oeaw.ac.at

Space Research Institute, Austrian Academy of Sciences, Graz, Austria Zoltan Voeroes, zoltan.voeroes@oeaw.ac.at

Space Research Institute, Austrian Academy of Science, Schmiedlstrasse 6,, Graz, Austria

Near-Earth space is a most suitable place to study fundamental space plasma processes due to recent advancements in the in-situ measurements from multi-point spacecraft at high cadence. In particular, MMS, launched in March 2015, enables to investigate the energy conversion processes in thin boundary and current layers both on the dayside and nightside magnetosphere. The four point measurements by MMS with spatial separation down to electron scales resolve spatial structures and temporal evolution of the thin current sheets. In this talk, we highlight selected MMS observations of thin current sheets and localized plasma signatures observed in the magnetosheath, magnetopause, and magnetotail associated with magnetic reconnection and other current sheet instabilities. We discuss the implication of these small-scale processes to the large-scale magnetospheric dynamics.

D3.1-0004-18 NATURE'S GRAND EXPERIMENT: LINKAGE BETWEEN MAGNETOSPHERIC CONVECTION, SUBSTORMS AND THE RADIATION BELTS

C. J. Rodger, crodger@physics.otago.ac.nz University of Otago, Dunedin, New Zealand

Kathy Cresswell-Moorcock, creal158@student.otago.ac.nz University of Otago, Dunedin, New Zealand

Mark Clilverd, macl@bas.ac.uk

British Antarctic Survey, Cambridge, United Kingdom

The solar minimum of 2007-2010 was unusually deep and long-lived. In the later stages of this period the electron fluxes in the radiation belts dropped to extremely low levels. The flux of relativistic electrons (>1 MeV) was significantly diminished, and at times were below instrument thresholds both for spacecraft located in geostationary orbits and also those in lowEarth orbit. This period has been described as a natural "grand experiment" allowing us to test our understanding of basic radiation belt physics and in particular the acceleration mechanisms which lead to enhancements in outer belt relativistic electron fluxes.

Here we test the hypothesis [1] that processes driven by magnetospheric convection initiate repetitive substorm onsets, which in turn triggers enhancement in whistler mode chorus that accelerates radiation belt electrons to relativistic energies. Conversely, individual substorms would not be associated with radiation belt acceleration. Contrasting observations from multiple satellites of energetic and relativistic electrons with substorm event lists, as well as chorus measurements, shows that the data are consistent with the hypothesis.

We show that repetitive substorms are associated with enhancements in the flux of energetic and relativistic electrons and enhanced whistler mode wave intensities. This is consistent with the recent RBSP case studies [2], which suggested that substorms were the trigger for chorus which lead to acceleration of radiation belt electrons to relativistic energies. However, in our study we see a two stage chorus wave power enhancement, the first starts slightly before the repetitive substorm epoch onset, suggesting that magnetospheric convection leading the chorus activity may be the trigger. This conclusion requires some care, as the second and strongest enhancement in chorus is very slightly after the onset, complicating the picture

During the 2009/2010 period the only relativistic electron flux enhancements that occurred were preceded by repeated substorm onsets, consistent with enhanced magnetospheric convection and repetitive substorms as a trigger. This work has been recently published in JGR [3].

D3.1-0005-18 IMAGING DAYSIDE INTERACTIONS

David Sibeck, david.g.sibeck@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States

Understanding the nature of the solar wind-magnetosphere interaction and the causes of space weather within the Earth's magnetosphere are fundamental objectives for the Heliophysics discipline. A host of mechanisms have been proposed to govern the solar wind's interaction with the Earth's dayside magnetosphere. In situ observations at the magnetopause and in the high latitude dayside ionosphere provide ample evidence for steady and bursty, local and extended, component, antiparallel, and maximum magnetic field shear reconnection, the Kelvin-Helmholtz instability, and boundary waves driven by both intrinsic solar wind and foreshock-generated variations. In conjunction with results from numerical simulations, global observations from imagers and arrays of observatories can provide the information needed to evaluate the significance of each proposed mechanism as a function of the prevailing solar wind conditions. The amplitude, location, and extent of the magnetopause motion driven by each mechanism can serve as proxies for the solar wind mass, energy, and momentum that it transfers to the magnetosphere. The same is true for the perturbations that each mechanism drives in the dayside auroral oval. This talk outlines some of the global interaction puzzles that remain to be solved and some of the tools that can be used to address them, including global MHD and hybrid code numerical simulations, global imagers (e.g., soft X-ray, ENA, EUV, FUV, Thomson scattering), cubesat constellations for in situ measurements and tomography, and arrays of well-instrumented ground observatories.

We present results from a recent study [Wilson et al., 2017] of the structure of 145 low Mach number (M 3), low beta (β 1), quasi-perpendicular interplanetary collisionless shock waves observed by the Wind spacecraft has provided strong evidence that these shocks have large amplitude whistler precursors. The common occurrence and large amplitudes of the precursors raise doubts about the standard assumption that such shocks can be classified as laminar structures. This directly contradicts standard models. In 113 of the 145 shocks (78

D3.1-0007-18 VARIABILITY OF KEV ELECTRONS IN THE EARTH'S MAGNETOSPHERE

Natalia Ganushkina, natalia.ganushkina@fmi.fi Finnish Meteorological Institute, Helsinki, Finland

Our daily life depends more and more on space. The communication satellites are the best example of such dependence. There are about 1000 operational satellites at different orbits in near-Earth space. All of them pass through the Earth's magnetosphere where the radiation environment is hazardous for them and varies significantly with solar activity. The presence of rapidly-varying low energy (<200 keV) electrons causes surface charging effects on satellites, changes in the satellite potential and degradation of satellite surface materials. Understanding the physical processes responsible for the keV electron variations in the near-Earth space is, therefore, a timely and extremely pressing issue. Variations of solar wind parameters such as solar wind velocity and/or density have been clearly associated with changes in the electron fluxes of both keV and MeV energies in the inner Earth's magnetosphere. Interplanetary Magnetic Field (IMF) and Interplanetary Electric Field (IEF) variations are also geoeffective since they result in storms and substorms. The distribution of keV electrons further accelerated to MeV energies by various processes is critically important for radiation belt dynamics. The near-Earth plasma sheet (at about 10 RE, RE=6371 km) is the source region. Although, there have been several statistical studies for plasma sheet electrons, no final knowledge on the variations of source electrons with solar activity is available. The electron flux at keV energies varies significantly with geomagnetic activity. Substorms play a key role in electron dynamics but the associated electromagnetic fields are usually very complex and very difficult to model. The chain of physical processes starting with the analysis of solar wind driving of the source population in the plasma sheet, transport and acceleration of low energy electrons from the plasma sheet to geostationary orbit and further inside, including the roles of substorm-associated electromagnetic fields will be presented and discussed. Studying the keV electrons in the inner magnetosphere provides a critical link for our community to understand the dynamics of the radiation environment in geospace driven by the Sun.

D3.1-0008-18 THE INDUCED MAGNETOSPHERE OF VENUS: HIGHLIGHTS FROM VENUS EXPRESS

Stas Barabash, stas@irf.se

Swedish Institute of Space Physics, Kiruna, Sweden Yoshifumi Futaana, futaana@irf.se

Swedish Institute of Space Physics, Kiruna, Sweden

When the solar wind flow carrying frozen-in interplanetary magnetic field impacts a conductive sphere, for instance Venus surrounded by its ionosphere, currents are induced in the conductive layer and the associated magnetic fields deviate the solar wind flow. A void of the solar wind called an induced magnetosphere forms. The interaction of the supersonic solar wind plasma with this obstacle results in drapping of the interplanetary magnetic field lines and the formation of domains and boundaries somewhat similar to the magnetosphere proper, despite different underlying physics. Those include a bow shock, magnetosheath, induced magnetosphere boundary (IMB, somewhat similar to the magnetopause), magnetotail, ionopause. It is the convective electric field that governs plasma dynamics in an induced magnetosphere contrary to the Earth case where it is the inductive electric field. As a consequence the Venus plasma sheet orientation is fully controlled by the interplanetary magnetic field. The convective electric field also results in asymmetries in both the magnetosheath, polar ionospheric field strength as well as in the drapping magnetic field.

Topologically, drapping magnetic field of the induced magnetosphere's tail and stretched dipole field of the terrestrial magnetospheric tail are quite different but both configurations result in anti-parallel magnetic field lines, which may reconnect. Indeed, reconnection events were observed in the Venus magnetotail.

The solar wind energy, momentum, and matter transfer constantly occur through IMB.The solar wind matter transfer through IMB results in the deposition of α-particle (helium) into the atmosphere. The energy transfer results in the planetary ion acceleration. The acceleration to energies above the escape energy results in the ion escape, which, due to high gravity at Venus, is the main escape process. The ions are accelerated by the convective electric field, electric field due to the electron pressure gradients ("polar wind"), and the Hall electric field. The total escape rate of planetary ions ((3-6)×1024 s–1 for oxygen ions) is similar to the Martian one despite higher gravity, by far more dense atmosphere, higher UV flux, and higher dynamic pressure. Is it a coincidence?

In this talk we review the physics of an induced magnetosphere with the focus to Venus and the latest relevant findings from the Venus Express mission.

D3.1-0009-18 ON THE CROSS-SCALE COUPLING FROM FLUID-SCALE KELVIN-HELMHOLTZ WAVES INTO ION AND ELECTRON SCALES AND ASSOCIATED PLASMA HEATING

Understanding the energy transfer between different scales is a major challenge in collisionless plasmas. Kelvin-Helmholtz instability (KHI) is a universal shear flow instability taking place in many plasma systems such as magnetospheres of magnetized and non-magnetized planets, solar corona, Coronal Mass Ejectas, astrophysical accretion disks, as well as in laboratory plasmas. During recent years it has been shown that KHI can produce significant plasma transport via reconnection in the vortices as well as via secondary mechanisms such as kinetic wave activity and diffusion through thin boundaries created by the KHI. Likely sssociated with this transport, statistical studies have shown that cold-component ions are about 30-40 percent more abundant and hotter on the dawn side of the Earth's plasma sheet. In this talk we discuss the origin of the asymmetric evolution of the KHI and associated plasma heating via various physical mechanisms associated with the KHI such as kinetic plasma waves and magnetic reconnection, and by using data from ESAs Cluster mission, NASAs THEMIS and MMS missions, as well as high-resolution numerical simulations that can address the generation of unstable ion velocity distribution functions. Kelvin-Helmholtz instability and associated non-adiabatic heating mechanisms play also an important if not a dominant role in Jovian magnetospheric system.

D3.1-0010-18 MULTI-SPACECRAFT OBSERVATIONS OF WHISTLER-MODE WAVES: RECENT PROGRESS AND OUTSTANDING QUESTIONS

Whistler mode waves exist in the Earth's magnetosphere in a variety of forms. For instance, chorus waves appear as intense, coherent bursts of electromagnetic wave power at a few tenths of the equatorial electron cyclotron frequency, located predominantly on the dawn side outside the plasmasphere and are believed to play a crucial role in accelerating electrons to relativistic energies. Plasmaspheric hiss waves on the other hand, appear as a constant frequency band of incoherent waves, typically at 0.2-2kHz within the dayside plasmasphere, and are thought to precipitate energetic electrons from the slot region. Recent multi-point measurements performed by various satellite missions (including Van Allen Probes and THEMIS) revealed structure within these individual whistler-mode waves types, and teleconnections between the two types. This talk focuses on some of the recent multi-point observations of chorus and hiss waves, their connections to each other, and the open questions that these observations raise, particularly as we being to realize that the large scale structure of these waves is understood relatively poorly.

D3.1-0011-18 RELATIVISTIC ELECTRON ACCELERATION DUE TO AN EXTREME FAST SOLAR WIND STREAM

Richard Horne, r.horne@bas.ac.uk

University of Surrey, Guildford, United Kingdom Wen Li, wenli77@bu.edu

Boston University, Boston, Massachusetts, United States

Coronal holes on the Sun are a source of fast solar wind flowing out into the solar system. When they encounter the Earth's magnetosphere they are associated with some of the highest relativistic electron flux enhancements in the Earth's van Allen radiation belts and a special type of plasma wave known as chorus. Here we present a statistical analysis of chorus waves and show that for an event lasting 5 days the waves are strong enough to accelerate electrons and increase the flux greater than 2 MeV by 4 orders of magnitude. The flux increases rapidly but tends towards a plateau suggesting there is a limit to the acceleration. The flux remains high for several days even after the solar wind stream has passed. The flux level depends on the wave properties but is relatively insensitive to the presence of a pre-existing radiation belt. For satellites at geostationary orbit the flux results in a charging current that exceeds the NASA recommended guidelines for triggering an electrostatic discharge by more than a factor of 2. As a result, satellites at geostationary orbit are more at risk from a fast solar wind stream lasting 5 days or more than they are from an extreme geomagnetic storm.

D3.1-0012-18 PARTICLE ACCELERATION MECHANISMS IN MAGNETOSPHERIC PLASMAS

Danny Summers, dsummers@mun.ca

Memorial University of Newfoundland, St John's, Canada

Fundamental questions in magnetospheric physics relating to radiation belts concern how the belts are created and evolve. Inevitably these questions involve issues of particle acceleration. Relativistic particle acceleration at both Earth and Jupiter is still not fully understood,despite extensive research efforts. Here we briefly review some recently developed particle acceleration mechanisms. Then we examine a particularly efficient particle acceleration mechanism called ultra-relativistic acceleration (URA). URA comprises electron energization due to a special form of nonlinear phase trapping by a coherent whistler-mode wave for electrons with an initial Lorentz factor that exceeds a certain critical value. Radiation belt electrons that encounter a combination of relativistic turning acceleration followed by multiple URA interactions can undergo significant energy increase. Under ideal conditions,at Earth (L = 4) several-hundredkeV electrons can be energized to several MeV within a few seconds,while at Jupiter (L = 8),several-hundred-keV electrons can be energized by tens of MeV in a few tens of seconds. URA can play a prominent role in generating the several-MeV electrons observed in Earth's outer zone and the tens-of-MeV electrons observed in Jupiter's magnetosphere. More generally, we expect URA to be an effective particle energization mechanism in cosmic plasma environments that contain a magnetic mirror geometry and sufficiently intense electromagnetic emissions.

The whistler mode chorus waves work dual role for the acceleration and precipitation of energetic electrons. The Arase satellite that was launched in December, 2016 has obtained comprehensive data sets for plasma/particles and fields/waves. In March and April, 2017, the Arase satellite observed several magnetic disturbances driven by CIR and subsequent coronal hole streams. During the period, the Arase satellite observed continuous chorus activities for a few days associated with the high-speed solar wind. During this period, comprehensive observations from the Arase satellite and ground-based observations are realized. EISCAT at Tromso, Norway observed strong ionization at the low altitude, indicating sub-relativistic electrons of the radiation belts precipitate into the atmosphere. During the period, the Arase satellite successfully observed intense chorus waves outside the plasmapause, indicating the resonance with chorus waves causes the pitch angle scattering of energetic electrons. Simultaneously, large flux enhancement of the outer belt electrons was observed with enhancement of chorus waves. We discuss the dual role that chorus waves play in controlling the dynamics of the radiation belts.

D3.1-0015-18 NEW OBSERVATIONS AND MODELING CLARIFYING THE ROLE OF EMIC WAVES FOR ULTRA-RELATIVISTIC ELECTRON LOSS IN THE HEART OF THE RADIATION BELTS.

Recent observations and modeling provided significant improvements in our understanding of the energization mechanisms for the electrons in the radiation belts. However, loss processes remain poorly understood. In this study we present analysis of the evolution of electron radial profiles of fluxes, pitch angle and energy distributions. Our modeling and observational results show that different loss mechanisms are operational at different energies. Global simulations at all energies, radial distances, and pitch angles are compared to Van Allen Probes observations of electron fluxes. The VERB 3D model including various waves is capable of reproducing the dynamics of pitch angle distributions and energy spectra, demonstrating which loss mechanisms dominate at different energies. Analysis of the profiles of phase space density provides additional confirmation for our conclusions and presents a novel technique that identifies the region of intense local loss due to EMIC wave scattering. This technique allows us to identify the minimum energy affected by the EMIC loss and the location of the EMIC-induced loss. Modeling and observations clearly show that EMIC waves produce loss of 2-4 MeV in the heart of the belts but it remains unclear if they can contribute to the loss at lower energy.

D3.1-0016-18 NORMAL-MODE MAGNETOSEISMOLOGY AS A VIRTUAL INSTRUMENT FOR INVESTIGATION OF PLASMA MASS DENSITY IN THE INNER MAGNETOSPHERE

Peter Chi, pchi@igpp.ucla.edu

University of California, Los Angeles, Los Angeles, California, United States Kazue Takahashi, kazue.takahashi@jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, United States Richard Denton, richard.e.denton@dartmouth.edu

United States

Previous studies have demonstrated that the field line resonance (FLR) frequencies detected on closed field lines can be used to infer the plasma mass density distribution in the inner magnetosphere. This “normal-mode magnetoseismology” technique can act as a virtual instrument that turns spacecraft measurements of the magnetic and/or electric field into plasma mass density, which is a fundamental physical quantity that is difficult to measure directly but important to investigations involving the MHD timescales, reconnection rates, or instability/wave growth rates. This paper presents examples of normal-mode magnetoseismology results based on Magnetospheric Multiscale (MMS) measurements. During the October 2015 magnetic storm, MMS passed through the dayside magnetosphere once per day, and the observed FLR frequencies indicate a clear enhancement in the plasma mass density starting from the beginning of the magnetic storm. Simultaneous charge density values inferred from the upper hybrid resonance frequency measurements imply that the average ion mass also increased. On the third day in the recovery phase, MMS observed a significant enhancement in both mass density and the average ion mass in a narrow region spanning 1RE in the radial direction, indicating the existence of an oxygen torus. The O+ concentration in this oxygen torus is estimated to be as high as 40%. Multiple FLR harmonics can also be used infer the distribution of plasma mass density along the field line, and we will present examples of the results based on MMS observations.

D3.1-0017-18 MAGNETIC RECONNECTION ASSOCIATED WAVES IN TURBULENT MAGNETOSPHERIC PLASMAS

Space Research Institute, Austrian Academy of Sciences, Graz, Austria

Recent observations by the MMS spacecraft have confirmed that magnetic reconnection can occur not only at large scale boundaries, such as the magnetopause or magnetotail current sheets, but also in the turbulent magnetosheath. Secondary reconnection can also take place within reconnection jets. The high resolution MMS field, plasma and particle data allowed to identify the fluid and particle signatures of reconnection in a turbulent environment. It has been found that these signatures resemble the observed features in inflow/outflow, electronand iondiffusion regions of reconnection events at large-scale boundaries. Here we investigate the wave generation mechanisms for lower hybrid, whistler and electrostatic waves which are expected to occur in different regions of magnetic reconnection in a turbulent environment. The wave activity driven by reconnection outflow events are compared in the terrestrial magnetosheath and magnetotail. The identification of the expected fluid, kinetic and wave signatures provides efficient tools to further strengthen our ability to observe magnetic reconnection in turbulent plasmas.

D3.1-0018-18 SHEAR ALFVEN WAVES IN MULTI-ION PLASMAS

Jeffrey Robertson, jsrobertson0@gmail.com

University of California, Los Angeles, Oak Park, California, United States UCLA Shear Alfven Waves

J. Robertson, T. Carter, S. Vincena, S. Tripathi

Understanding the behavior of plasma waves in mixed-species plasmas is important for explaining many observations seen in both space and laboratory plasmas. The addition of a second ion species in a magnetized plasma introduces new cutoffs and resonances, such as the ion-ion hybrid cutoff frequency for parallel propagating shear Alfven waves [1]. Previous experiments on the Large Plasma Device (LAPD) have demonstrated the existence of a propagation gap between the ion cyclotron frequencies of the two ion species [2]. Additional experiments have been performed on the LAPD in order to better characterize the propagation of these waves for a wider range of plasma conditions. An antenna was used to launch shear Alfven waves in a mixed helium and neon plasma across a range of frequencies, and the results were documented and will be presented.

Morales (2011), Laboratory realization of an ion-ion hybrid Alfvén wave resonator, Geophys. Res. Lett., 38, L11101, doi:10.1029/2011GL047399.

D3.1-0019-18 ELECTROMAGNETIC FIELDS OF MAGNETOSPHERIC DISTURBANCES IN CONJUGATE IONOSPHERES: CURRENT/VOLTAGE DICHOTOMY

Vyacheslav Pilipenko, pilipenk@augsburg.edu

(1) Space Research Institute (IKI) Russian Academy, Moscow, Russia Michael Hartinger, mdhartin

University of Michigan, Ann Arbor, Michigan, United States Mark Engebretson, engebret@augsburg.edu

Augsburg College, Minneapolis, Minnesota, United States Evgeniy Fedorov, enfedorov1@yandex.ru

Institute of Physics of the Earth Russian Academy of Sciences, Russia

A circuit analogy for the magnetosphere-Ionosphere current systems has two extremes for drivers of ionospheric currents: the “voltage generator” (ionospheric electric fields/voltages are constant while current varies) and the “current generator” (current is constant while the electric field varies). Here we indicate another aspect of magnetosphere - ionosphere interaction which should be taken into account when considering the current/voltage dichotomy. We show that oscillatory FAC interact with the ionosphere in a different way depending on forced driving or excitation of resonant field line oscillations. A quasi-DC driving corresponds to a voltage generator, when the ground magnetic response is proportional to the ionospheric Hall conductance. The excitation of resonant field line oscillations corresponds to the current generator, when the ground magnetic response practically does not depend on the ionospheric conductance. According to the suggested conception such ULF phenomena as TCV, Pc5 waves, should be considered as resonant response of the magnetospheric field lines and they correspond to current generator. Quasi-DC non-resonant disturbances such as SC correspond to voltage generator. However, there quite a few factors that obscure the determination of the current/voltage dichotomy - occurrence of the auroral oval, ionospheric ihomogeneities, shielding of higher frequency ULF waves by the E-layer.

D3.1-0020-18 NON-LINEAR LEAST SQUARE FITTING TECHNIQUE FOR THE DETERMINATION OF FIELD LINE RESONANCE FREQUENCY IN GROUND MAGNETOMETER DATA: APPLICATION TO THE REMOTE SENSING OF PLASMASPHERIC MASS DENSITY

Athanasios Boudouridis, thanasis@spacescience.org

Space Science Institute, Boulder, Colorado, United States Eftyhia Zesta, eftyhia.zesta@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States Mark Moldwin, mmoldwin@umich.edu

University of Michigan, Ann Arbor, Michigan, United States

The accurate determination of the Field Line Resonance (FLR) frequency of a resonating geomagnetic field line is necessary for the remote monitoring of the plasmaspheric mass density during geomagnetic storms and quiet times alike. Under certain assumptions the plasmaspheric mass density at the equator is inversely proportional to the square of the FLR frequency. The most common techniques to determine the FLR frequency from ground magnetometer measurements are the amplitude ratio and phase difference techniques, both based on geomagnetic field measurements at two latitudinally separated ground stations. Previously developed automated techniques have used statistical methods to pinpoint the FLR frequency using the amplitude ratio and phase difference calculations. We now introduce a physics-based automated technique, using non-linear least square fitting of the ground magnetometer data, to reproduce the resonant wave characteristics on the ground, and from those determine the FLR frequency. One of the advantages of the new technique is the estimation of physically determined errors of the FLR frequency. These yield physically determined errors of the equatorial plasmaspheric mass density. We present analytical results of the new technique, and test it using data from the Inner-Magnetospheric Array for Geospace Science (iMAGS) ground magnetometer chain along the coast of Chile and the east coast of the United States. We compare the results with the results of previously published statistical automated techniques.

D3.1-0021-18 IMPLICATIONS OF EXTRA-NONLINEAR STRUCTURES IN AURORAL PLASMAS

Steffy Sara Varghese, steffystephan28@gmail.com Indian Institute of Geomagnetism, New Panvel, India Suktisama Ghosh, sukti@iigs.iigm.res.in

Indian Institute of Geomagnetism, Navi Mumbai, India

The satellite electric borne instruments recorded the signatures of solitary waves in magnetospheric plasma as bipolar, monopolar and tripolar in the Electric field (E) data. These structures be either parallel or perpendicular to the local magnetic field. The E-field bipo- lar structures moving parallel to the background magnetic field (Electrostatic Solitary Waves (ESWs)) is observed ubiquitous in different magnetospheric boundary regions. Apart from conventional bipolar E-field signatures there are signatures of offset bipolar pulses for which the distance between the bipolar peaks is much more than the characteristic width of each peak. In this regard we are intended to provide a theoretical understanding of those kinds of structures.

In our work, two electron temperature warm multi-ion plasma which is quite significant in magnetospheric studies have been analyzed by using conventional Sagdeev pseudopotential technique. Apart from conventional solitary wave solution this model support different kinds of extra nonlinear structures like Super Solitary Waves and Double Layers. Super solitary Waves are a new class of nonlinear structure which are characterized in having wiggled bipolar E-field pulses. It had been found the the ambient cooler electron concentration plays a deterministic role in initiating the transition process of a compressive ion acoustic solitary to the corresponding SSW and DL. In the transitional process of an ion acoustic solitary wave to a DL it has been observed that beyond a critical value of cooler electron the width of the solitary wave increases rapidly with the increasing amplitude. This anomalous increase in the width with the amplitude motivated us to compare our results with the satellite observations of Temerin et al [1]. It shows a good agreement. This further validates our model for its applicability to interpret the slowly moving ESWs in the auroral region.

D3.1-0022-18 FIRST EVER FINDING OF A NOVEL STRUCTURE CALLED FOLDED DOUBLE LAYER (FDL) IN A MAGNETIZED PLASMA

Kamalam T, kamalam.unom@gmail.com

Indian Institute of Geomagnetism, Navi Mumbai, India Suktisama Ghosh, sukti@iigs.iigm.res.in

Indian Institute of Geomagnetism, Navi Mumbai, India

Broadband Electrostatic Noise (BEN) have been observed by satellites in various regions of the magnetosphere such as the plasma sheet boundary layer, the polar cusp, bow shock, auroral region, etc. Satellite observations of BEN revealed the signatures of the Electrostatic Solitary Waves (ESWs), which are monopolar and bipolar pulses in the electric field data. The high frequency part of the BEN is often studied by the electron acoustic solitary waves and double layers. Besides the usual monopolar and bipolar pulses, CLUSTER satellite observations also revealed more composite structures like tripolar ESWs. The interpretation for these kind of structures may further provides a key to understand the Earth's magnetosphere.

A novel structure called 'Super Solitary Waves (SSWs)' have captured the attention considerably in recent days. They are extra nonlinear solitary wave pulses with an extra wiggles in their bipolar electric field profile. Besides SSWs, there exists a unique type of solitary wave structure called as 'cusp like solitary waves', arising due to the imminent singularity in the Sagdeev pseudopotential profile. It is a unique trait for a magnetized plasma and has no counterpart for an unmagnetized case. In the vicinity of singularity like solutions, we have obtained the first ever electron acoustic SSW in a magnetized plasma. Due to its presence near the singularity, we presume that the SSW and singularity like solutions have some association in a magnetized plasma. While investigating it, we have encountered a novel structure, which shows the signatures of an SSW and a DL (Double Layer), we prefer to call this new structure as "Folded Double Layer (FDL)". This structure have a monopolar electric field with a wiggle or fold and exhibits an extra large amplitude solution.

In this present work, we are reporting the first ever finding of an electron acoustic FDL and its association with the cusp like solitary wave. We have considered a model comprising of beam and bulk electron fluids along with two ions and the plasma is magnetized. The ions are assumed to be hotter than electrons and obeying Boltzmann distribution. We have incorporated a new analytical tool to investigate these kind of structures. We intend to apply our theoretical analyses to interpret the observations and the further investigation may throw some light upon the role of FDL in Earth's magnetosphere.

D3.1-0023-18 WHISTLER MODE WAVES MODULATION OF LANGMUIR WAVES IN THE RADIATION BELTS AND DAYSIDE MAGNETOPAUSE

Jinxing Li, jinxing.li.87@gmail.com

University of California, Los Angeles, Los Angeles, California, United States Jacob Bortnik, jbortnik@gmail.com

UCLA, Los Angeles, California, United States Xin An, xinan@atmos.ucla.edu

University of California, Los Angeles, Los Angeles, California, United States Wen Li, wenli77@bu.edu

Boston University, Boston, Massachusetts, United States Richard Thorne, rmt@atmos.ucla.edu

University of California, Los Angeles, Los Angeles, California, United States Meng Zhou, mzhou@physics.ucla.edu

University of California, Los Angeles, Los Angeles, California, United States

Using high-resolution waveforms measured by the Van Allen Probes and Magnetospheric Multiscale satellites, we report a novel observation that occurs both in the radiation belts and the dayside magnetopause. Namely, whistler mode waves modulate electrostatic Langmuir wave bursts. In the radiation belts, the modulation of these two wave modes occur over two time scales: rising-tone time scale and chorus wave phase period time scale. At the magnetopause region, the modulation occurs on whistler mode phase period time scale, while these two wave modes can have very large amplitudes. The periodic Langmuir wave bursts are generally observed at the phase location where the whistler mode wave E|| component is oriented opposite to its propagation direction. The electron phase space density measurements show a beam at the velocity that matches the parallel phase velocity of the whistler mode waves. Based on this evidence, we conclude that the whistler mode waves accelerate the suprathermal electrons via Landau resonance, and generate a localized periodic electron beam in phase space density. Consequently, the Langmuir waves are excited locally and are modulated by the whistler mode wave phase. This microscale interaction between whistler mode waves and high frequency electrostatic waves provides a new insight into the nonlinear wave-particle interaction and the energy conversion processes occurred both in the radiation belts and in the reconnection regions.

D3.1-0024-18 KEY PROCESSES AT THE PISTON SHOCK REGION

Pavel Sedykh, pvlsd@iszf.irk.ru

Institute of Solar-Terrestrial Physics SB RAS, Irkutsk, Russia

Identifying blast-wave shocks, which can arise during CME formation, is a much more complex problem. The difference from piston shocks is that a blast-wave shock originates from the explosions that frequently accompany CME formation, and further propagates freely without any CME piston effects. Earth's bow shock (BS) is a piston shock. Behind the bow shock front there is a flow of the modified solar wind plasma: transition layer, which also carries the modified magnetic field of solar wind. Velocity and density of plasma as well as parameters of magnetic field of this current can be estimated if the form of the bow shock front and of magnetopause are considered to be known. In this paper we assumed them to be paraboloids of rotation. In this paper we have determined potential distribution along magnetopause from the balance condition of substance coming into transition layer from the solar wind on one side and leaving through the gap between magnetosphere and the bow shock front and through magnetopause on another. To a first approximation this distribution differs from potential distribution at the BS front only in a constant multiplier. We used the established potential distribution as a boundary condition while solving the problem on potential distribution in the magnetosphere. The first solution harmonic turned out to coincide in the form with the boundary condition on magnetopause. I have constructed the full solution for electric field in the magnetosphere having limited ourselves to the first harmonic and corotation field. I have obtained necessary equations to model processes in the region of bow shock.

D3.1-0025-18 VARIABILITY OF THE MAGNETIC FIELD OF THE SUN AND EARTH

Helen Popova, popovaelp@mail.ru

The Schmidt Institute of Physics of the Earth of the Russian Academy of Sciences (IPE RAS), Moscow, Russia

The geomagnetic field determines the shape of the magnetosphere. The magnetosphere changes significantly during the inversion of the geomagnetic field. Solar magnetic activity affects the shape of the magnetosphere and the processes occurring in it. So modeling of solar and geomagnetic activity is very important for studying and forecasting the state of the magnetosphere on large and small scale time ranges. Using the Parker dynamo model which is based on the combined effect of differential rotation and the alpha-effect and taking into account meridional flows we simulate the inversion of the geomagnetic field and solar cyclic magnetic activity including global minima. Analysis of observational data for the Sun does not give a complete picture of the distribution of meridional fluxes as function of depth. Large-scale meridional fluxes can also exist in the liquid core of the Earth. We analyzed how many cells can be formed for meridional fluxes. The dynamo model with various forms of meridional fluxes is analyzed analytically and it is established, as in this case the generated field will look like. The relationship between meridional fluxes and differential rotation is discussed.

D3.1-0026-18 COMPARISON OF AE ELECTROJET INDICES TO SUPERDARN MEASUREMENTS OF SUNWARD LOW LATITUDE PLASMA CONVECTION VELOCITIES

Michael Earl, mie263@mail.usask.ca

University of Saskatchewan, Saskatoon, Canada Kathryn McWilliams, kathryn.mcwilliams@usask.ca University of Saskatchewan, Saskatoon, Canada

The auroral electrojet (AE) indices, a quantitative indicator of ionospheric electrojet current intensity, can depend significantly on the strength of magnetospheric convection, substorm activity, and conductivity variations. The Super Dual Auroral Radar Network (SuperDARN) provides a nearly constant global-scale monitoring of ionospheric plasma convection. By comparing the AE indices to the sunward low-latitude plasma convection velocities, a comparison of electrojet current intensity to current carrier velocity can be conducted. Such a comparison provides insight into the plasma conductivity that relates the two measurements. This paper describes some of the similarities and differences that were observed when comparing the AE indices to the sunward low latitude plasma convection velocities measured by SuperDARN.

D3.1-0027-18 STATISTICAL ANALYSIS OF IONOSPHERIC BOUNDARY WAVE PHENOMENA ON VENUS.

Ghai Siung Chong, gschong1@sheffield.ac.uk University of Sheffield, 3JD, United Kingdom Simon Pope, s.a.pope@sheffield.ac.uk University of Sheffield, 3JD, United Kingdom Simon Walker, simon.walker@sheffield.ac.uk

University of Sheffield, Sheffield, United Kingdom

In contrast to Earth, Venus does not possess an intrinsic magnetic field. Hence the interaction between solar wind and Venus is significantly different when compared to Earth. Within the induced magnetosphere and ionosphere of Venus, previous studies have shown the existence of vortex like structures. These structures may play an important role in the atmospheric evolution of Venus. Using Venus Express data, all of the photoelectron boundaries (PEBs) are determined from 2006 to 2014 and used as an identifier for the ionopause. Pulses of dropouts in the electron energy spectrometer were observed in 371 events, which suggests potential perturbations of the boundary. Minimum variance analysis of the 1Hz magnetic field data for the perturbations is conducted and used to confirm the occurrence of the boundary waves. Statistical analysis shows that they were propagating mainly in the +-Y direction in the polar north terminator region. The generation mechanisms of boundary waves and their evolution into the potential nonlinear regime are discussed and analysed.

D3.1-0028-18 STABILITY ANALYSIS OF HIGH-M POLOIDAL WAVES IN THE MAGNETOSPHERE

Peter Chi, pchi@igpp.ucla.edu

University of California, Los Angeles, Los Angeles, California, United States

C. Z. Cheng, frankcheng@pssc.ncku.edu.tw

Andrews University, Berrien Springs, Michigan, United States

High-m poloidal waves are a class of ultra-low-frequency (ULF) waves that are excited either internally in the magnetosphere or externally driven by wave sources from the magnetopause. These waves are important in exchanging energy with particles in the inner magnetosphere, but when and where these waves will occur is still difficult to predict because the physics involved has not been fully understood. Past studies have shown that the high-m poloidal waves during magnetic storms are caused by enhanced energy in the ring current. Recent studies based on NASA ST-5 data demonstrate that high-m poloidal waves can also occur frequently during magnetically quiet times, but the mechanism of wave generation is still unclear. Quiet-time poloidal waves have also been found in recent MMS observations.

In this study, we examine satellite field and particle measurements during high-m poloidal wave events to assess whether these waves can be excited by ballooning-mirror instabilities. The field-aligned eigenmode stability criterion is based on a kinetic-MHD theory for low-frequency instabilities formulated by Cheng and Qian (1994). The theory predicts that anti-symmetric ballooning-mirror modes (e.g. the second harmonic) can be unstable during magnetic storms. Ballooning modes with a dominant transverse magnetic component may occur in plasmas with very low beta and pressure anisotropy. We present both storm-time and quiet-time high-m poloidal wave events observed by MMS, Van Allen Probes, and ST-5 satellites, and examine whether the ballooning-mirror or ballooning instability conditions are met.

D3.1-0029-18 PLASMA WAVES AT THE SHOCK FRONT: MODE IDENTIFICATION.

Simon Walker, simon.walker@sheffield.ac.uk University of Sheffield, Sheffield, United Kingdom

Data from multi-spacecraft missions such as Cluster and MMS enable the determination of the wave propagation vector based on observations alone. In this poster we investigate the plasma wave modes observed in the vicinity of a quasi-perpendiclar shock. Knowledge of the wave mode provides insight into the acceleration and energy redistribution processes occurring at the shock front. The source of free energy to drive the waves is determined and the effects of the observed waves on the observed electron distribution investigated.

D3.1-0030-18 PIC SIMULATION OF NONLINEAR UPPER HYBRID WAVES GENERATED BY AGYROTROPIC ELECTRON DISTRIBUTION NEAR THE ELECTRON DIFFUSION REGION

Kyunghwan Dokgo, korn1009@gmail.com

NASA/GSFC, Greenbelt, Maryland, United States

Recently, MMS spacecraft observed upper-hybrid (UH) wave activities near the electron diffusion region (EDR) of dayside asymmetric reconnection. Agyrotropic electron beam and/or crescent distributions are found together and analysis of linear instability shows that agyrotropic electrons are free energy sources of UH waves. Because observed UH waves are very intense, it is believed that nonlinear phenomena, such as wave-particle and wave-wave interactions, can play important roles in EDR dynamics. We investigate nonlinear evolutions of UH wave activities using 2-D electromagnetic particle-in-cell (PIC) simulation. Our simulation shows that the nonlinear beam-plasma interaction by the agyrotropic beam leads fundamental and second harmonic of electrostatic UH modes and radio emissions. Simulation results are well explained by the sequential processes of wave-wave interactions, which account the electromagnetic radiation of the solar type-II and type-III radio burst. The electromagnetic decay of the fundamental UH mode generates the fundamental radio emission, while the electrostatic decay generates the backscattered mode propagating backward direction to the beam. The coalescence of the fundamental UH mode and the backscattered mode leads second harmonics radio emission.

D3.1-0031-18 THE SYSTEM SCIENCE DEVELOPMENT OF LOW ENERGY ELECTRON FLUX MODELS FOR GEOSTATIONARY ORBIT

Richard Boynton, rboynton85@gmail.com University of Sheffield, Sheffield, United Kingdom Simon Walker, simon.walker@sheffield.ac.uk University of Sheffield, Sheffield, United Kingdom

The low energy electrons within the radiation belts can interfere with satellite electronic systems through the process of surface charging. Therefore, the prediction of these low energy electrons is vital to mitigate hazards to spacecraft. At Geosynchronous Earth Orbit, the fluxes of low energy electrons, with energies up to several hundred keV, can vary widely in Magnetic Local Time (MLT). This is antithetical to higher energies, which are uniform in MLT. This study aims to develop Nonlinear AutoRegressive eXogenous (NARX) models that account for the spatial variation in MLT. This is difficult for system science techniques, since there is sparse data availability of the electron fluxes at different MLT. To solve this problem we investigated two different approaches. The first approach binned data from GOES 13 and 15 by MLT and deduced a separate NARX model for each bin using solar wind inputs then conjugated these into one spatio-temporal forecast. The second approach employed the MLT at the point of measurement as an input along with solar wind parameters to deduce one NARX model.

D3.1-0032-18 SURVEY OF ELECTROMAGNETIC SHIELDING INSPIRED FROM MAGNETO PLASMA SAIL FOR NANOSATELLITE APPLICATIONS

Yiğit Çay, yigitcay.34@gmail.com

Kyushu Institute of Technology, Kitakyushu, Japan Kazuhiro Toyoda, toyoda@ele.kyutech.ac.jp

Kyushu Institute of Technology Japan, Kitakyushu, Japan

Corpuscular radiation environment in space threatens space missions in terms of device losses as well as human damage and hence the loss of big amounts of money spent on satellites. In order to overcome the hazardous radiation effects, passive and active shielding methods are being used although the passive shielding is the more desirable choice due to it's the usage of the natural ability of shielding of the material implemented on satellites and cost is comparatively lower. However, the amount of particle radiation that can be stopped is limited and has the risk of generating secondary emissions inside the spacecraft, which is more dangerous compared to ambient irradiance. Hence, the active shielding is being used in big satellites to overcome higher energetic particles then the passive shielding methods and due to their ability of particle deflection, it's more desirable so as not to generate secondary particles. In this study, the electromagnetic shielding demonstration that is inspired by Magneto Plasma Sail concept design applications is investigated by experiments conducted in Laboratory of Spacecraft Environment INteraction Engineering (LaSEINE) in Kyushu Institute of Technology. In the experiments, the ion plasma behavior around the artificial magnetosphere is investigated with magnetic field measurements in the vacuum chamber. Moreover, the results are compared with the developed hybrid particle-in-cell simulation to point out the trustworthiness of the study. In the discussion, the results are compared and argued the applicability of electromagnetic shielding on nanosatellites.

D3.2-0001-18 MULTI-SCALE STRUCTURE OF WHISTLER WAVES WITHIN EARTH'S SUPERCRITICAL BOW SHOCK: MMS OBSERVATIONS

Arthur Hull, ahull@berkeley.edu

Space Sciences Laboratory, University of California, Berkeley, California, United States Laurent Muschietti, laurent@ssl.berkeley.edu

Space Sciences Laboratory, University of California, Berkeley, California, United States

Whistler waves are well-known to be an important part of the shock structure, and thus have garnered a considerable amount of attention in theoretical and observational studies. Despite that attention, their generation mechanisms, their role in shock internal structure, and consequences to plasma transport are not fully understood. We report the results of our analysis of whistler waves observed by the Magnetospheric Multiscale (MMS) mission within Earth's bow shock. The long duration high-time-resolution data make apparent the multi-scale structure of whistler waves within the layer. Characteristic of high-Mach number supercritical shocks, the macrostructure is composed of a pedestal, ramp, overshoot and undershoot on ion scales, and also sub-ion scale substructures. Superposed on the ramp substructures are bursts of intense, upstream directed, oblique whistlers at lower-hybrid frequencies and below, indicating those are important sites for the generation of these waves. Based on a detailed characterization of these intense whistler waves, comparisons with the ion distribution features, and dispersion analysis, our results indicate that the likely source of these intense whistlers is the modified two-stream instability (a.k.a. kinetic cross-field streaming instability) due to the relative drift between reflected ions and electrons. We also show that these intense whistlers are affecting shock structure and plasma transport in a significant way, by inducing electron anisotropies and carrying sizable currents that lead to secondary higher frequency whistler (0.1 0.5Ωce) and electrostatic instabilities, respectively. These observed features are indicative of an intricate coupling between small-scale interaction processes and the large-scale shock structure transpiring within the layer, with significant ramifications to shock structure, and also to plasma energization and thermalization processes occurring therein. Such a characterization is only made possible now, since the high-time-resolution measurements from MMS yield accurate estimates of currents, drifts and plasma moments on sub-ion scales together with accurate determinations of wave vectors, polarizations, phase velocities, and other wave characteristics.

The Universe is permeated by hot, turbulent magnetized plasmas. They are found in galaxy clusters, in accretion disks, in the intergalactic and interstellar medium, as well as in the solar corona, the interplanetary medium and planetary magnetospheres. Our comprehension of the plasma Universe is largely based on measurements of electromagnetic radiation, such as light or X-rays, which originate from charged particles that are heated and accelerated as a result of energy dissipation of turbulent fluctuations. Therefore, it is of key importance to study and understand how plasma is energized by turbulence. Most of the energy dissipation occurs at kinetic scales, where plasma no longer behaves as a fluid and the properties of individual plasma species (electrons, protons and heavier ions) become important. The Turbulent Heating ObserveR (THOR) is one of the three missions which performed Phase A studies for selection as the fourth ESA M-class mission (M4). It is the first in situ spacecraft concept that is fully dedicated to study turbulence and how turbulence energizes plasma, which ties in with ESA's Cosmic Vision science. THOR's science focuses on kinetic plasma processes aiming to understand the basic plasma heating and particle acceleration mechanisms, how energy is partitioned among different plasma components and how dissipation operates in different regimes of turbulence. To reach this goal, THOR spacecraft and payload are designed to make detailed in situ measurements of the closest available dilute and turbulent magnetized plasmas the Near-Earth's space - at unprecedented temporal and spatial resolution. THOR focuses on particular regions in space: the pristine solar wind, the Earth's bow shock and interplanetary shocks, and the compressed solar wind regions downstream of shocks. These regions are selected because of their different turbulence properties and they reflect the properties of a number of distant astrophysical environments. In such way, THOR measurements can help understanding the fundamental behavior of plasma in the Universe. Here we present THOR's science as well as the results from mission and payload Phase-A studies.

D3.2-0003-18 STATISTICS OF GEOMETRICAL INVARIANTS OF MAGNETIC FIELD GRADIENT TENSOR IN TURBULENT SPACE PLASMAS

Giuseppe Consolini, giuseppe.consolini@iaps.inaf.it Istituto Nazionale di Astrofisica, Rome, Italy

Virgilio Quattrociocchi, virgilio.quattrociocchi@iaps.inaf.it Istituto Nazionale di Astrofisica, Roma, Italy

Maria Federica Marcucci, federica.marcucci@iaps.inaf.it Istituto Nazionale di Astrofisica, Roma, Italy

The nature of spatio-temporal fluctuations in turbulent fluids and magnetofluid media, such as space plasmas, is very complex due to the highly non-Gaussian and strongly long-range correlated feature of these fluctuations and the role that structure formation plays in generating such fluctuations. The investigation of such turbulent fluctuations is generally done by investigating the spectral and scaling features. Here, we present a characterisation of these fluctuations by the geometric invariants of the magnetic field gradient tensor computed using measurements from multipoint satellite missions in different space regions from MHD scales down to kinetic ones. The analysis allows the identification of the different structures responsible for the observed turbulent character. Furthermore, a clear evolution of the joint-statistics of geometrical invariants with the distance from the proton inertial length scale is observed, indicating the formation of tube-like and/or sheet-like coherent structures at the smallest scales where Ohmic dissipation concentrates.

This work is funded by Italian Space Agency under Grant agreement No. ASI-INAF 2015- 039-R.O. “Missione M4 di ESA: Partecipazione italiana alla fase di assessment della missione THOR”.

D3.2-0004-18 OPTIMAL FIELD GRADIENTS DERIVED FROM MULTI-SPACECRAFT OBSERVATIONS

Gerard Chanteur, gerard.chanteur@lpp.polytechnique.fr CNRS, Palaiseau, France

The MMS mission offers the unique opportunity to check the quality of magnetic gradient estimates made by multi-spacecraft analysis methods. Particle detectors onboard MMS have enough energy and time resolution to provide ion and electron currents hence the electric particle current Jp. Magnetic records from the four spacecraft are used to estimate the tensor gradient of the vector magnetic field from which the magnetometer current Jm and divB are derived. Since the early 90’s when preparing the CLUSTER mission several methods have been designed for estimating gradients of vector fields which differ by their approaches and abilities meanwhile they all give the same weight to the four spacecraft. The theory based on reciprocal vectors allows a detailed analysis of errors affecting the estimated components of the tensor gradient of a vector field which demonstrates that less regular is the tetrahedron larger are the uncertainties. An alternative to this Standard Reciprocal Vectors (SRV’s) approach is the Generalized Reciprocal Vectors (GRV’s) approach which improves the estimate of the gradient when the tetrahedron is not regular. GRV’s will be introduced first, and then shown to improve the estimated divergence of B and the agreement between Jp and Jm on MMS event cases. GRV’s applied to CLUSTER data lead to an improved estimation of divB, i.e. closer to zero, meanwhile leading to new current estimates. It is expected that improving divB with CLUSTER data is an indication of improvement of the estimated current as for MMS data. It should nevertheless be mentioned that deformations of the tetrahedron are generally much smaller for MMS than for CLUSTER. This study will be completed by looking for MMS observation with more irregular tetrahedra.

The NASA Magnetospheric Multiscale (MMS) mission uses four closely-spaced spacecraft to investigate magnetic reconnection in the boundary regions of the Earth's magnetosphere by measuring charged particles and electric and magnetic fields at the electron scale for the first time in space. MMS benefits from several well-developed plasma simulation research programs, which reached the electron scale prior to MMS, and these efforts were augmented by the MMS Theory and Modeling team and its team of Interdisciplinary Scientists. Many of the plasma-simulation predictions on reconnection were confirmed early in the mission, while other phenomena were discovered and in some cases confirmed by simulation. The prime mission was conducted in two phases, the dayside magnetopause and the magnetotail with four spacecraft in a tetrahedron formation with separations varied from 160 km down to 7 km and a lowinclination, highly elliptical orbit with apogee at 12 Earth radii on the day side and 25 Earth Radii in the tail. The general result is that reconnection is driven by electron dynamics and is to a large extent laminar. Although turbulence is commonly observed, it does not seem to drive reconnection or to dissipate the characteristic electron distributions that form the reconnection electric field and carry the out-of-plane current. Crescent-shaped agyrotropic electron distributions were predicted by simulation to occur in the electron stagnation region and were observed early in the dayside phase of the mission. The crescents, which form in the plane normal to the magnetic field are produced by meandering motions of magnetosheath electrons as they cross the current sheet into the boundary layer and oscillate between the magnetospheric and magnetosheath magnetic field directions. The perpendicular crescents were observed to evolve into field-aligned crescents, which carry electron jets, and these distributions were subsequently confirmed by plasma simulation. The reconnection electric field is generated primarily by divergence of the electron pressure tensor although electron inertia is partially responsible. While the energy conversion occurs primarily in the electron stagnation region when the out-of-plane (guide) magnetic field is small, larger guide fields lead to equally strong energy conversion near the X-line. An unexpected result is the association of intense standing oblique whistler waves with the energy conversion. 3D plasma simulation with highly increased numbers of electrons have since confirmed the existence of these waves. In the tail where reconnection is symmetric, the X-line is coincident with the electron stagnation point. MMS has observed multiple crescent signatures in this environment.

Magnetic reconnection is a cross-scale process through which plasma energization and mixing occurring in the small-scale reconnection layer modify the large-scale plasma environment. In this talk, observations resolving the electron gyro-radii by the four-spacecraft mission Magnetospheric Multiscale (MMS) will be discussed to shed light on how large-scale plasma conditions influence the electron-scale physics during reconnection. As a current sheet thins and the current density intensifies, electrons are demagnetized, enabling a reconnection electric field to accelerate them and sustain the current. However, for reconnecting current sheets with only weak magnetic fields guiding the current, the signature of this acceleration on electron distribution functions depends upon upstream conditions, and presents an example for how large-scale plasma conditions are imprinted in the electron-scale dynamics. In magnetotail reconnection when the upstream electrons are sufficiently cold, the distributions exhibit discrete striations, as predicted by simulations [Bessho et al., 2014; Shuster et al., 2015]. At the magnetopause, the signature carved by the reconnection electric field is observed as a widened crescent in the distribution functions [Chen et al., 2017; Bessho et al., 2017]. The measurements not only show signatures of acceleration but also reveal the evidence for a process that limits this acceleration without the aid of collisions.

Ion heating during reconnection is investigated using magnetotail observations from the MMS spacecraft, aided by comparisons with magnetopause observations and particle-in-cell simulations. In the diffusion region, the major temperature increase is due to mixing of demagnetized ions energized by the reconnection electric field and the in-plane electrostatic potential. The single population of inflowing ions is observed to be heated across the separatrix region. Such heating will be quantified, and the effect of the electric field spatial gradient and wave fluctuations will be discussed.

Before the launch of the Magnetospheric Multiscale mission (MMS), our understanding of the electron kinetic physics of magnetic reconnection was primarily determined by the predictions of theories and numerical simulations. These predictions can be broadly divided into two categories, depending on which process is responsible for the reconnection electric field in the inner, electron, diffusion region. The first category includes wave-particle interactions leading to anomalous resistivity, which scatters current-carrying electrons. The second class is based in a thermal inertial, "quasi-viscous," effect related to the transient nature of electron orbits in the electron diffusion region. Both categories have rather different predictions for the structure of the electron diffusion region. In this presentation, we present a brief review of the predictions of these two classes of theories. We will then review key MMS events with these predictions in mind, and interpret the data analysis in this context.

D3.2-0009-18 CONFRONTING RECONNECTION SIMULATIONS WITH MMS OBSERVATIONS

James Drake, drake@umd.edu

University of Maryland, College Park, College Park, Maryland, United States Lora Price, lorajm@umd.edu

University of Maryland, College Park, College Park, Maryland, United States Marc Swisdak, swisdak@umd.edu

University of Maryland, College Park, College Park, Maryland, United States

The observations at the Earth's magnetopause by the MMS have produced an extraordinarily detailed view of the dynamics of reconnection. While some theoretical ideas on the structure of the electron diffusion region have been confirmed in the observations (e.g., the crescents in the electron velocity distributions and the shift in the peak of the reconnection-driven current toward the magnetosphere), there have been a number of surprises that contradict the expectations of pre-MMS theory and models. The electron diffusion region is much more turbulent than expected, even in reconnection events with weak magnetic shear and a strong ambient guide field. Measured magnetic energy dissipation rates can take on extreme values, more than two orders of magnitude greater than in pre-MMS predictions. 2D and 3D PIC simulations of specific MMS reconnection events have been instrumental in unraveling some of these MMS discoveries. 3D simulations of the Oct 16, 2015, (weak guide field) and the December 8, 2015, (strong guide field) events both exhibit strong LHDI-like turbulence peaked along the magnetopause separatrix. In the simulations the turbulence is strong enough to prevent the reconnection-driven current layer from collapsing to electron scales and controls the local Ohm's law in the electron diffusion region through anomalous viscosity and drag. Simulations suggest that the intense dissipation in the electron diffusion region revealed in the MMS data corresponds to a whistler-like standing structure that is driven by the annihilation of the self-generated Hall magnetic magnetic field BM rather than BL as in symmetric reconnection. Surprises in the physics of symmetric reconnection in the magnetotail are also being explored and will be discussed.

D3.2-0010-18 SIMULATION STUDY OF THE THE ENERGY AND MOMENTUM CONVERTED BY RECONNECTION

UCLA-IGPP, Los Angeles, California, United States

From a global point of view reconnection uses magnetic energy to produce kinetic (flow and thermal) energy and momentum. Part of this energy is carried by the electromagnetic fields (Poynting flux), part by the plasma species. Intuitively speaking ,one expects that the energy carried by the ions overwhelms that carried by the electrons that overwhelms that carrie by the fields. The means of transport of the energy released have been analyzed by observational studies have been based on CLUSTER, THEMIS and MMS events (see e.g. [1,2]), via laboratory experiments [3] and simulations [4]. More recently, the momentum released by reconnection has been analyzed under different conditions to explore the possibility of practical applications [5]. All these studies were either local (specific crossings) or used artificial setups (in laboratory or simulation). We will present here a new approach based on using realistic equilibria [6]. We spawn kinetic fully PIC simulations form a global MHD model of the magnetosphere. We zoom into two reconnection regions: at the dayside and at the magnetotail and we observe the momentum and energy flows produced by reconnection, comparing the MHD description with the kinetic description.

Flux Transfer Events (FTEs) are the product of magnetic reconnection at the dayside magnetopause. They may play significant roles in determining the global rate of reconnection and accelerating particles. This study investigates the magnetohydrodynamic forces inside and outside FTEs to infer the process through which these structures become force-free using Magnetospheric Multiscale (MMS) measurements. Akhavan-Tafti et al. [2017] demonstrated that FTE size at the subsolar magnetopause follows an exponential distribution. The observed non-linear distribution appears consistent with the plasmoid instability theory in which coalescence plays a significant role in generating large-scale flux ropes (e.g., Daughton et al., 2009; Fermo et al., 2010; Huang Bhattacharjee, 2010; Loureiro et al., 2007; Shibata Tanuma, 2001; Uzdensky et al., 2010). FTEs are also shown to contain regions of elevated plasma density which greatly contribute to thermal pressure gradient forces inside FTEs. It is shown that as FTEs evolve, the plasma is evacuated as the core magnetic field strengthens and the structure becomes more magnetically force-free. The neighboring ion-scale FTEs formed at the subsolar magnetopause due to multiple X-line reconnection are forced to interact, and likely coalesce. Entropy is invoked to motivate the discussion on the essential role of coalescence in reconfiguring magnetic fields and current density distributions inside FTEs facilitating their observed exponential growth. Magnetic pressure gradient and ion thermal pressure gradient are shown to be the dominant forces inside FTEs. Local electron kinematics are studied and used to compare the contributions of parallel electric field, Fermi acceleration, and betatron acceleration mechanisms to particle energization (e.g., Dahlin et al., 2014; Drake et al., 2006) Parallel acceleration mechanisms are shown to be dominant inside and, more significantly, in the outer perimeters of FTEs (i.e., 10 ion-inertial lengths from the outer boundary) in the vicinity of the reconnection site. On the other hand, betatron acceleration controls perpendicular heating inside the FTE in the presence of magnetic pressure gradients. Downstream of the reconnection

site, the 'freshly' reconnected field lines start to straighten due to the magnetic curvature force. Straightening field lines accelerate trapped electrons parallel to the local magnetic field as they shorten themselves (i.e., first-order Fermi acceleration). These acceleration mechanisms are shown to explain the observed anisotropic pitch angle distributions in the core and then at the edges of FTEs. Finally, the anisotropic plasma temperature and plasma instabilities are shown to be correlated. In particular, fire-hose instability is shown most pronounced inside FTEs, causing magnetic reconnection and associated particle acceleration to shut down, while the anisotropic plasma moments indicate the presence of the mirror-mode instability in the outer perimeters of quasi-force free FTEs [Drake et al., 2010].

D3.2-0012-18 MOTION OF THE X-LINE AT THE DAYSIDE MAGNETOPAUSE

Lorenzo Trenchi, lorenzo.trenchi@esa.int ESA/ESRIN, Frascati (Roma), Italy

Maria Federica Marcucci, federica.marcucci@iaps.inaf.it Istituto Nazionale di Astrofisica, Roma, Italy

Robert Fear, r.c.fear@soton.ac.uk

University of Southampton, Southampton, United Kingdom

Magnetic reconnection at the dayside magnetopause occurs with a large density asymmetry and for a large range of magnetic shears. In these conditions, a motion of the X-line has been predicted in the direction of the electron diamagnetic drift. When this motion is superAlfvenic, reconnection should be suppressed. We analysed a large dataset of Double Star TC1 dayside magnetopause crossings, which includes reconnection and non-reconnection events, comprising several events during which TC-1 is near the X-line. With these close events we studied the motion of the X-line along the magnetopause: the X-line moves northward or southward according to the orientation of the guide-field, which is related to the interplanetary magnetic field BY component, in agreement with the diamagnetic drift. This motion of the X line could be responsible for non-stationary reconnection even when the boundary conditions are stable. The study of the close events permitted also to verify the diamagnetic suppression condition with local observations near the X-line: the local observations at the X line are very important to test the diamagnetic suppression condition, given the substantial variation of the magnetic shear along the magnetopause.

D3.2-0013-18 AN INTUITIVE TWO-FLUID PICTURE OF SPONTANEOUS COLLISIONLESS MAGNETIC RECONNECTION AND WHISTLER WAVE GENERATION INVOLVING FROZEN-IN CANONICAL VORTICITY

Young Dae Yoon, yyoon@caltech.edu

California Institute of Technology, Pasadena, California, United States Paul Bellan, pbellan@caltech.edu

California Institute of Technology, Pasadena, California, United States

An intuitive description of spontaneous 2D collisionless magnetic reconnection is presented in the framework of 3D electron-magneto-hydrodynamics (EMHD). The relevant EMHD equations reduce to the condition that the electron canonical vorticity Qe = me ue +qeB is frozen into the electron fluid motion. Therefore, just as frozen-in magnetic flux tubes can be defined in ideal magneto-hydrodynamics, frozen-in Qe flux tubes can be defined in this regime. Following the three-dimensional behavior of the Qe flux tubes in the reconnection geometry enables an intuitive, physical portrayal of the reconnection phenomenon that has been hard to perceive via examinations of 2D projections.

In particular, physical answers to three important questions are given. First, the spontaneity of magnetic reconnection is explained by the coupling between the curvature of the Qe field lines and the central current. Any small perturbation to the current sheet will bring a localized segment of a typical Qe field line towards the null point, effectively inducing a velocity shear perpendicular to the field line which initiates an instability. Second, extreme particle acceleration is explained by a combination of Qe flux tube thinning and magnetic field cancellation. As a segment of a typical Qe flux tube convects downwards with the current sheet, the tube gets stretched and thinned, effectively increasing the magnitude of Qe within. This, coupled with magnetic field cancellation, yields an exponential increase of particle fluid velocity. Third, whistler wave generation is explained by the current sheet's role as a source of electron canonical helicity. The current sheet effectively winds up a Qe flux tube, and whistler waves represent its dynamic unwinding, just as torsional Alfvèn waves do of magnetic flux tubes.

Generalizations of this description including other factors (e.g. ion motions, compressibility, anisotropic pressure) are also briefly discussed.

D3.2-0014-18 VLASIATOR: THE INTERCONNECTED WORLD OF KINETIC PHENOMENA IN THE MAGNETOSPHERE.

Global kinetic simulations allow bridging the gap between the scales resolvable within spacecraft constellations and the distances between them.

Using the Hybrid-Vlasov simulation system Vlasiator to simulate the entire Magnetosphere on ion kinetic scales in global simulation runs has uncovered previously unknown couplings and interdependencies of seemingly unrelated magnetospheric processes:

The effects of magnetosheath mirror modes on dayside reconnection rates have been studied, and been shown to modulate the reconnection rate significantly. Further, the reconnection outflows themselves create fast-mode waves in the sheath which act back on accelerated particles, and these have measurable effects on the bowand foreshock regions. Even beyond the polar cusps, variability of dayside reconnection outflows shows influences on tail reconnection behaviour.

We present the surprising interconnections of multiple ion kinetic magnetospheric phenomena that have previously been treated in isolation, how their features can be compared and studied in spacecraft data and how further connections can be discovered in the future.

Near-Earth magnetotail reconnection is considered to be a major energy conversion process leading to large-scale reconfiguration of the magnetotail. An important consequence of the magnetotail reconnection is the fast plasma jet (known as bursty bulk flow), which contributes to energy transport toward inner magnetosphere. Interaction with the reconnection jets and the Earth's dipole field leads to acceleration of particles and formation of field-aligned currents. High-time resolution measurements from MMS, launched in March 2015, enables to study of the dynamics of the sub-ion/electron-scale processes in the reconnection region as well as the fronts and plasma boundaries formed between the near-Earth reconnection and flow-braking regions. In this presentation, we highlight the new observational signatures in the reconnection region, reconnection jet, and flow braking region obtained by the four MMS spacecraft.

D3.2-0016-18 MULTISCALE MAGNETOTAIL RECONNECTION

Mikhail Sitnov, mikhail.sitnov@jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, United States Viacheslav Merkin, slava.merkin@jhuapl.edu

JHU/APL, Laurel, Maryland, United States

Magnetic reconnection in the tail of Earth's magnetosphere is inherently multiscale. Even when compared to similar processes at the magnetopause and in laboratory plasmas, it involves a much wider range of scales. First of all, because of the stabilizing effect of the northward magnetic field component Bz, the tearing stability region in the magnetotail extends from micro (electron) to global scales. Second, to be unstable on the macro-scale edge of the stability region, the tail must have a region of a tailward Bz gradient. The corresponding Bz "hump" introduces a mesoscale, intermediate between the tail current sheet thickness and its length. Finally, when the hump configuration becomes unstable it results in the formation of dipolarization fronts (DFs), which introduce structures with finer scales down to the electron inertial scale. Here we present results of 3-D PIC simulations of the tail reconnection, which starts on the macro-scale edge of the tearing stability region and proceeds through an ideal MHD stage followed by the ion tearing instability when ions become unmagnetized. The distinctive features of this region of the ion demagnetization-dominated reconnection (IDMR) are spontaneous generation of bursty bulk flows and DFs that may precede the magnetic topology change; new Hall patterns, different from the classical quadrupole pattern; and new plasma dissipation regions different from the electron diffusion region and associated with DFs. The multiscale reconnection structure extends to 3D because the IDMR processes compete with kinetic ballooning/interchange instability and flapping motions of the current sheet.

Understanding the structure and dynamics of magnetic reconnection outflows at Earth's dayside magnetopause is challenging because it involves both the global evolution of the dayside magnetosphere and the local dynamics of kinetic processes. To this end we have carried out three-dimensional semi-global kinetic simulations to investigate how plasma distributions and electromagnetic fields, as well as filamentary structures, develop, evolve, and interact in the outflow regions for different plasma parameters and magnetic field shears at the magnetopause. The simulation approach consists of first using global magnetohydrodynamic (MHD) simulations to determine the large-scale stresses imposed on the dayside magnetosphere by the solar wind, and then using the results of the MHD simulations to set the initial state and evolving boundary conditions of fully kinetic implicit particle-in-cell simulations. This approach allows us to simulate large domains both in space and energy. We discuss the results of the simulations by comparing electromagnetic fields, plasma parameters, and particle velocity distribution functions observed in different regions of the simulation domain with local spacecraft observations at the dayside magnetopause.

D3.2-0018-18 UPDATE ON SMILE - A NEW MISSION TO IMAGE THE MAGNETOSPHERE

MSSL, University College London, Holmbury St Mary, Surrey, United Kingdom

C. Philippe Escoubet, philippe.escoubet@esa.int ESA-ESTEC/RSSD, Noordwijk, Netherlands

Solar wind - Magnetosphere - Ionosphere Link Explorer (SMILE) is a novel self-standing mission jointly developed between the European Space Agency (ESA) and the Chinese Academy of Sciences (CAS). It will observe the solar wind-magnetosphere coupling via simultaneous in situ solar wind/magnetosheath plasma and magnetic field measurements, X-ray images of the magnetosheath and polar cusps, and UV images of global auroral distributions. Remote sensing of the magnetosphere with X-ray imaging is now possible thanks to the discovery of solar wind charge exchange (SWCX) taking place in the Earth's environment. The SMILE mission is currently under phase B study. The overview and recent development of SMILE will be presented.

D3.2-0019-18 MODELING OF TAIL PROCESSES: PARTICLE ACCELERATION IN DIPOLARIZATION FRONTS

University of Bergen, Bergen, Norway

Using three-dimensional MHD simulations, we model near tail reconnection and the formation and earthward propagation of dipolarization fronts. The simulations form the basis for particle orbit studies. Using Liouville mapping of the conservation of the phase space density along trajectories, we construct particle distribution functions, spatial maps, and energy time spectrograms that compare favorably with THEMIS and MMS observations. and shed light on accleration mechanisms and sources.

D3.2-0020-18 MULTISCALE KINETIC PROCESSES ASSOCIATED WITH FAST FLOWS AND DIPOLARIZATION FRONTS

Olivier Le Contel, olivier.lecontel@lpp.polytechnique.fr LPP/CNRS, PARIS, France

Fast flows and associated dipolarization fronts play a crucial role in plasma, energy and magnetic field transports through the Earth's magnetotail. They also host complex particle acceleration and energy dissipation processes. Various electrostatic and electromagnetic waves have been detected during front crossings thanks to in situ measurements provided by single (Geotail, Polar) and multisatellite (ISEE, Cluster, THEMIS and MMS) missions. In particular, large amplitude electrostatic fields related to lower-hybrid drift waves at the front and intense electromagnetic whistler waves behind the front in the region of the magnetic compression were measured. Non linear electrostatic and electromagnetic coherent structures are also often observed in the vicinity of these fronts although formation mechanisms are not fully understood. In the present study, we show recent MMS data gathered in the magnetotail and discuss possible multiscale kinetic processes related to wave-particle interactions and associated with dipolarization front crossings.

D3.2-0021-18 CONTRIBUTION OF ENERGETIC AND HEAVY IONS TO THE PLASMA PRESSURE IN THE MAGNETOTAIL AND THE RING CURRENT

IRAP, University of Toulouse / CNRS, Toulouse, France

Ions in the magnetospheric plasma sheet drift toward the Earth and populate the ring current. The enhanced plasma pressure in the ring current distorts the terrestrial internal magnetic field at the surface, and this disturbance strongly affects the strength of a magnetic storm. The contribution of energetic ions (> 40 keV) and/or of heavy ions to the total plasma pressure on the closed field lines is not always considered. In this study, we assess the contribution of low-energy and energetic ions of different species to the total plasma pressure for the storm observed by the Cluster mission from 27 September until 3 October 2002. We show that the contribution of energetic ions (> 40 keV) and of heavy ions to the total plasma pressure is about 14-59% in the magnetotail and about 76-97% in the ring current. This shows that it is necessary to consider heavy ions and the energetic part of the ion distribution in simulations of the terrestrial magnetosphere. We compare the derived from Cluster observations plasma pressure in the ring current for the magnetic storm event with simulations of the Space Weather Modeling Framework, which include ionospheric ion outflows from two different models. Both models produce reasonable results. The model which produces the most heavy ions agrees best with the observations. The assessment of our current capability to reproduce the ionospheremagnetosphere coupling suggests that there is still potential for refinement in the simulations.

D3.2-0022-18 THEMIS CONJUGATE ASI AND NEAR-EARTH PLASMA SHEET OBSERVATIONS OF WAVES WITH KINETIC BALLOONING-INTERCHANGE SIGNATURES

Eight THEMIS events of plasma sheet oscillations with kinetic ballooning/interchange instability (BICI) signatures were collected in conjunction with ground all-sky imager (ASI) observations, using an adapted model for THEMIS footprints' mapping. Here we aim at showing the auroral signatures of the BICI waves, which appear to resemble a reach activity often being diffuse and patchy aurora slightly poleward of the auroral oval. We further use the adapted model to test whether the background plasma sheet shape affects the BICI waves and the auroral shapes.

D3.2-0023-18 TURBULENCE IN THE PLASMA SHEET FROM MULTIPOINT CLUSTER AND THEMIS MEASUREMENTS.

Skobeltsyn Institute of Nuclear Physics Lomonosov Moscow State Univetsity (1), Space Research Institute RAS (2), Moscow, Russia

We present a review of main properties of the turbulence in the plasma sheet including the eddy diffusion, energy transport, intermittency, and the influence of the bursty bulk flow events. These studies have been done using the CLUSTER and THEMIS satellites. It was found that the properties of the turbulence are strongly dependent on the location within the plasma sheet and less on the geomagnetic conditions. Even during quiet geomagnetic conditions plasma in the plasma sheet is strongly turbulent. The level of turbulence increases to the tail and intensifies during geomagnetic substorms, especially during the expansion phase. Study of spatial distribution of the BBFs in the inner and outer plasma sheet for quiet and disturbed geomagnetic conditions also showed that BBFs could be an inherent component of the intermittent turbulent cascade in the central plasma sheet.

D3.2-0024-18 THE ROLE OF PLASMA SHEET O+ IN FORMING THE STORM-TIME RING CURRENT

Lynn Kistler, lynn.kistler@unh.edu

University of New Hampshire, Durham, North Carolina, United States Christopher Mouikis, chris.mouikis@unh.edu

University of New Hampshire, Durham, New Hampshire, United States Andrew Menz, ast63@wildcats.unh.edu

University of New Hampshire, Durham, New Hampshire, United States Sam Bingham, s.bingham@wildcats.unh.edu

University of New Hampshire, Durham, New Hampshire, United States

During storm times, the particle pressure that creates the storm-time ring current in the inner magnetosphere can be dominated by O+, and the fraction contributed by O+ is higher toward the inner edge of the ring current. The storm-time ring current is predominantly formed by inward convection of the plasma sheet, and there is no evidence that an inner source of O+ makes a significant contribution. Thus the O+/H+ pressure ratio gradient must reflect a property of the plasma sheet source. The plasma sheet population gets accelerated as it convects into the inner magnetosphere, so the range of the phase space density that dominates the pressure changes. In addition, the time to reach low L-values (L 3) can be hours longer than the time to reach the outer L-values (L 5). Therefore, the higher O+/H+ pressure ratio at the inner edge of the ring current population could result from a difference in the H+ and O+ spectra in the near-earth plasma sheet source spectrum, or from time dependence in the source, with O+ enhanced in the plasma sheet early in the storm main phase. We will use MMS and Van Allen Probes data to test which of these scenarios is more important.

D3.2-0025-18 HELIOSPHERIC PLASMA SHEET (HPS) IMPINGEMENT ONTO THE MAGNETOSPHERE AS A CAUSE OF RELATIVISTIC ELECTRON DROPOUTS (REDS) VIA COHERENT EMIC WAVE SCATTERING WITH POSSIBLE CONSEQUENCES FOR ATMOSPHERIC VORTICITY

Bruce Tsurutani, bruce.tsurutani@jpl.nasa.gov JPL, Pasadena, California, United States

A new scenario is presented for the cause of magnetospheric relativistic electron decreases (REDs) and potential effects in the atmosphere and on weather. High density solar wind heliospheric plasmasheet (HPS) events impinge onto the magnetosphere, compressing it along with remnant noon-sector outer-zone magnetospheric 10-100 keV protons. The betatron accelerated protons generate coherent EMIC waves through a temperature anisotropy (Tperp/Tpar > 1) instability. The waves in turn interact with relativistic electrons and cause the rapid loss of these particles to a small region of the atmosphere. A peak total energy deposition of 3 x 1020 ergs is derived for the precipitating electrons. Maximum energy deposition and creation of electron-ion pairs at 30-50 km and at < 30 km altitude are quantified. We focus attention on the relevant Wilcox et al. [1973] correlation between solar wind heliospheric current sheet (HCS) crossings and high atmospheric vorticity centers at 300 mb altitude. Other possible scenarios potentially affecting weather are discussed.

D3.2-0026-18 MULTIPOINT MEASUREMENTS OF WHISTLER MODE CHORUS IN THE RADIATION BELTS

Ondrej Santolik, os@ufa.cas.cz

Nagoya University, Chikusaku, Japan Craig Kletzing, craig-kletzing@uiowa.edu

University of Iowa, Iowa City, Iowa, United States

The Van Allen radiation belts are influenced by the presence of whistler-mode waves. Nonlinear wave packets of whistler mode chorus cause pitch-angle or energy diffusion of different energetic electron populations. This process leads to local exchange of energy between the electron populations and, subsequently, to acceleration of energetic electrons or to their precipitation into the Earth's atmosphere. We use measurements onboard two Van Allen Probes to analyze these waves during conjunctions. We also use measurements of the Arase spacecraft at close separations. We investigate correlation of the observed chorus wave packets as a function of the separation vector, while the collected multicomponent measurements allow us to determine detailed polarization and propagation characteristics as a function of time at each spatial point.

D3.2-0027-18 A CENSUS OF KINETIC ELECTRIC FIELD STRUCTURES AND WAVES IN THE INNER MAGNETOSPHERE

David Malaspina, david.malaspina@colorado.edu

LASP / University of Colorado, Boulder, Colorado, United States Xiangning Chu, chuxiangning@gmail.com

LASP / University of Colorado, Boulder, Colorado, United States Aleksandr Ukhorskiy, ukhoray1@outermail.jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, United States

Numerous observations from the Van Allen Probes mission have firmly established that kinetic electric field structures and waves abound in the terrestrial inner magnetosphere. Examples of such structures and waves include: kinetic Alfven waves, electron phase space holes, electron acoustic solitons, and nonlinear whistler-mode waves. These structures and waves can have high amplitudes (100 mV/m), strong electric fields parallel to the background magnetic field, and are ubiquitous at plasma boundaries such as injection fronts, the plasmapause, and the Earthward edge of the plasma sheet. But how important are these structures and waves for inner magnetospheric plasma dynamics? Some theoretical treatments suggest that these waves and structures can exert more influence than chorus or hiss waves for certain particle energies.

Quantifying the importance of these structures and waves is complicated by their non-unique signatures in wave power spectra. High resolution time series electric and magnetic field data is required to uniquely identify such structures and waves as well as to determine their properties (e.g. amplitude, spatial extent).

In this presentation, we describe analysis of long (> 45 min) unbroken intervals of high resolution time series fields data spanning an electron injection event and a crossing of the Earthward plasma sheet boundary. These data enable a census of kinetic electric field structures and waves, including the relative occurrence of various structure and wave types, and their 'typical' properties, determined without reliance on amplitude-triggered fields data.

The results of this census provide insight into generation of kinetic electric field structures and waves in the inner magnetosphere as well as their impact on inner magnetospheric plasma dynamics.

D3.2-0028-18 INNER MAGNETOSPHERE DYNAMICS: SIMULATIONS AND COMPARISONS WITH MULTI-SPACECRAFT OBSERVATIONS

University of Iowa, Iowa City, Iowa, United States

The largest variations in the inner magnetosphere plasma and fields occur during geomagnetic storms and are related to the intensification of the ring current, the magnetically trapped charged particles circling Earth inside of geosynchronous orbit. To investigate ring current development on a global scale, we use our RAM-SCBE model which evolves the H+, O+, and He+ ion and electron distribution functions in the dynamic inner magnetosphere. A distinct feature of RAM-SCBE is the use of self-consistently calculated electric and magnetic fields in balance with the anisotropic ring current ion and electron populations. We simulate the dynamics of the hot (10s of keV) particles injected from the magnetotail into the inner magnetosphere during storms and substorms on both macroand micro-scale. We investigate the effects from 1) non-dipolar magnetic field configuration, 2) plasma wave scattering, and plasma sheet source population considering various boundary conditions and electric field formulations. We compare our results with simultaneous plasma and field observations from the Energetic particle, Composition, and Thermal plasma (ECT) and the Electric and Magnetic Field Instrument Suite and Integrated Science (EMFISIS) investigations on the Van Allen Probes. The precipitating particle fluxes are compared with observations from multiple NOAA satellites. We find that the local acceleration by plasma waves of freshly injected electrons, occurring at the injection boundary, may be significant at energies as low as 50 keV and could strongly impact the ring current and radiation belt flux enhancements. The electron precipitation into the ionosphere increases significantly as well. Implications on the ionospheric conductivity and the highly coupled inner magnetosphere system are discussed.

D3.2-0029-18 AURORAL FRAGMENTATION INTO PATCHES

Kazuo Shiokawa, shiokawa@nagoya-u.jp

Institute for Space-Earth Environmental Research, Nagoya University, Nagoya, Aichi, Japan Katsuki Nishi, k-nishi@stelab.nagoya-u.ac.jp

Nagoya University, Nagoya, Japan

We review our recent progresses on the study of auroral fragmentation into patches using ground-based all-sky imagers and magnetospheric satellites. The auroral fragmentation has been reported by Shiokawa et al. (JGR, 2010; 2014) as finger-like structures developed in the diffuse aurora with horizontal scale sizes of 5-25 km (small scale) and 40-100 km (large scale). The development of these finger-like structures divides the diffuse aurora into patches. Thus we call it as the auroral fragmentation which is a cause of the patchy auroral structures in the diffuse aurora. Hashimoto et al. (JGR, 2015) made a statistical analysis of these auroral finger-like structures and found their occurrence rates of 13% and 4 % for largeand small-scale events, respectively. They also indicated that the finger-like structures tend to occur at the beginning of the substorm recovery phase in the post-midnight and dawn sectors.

The auroral finger-like structure suggests the development of pressure-driven instability in the magnetosphere. Recently Nishi et al. (JGR, 2017) made the first conjugate measurement of the auroral finger-like structures with the THEMIS-E satellite at 8 Re in the magnetosphere. They found clear anti-phase oscillations between the magnetic and plasma pressures in the postmidnight plasma sheet. This anti-phase variation is consistent with the idea of the pressuredriven instability. On the other hand, a conjugate event with the RBSP-A satellite at 5.5 Re does not show systematic phase relationship between the magnetic and plasma pressures. We also investigate statistical features of the phase relationship using two-year THEMIS-E observations in the nightside plasma sheet and obtained a high occurrence of the anti-phase oscillations between the magnetic and plasma pressures.

We try to solve the problem of outer radiation belt formation taking into account the latest results on the auroral oval mapping to the equatorial plane. Such mapping was based on the use of pressure as a natural marker, taking into account that in magnetostatic equilibrium the plasma pressure along a magnetic field line is conserved. We compared the results of the study of plasma pressure distribution at the equatorial plane using data of THEMIS mission and at low altitudes using data of DMSP observations and showed that most part of quiet time auroral oval maps to the surrounding the Earth plasma ring. Transverse currents in the plasma ring close inside the magnetosphere forming a high latitude continuation of the ordinary ring current. We obtained pressure distribution during magnetic storms at low latitudes and at the equatorial plane. We produced the nonlinear modelling of magnetic field distortion by obtained pressure profiles in the ring current region, and showed that distortion of magnetic field by the ring current permits to explain many features of the outer radiation belt electron dropouts and acceleration.

D3.2-0031-18 WAVE ACTIVITY AT A FRONT OF HIGH-BETA EARTH'S BOW SHOCK

Anatoli Petrukovich, apetruko@iki.rssi.ru

Space Research Institute (IKI), Russian Academy of Sciences, Moscow, Russia Olga Chugunova, ch_olga@nln.ru

Space Research Institute (IKI), Russian Academy of Sciences, Moscow, Russia Pavel Shustov, p.shustov@gmail.com

Space Research Institute of the Russian Academy of Sciences (IKI), Moscow, Russia

Earth's bow shock in high plasma β conditions (ratio of thermal to magnetic pressure in solar wind) is relatively rare phenomenon, since mostly solar wind β is about 1. However such a plasma object may be of interest for astrophysics. For example, high β plasma fills galaxy clusters and is observable in X-ray emissions, produced by heated electrons. We survey statistics of high-β shock observations by near-Earth spacecraft since 1995. Typical solar wind conditions are relatively low wind speed, high density and low IMF. The threshold of high β value equal to 10 allows reasonable statistics about 50 crossings. Cases of β more than 20-50 are unique. About 20 Cluster project crossings are available with spacecraft separation within several hundred km and allow estimates of wavelength of dominant plasma oscillations. Two types of mostly quasiperpendicular shocks were found: (1) with dominating coherent 1-2 Hz waves and (2) with dominating irregular 0.1-0.5 Hz waves.

D3.2-0032-18 TESTING EARTH'S BOW SHOCK MODELS

Thamer Alrefay, talrefay@kacst.edu.sa

King Abdulaziz City for Science and Technology, KACST, Riyadh, Saudi Arabia

Space plasma studies of bow shock dynamics, given the fundamental transport role and impact of natural transition boundaries, have continued to attract much interest. Using the overwhelming availability of data collected by various space science missions, several empirical models have been put forward to account for the location of the Earth's bow shock. Various solar wind and IMF parameters are used to constrain the proposed models published in the literature. For each of these empirical models, the bow shock nose velocity, at the standoff distance, is computed; each of these velocities is then compared with the observed shock speed, as determined from a multipoint present study reveals to what extent the commonly-used model parameters measurement provided by the Cluster quartet and MMS spacecraft. meters are significant and determinant, and suggests that some empirical models are more accurate than others.

D3.2-0033-18 ANISOTROPIC TURBULENCE IN THE MAGNETOSHEATH BASED ON THEMIS OBSERVATIONS

Turbulence is a complex phenomenon with driving mechanisms still not clearly understood. Such a behavior appears naturally in space plasmas, including the solar wind, also in the magnetosheath where the flow of the solar wind plasma is slowed down by the bow shock surrounding the Earth's magnetosphere. It is expected that turbulence is intermittent in the magnetosheath, but the level of intermittency somewhat differs depending on the direction of the local magnetic field. Using the wealth of data acquired from the THEMIS mission, we have recently obtained evidence for the anisotropy of intermittent turbulence in the magnetosheath (Macek et al. 2017). In particular, we have shown that for some cases of very strong shocks and very high plasma beta, which is the ratio of the thermal pressure to the pressure of the magnetic field, the fluctuations of parameters of the magnetized plasma exhibit substantial deviations from normal probability distributions, with a large kurtosis, in the directions transverse to the ambient magnetic field. On the other hand, along the local magnetic field the kurtosis is small, the plasma can be approximately described by normal distributions and is hence close to equilibrium. A similar behavior is observed in the case of the weaker shocks, provided that the thermal and magnetic pressures are comparable. However, behind the shocks of somewhat moderate strengths and plasma beta, turbulence seems to be also non-gyrotropic. Here we will present a more detailed analysis of intermittent anisotropic turbulence in the entire magnetosheath as a function of the shock characteristics, taking into consideration the Alfvén and magnetosonic Mach numbers and the plasma beta. We hope that these results could potentially be important for the development of theory of turbulence.

Max Planck Institut für Sonnensystemforschung, Göttingen, Germany

Here we want to present a new hybrid code CHIEF (Code Hybrid with Inertial Electron Fluid) that we have recently implemented. It combines an existing, well tested electronmagnetohydrodynamic (EMHD) code with an existing, well tested, state-of-the-art particle in cell (PiC) code. It simulates arbitrary kinetic ion species using a semi-lagrangian approach and describes the electrons as an inertial fluid. The fluid description uses no approximations for the electron contributions other than an equation of state relating electron pressure and temperature. Effects due to electron inertia or changes in ion flow speed or density in space and time are not neglected as in many other existing hybrid codes. Electromagnetic fields are calculated in the radiation-free limit which allows time steps that are sufficiently long to study effects on ion time scales even for heavy ions. The code has been successfully tested on a large number of test problems involving linear and non-linear plasma waves as well as instabilities that are driven by non-equilibrium ion velocity distributions. The code is particularly suited for the study of collisionless shocks – especially the acceleration of heavy ions which is computationally expensive in PiC codes – as well as collisionless magnetic reconnection and kinetic turbulence on scales above the electron dissipation range.

D3.2-0035-18 MHD SIMULATION OF THE FLUX TRANSFER EVENTS ON THE DAYSIDE MAGNETOPAUSE

Tianran Sun, trsun@spaceweather.ac.cn

National Space Science Center, Chinese Academy of Sciences, Beijing, China Chi Wang, cw@spaceweather.ac.cn

National Space Science Center, Chinese Academy of Sciences, Beijing, China

Flux transfer event (FTE) is a transient phenomenon occurring on the magnetopause caused by magnetic reconnection. By running the global MHD simulation code under different interplanetary magnetic field clock angles, we compared the FTEs in these simulation cases. It is revealed that the large scale characteristics of FTEs have apparent distinctions for different IMF clock angles. Further investigation shows that these distinctions are closely related to the dayside reconnections under different solar wind conditions.

Solar wind Magnetosphere Ionosphere Link Explorer (SMILE) is a novel self-standing mission, being designed in collaboration between ESA and the Chinese Academy of Science. Its objective is to observe solar wind-magnetosphere coupling via simultaneous in situ solar wind/magnetosheath plasma and magnetic field measurements, soft X-Ray images of the magnetosheath and polar cusps, and UV images of global auroral distributions. The observations of the cusps and magnetosheath with the X-ray imager are possible thanks to the relatively recent discovery of solar wind charge exchange (SWCX) X-ray emissions, first at comets and subsequently in the vicinity of the Earth's magnetosphere. To prepare for the mission, we must determine the expected morphology, motion, and in situ properties of the plasma (density, velocity, temperature) within the cusp and its associated structures (e.g., diamagnetic cavities). We have selected a series of Cluster cusp crossings that define these properties and can therefore be used to estimate X-ray emissions across the width of the cusp for different IMF orientations. We will show that the peak soft X-ray emissions occur near the centre of the cusp where ion densities maximize. We then show that the integral lines of sight emissions through the cusp are a factor of 2.4 times larger for IMF-Bz northward than for IMF-Bz southward. The mid-altitude cusp is a factor of 7 brighter than the exterior cusp. We will compare these observations with an MHD model.

The Earth's magnetospheric dynamics in response to changes of the solar wind (SW) and interplanetary magnetic field (IMF) conditions during magnetic storms and substorms is the result of both externally driven and internal processes that can be investigated via a set of geomagnetic indices (AE, AU, AL, AO, Dst, Sym-H). As a consequence of the solar wind-magnetosphere interaction, these indices display both regular and irregular variations/fluctuations on a very wide interval of timescales, ranging from a few tens of minutes up to two hundreds minutes, which are connected to the direct-driven and loading-unloading processes. All these features have been interpreted as evidences of a far-from-equilibrium nonlinear dynamics near a critical state. An important consequence of this nonlinear and near-critical-state dynamics of the Earth's magnetosphere is that there is not a one-to-one correspondence between the SW/IMF condition changes and those of the magnetospheric current systems as monitored by geomagnetic indices. In other words, the dynamics of the magnetospheric currents and of the overall magnetosphere, although triggered by the variation of the interplanetary conditions, is strongly affected by the internal conditions. This is exactly what has been understood since the early works on the nonlinear and pseudochaotic dynamics of the Earth's magnetosphere.

In this work, we present a detailed study of the timescale coupling between solar wind changes and the magnetospheric response in the course of two geomagnetic storms occurred in 2013 and 2015. To investigate the range of the coupled timescales we use the Empirical Mode Decomposition (EMD), which is particularly suitable for the analysis of nonlinear and nonstationary time series, and the Delayed Mutual Information (DMI), which is capable of providing a measure of the total linear and nonlinear correlation. Our findings support the common idea that the Earth's magnetosphere response consists of both directly driven and internal processes, where the internal processes instead of being driven have to be considered more reasonably to be triggered by external solar wind changes. Furthermore, there is a clear separation of timescales between the internal processes and the directly driven one, being the characteristic separation timescale of the order of 100-200 min.

D3.2-0038-18 SINGLE-SPACECRAFT METHOD FOR DETERMINING WAVEVECTOR K

Paul Bellan, pbellan@caltech.edu

California Institute of Technology, Pasadena, California, United States

A practical method is presented for determining the wavevector of a low frequency plasma wave using measurements from only a single-spacecraft. The method is described in detail in Ref.

and successful implementation using MMS spacecraft data is reported in Ref. [2].

The wavevector obtained by this method can then be used to remove the space-time ambiguity produced by frequency Doppler shift associated with spacecraft motion.

The method involves applying the Wiener-Khinchin theorem to cross-correlations of the current and magnetic field oscillations and to auto-correlations of the magnetic field oscillations. The method requires that each wave frequency component map to a unique wavevector, a situation presumed true in many spacecraft measurement situations and also implicitly required by multispacecraft methods.

D3.2-0039-18 PARTICLE AND FIELD DYNAMICS IN DIFFERENT SCALE OF MAGNETIC HOLES AND PEAKS

Quanqi Shi, sqq@pku.edu.cn

Shandong University at Weihai, Weihai, China Et Al., sqq@sdu.edu.cn

China

Different scale of magnetic structures (e.g. magnetic holes and peaks) are investigated in this study with the use of MMS and THEMIS spacecraft in the turbulent terrestrial magnetosheath, sheath boundary layer and the magnetotail. The plasma parameters, wave activities, geometrical characteristics, current systems and propagation features will be present, and test particle simulations are carried out to study the electron distribution functions in different cases and several new features have been revealed, implying that these magnetic structures may play some important roles in plasma instabilities, energy dissipation and energy conversion.

D3.2-0040-18 THE WEATHER IN THE INNER MAGNETOSPHERE: A CHANCE OF ELECTRON PRECIPITATION OUTSIDE OF THE PLASMASPHERE.

Alexa Halford, alexa.j.halford@aero.org

The Aerospace Corporation, Chantilly, Virginia, United States Joseph Mazur, joseph.mazur@aero.org

The Aerospace Corporation, Chantilly, United States David Malaspina, david.malaspina@colorado.edu

LASP / University of Colorado, Boulder, Colorado, United States Timothy Guild, timothy.guild@aero.org

The Aerospace Corporation, Chantilly, Virginia, United States Paul O'Brien, paul.obrien@aero.org

The Aerospace Corporation, Houson, Texas, United States

One of the exciting and long outstanding questions in the field of magnetospheric physics is to understand to the point of predictability, the dynamics of the radiation belts. Until recently, much of the knowledge gained about the radiation belts came from single point measurements. Recently, there have been multiple missions which have allowed for multipoint measurements to be used to better understand the daily dynamics. In this study we will focus on the 30 keV to MeV electron population lost to the atmosphere and observed in LEO orbits. The loss of these electrons to the atmosphere is often thought to be due to specific wave -particle interactions which have specific MLT and L dependencies. Recent work has shown that the location of two of the wave types, chorus and hiss which are expected to have a large impact on these electrons, is determined in part by the boundary of the plasmasphere. Specifically, there is a null in observed wave power of either hiss or chorus right at the plasmapause. Thus, we expect that the particle populations which interact with these waves would also follow this trend.

In this presentation we will use data from the Balloon Array for Radiation belt Relativistic Electron Loss (BARREL) to infer the loss of radiation belt electrons. The BARREL mission had a total of 40 launches during two Antarctic Campaigns, with an additional 15 launches during the August turnaround seasons of 2015 and 2016 in Kiruna Sweden. We will focus on the Antarctic campaigns which took advantage of the circumpolar winds allowing for on average an array of 6 payloads aloft and distributed in L and MLT at any given time. This work will be supplemented by using LEO observations allowing for higher temporal and spatial resolution of how the radiation belt particle populations respond to the weather of the inner magnetosphere

D3.2-0042-18 NUMERICAL STUDY ON THE DOPPLER EFFECT OF THE LOW EARTH ORBIT OBSERVATIONS

Jiwon Choi, jw.choi@khu.ac.kr

Kyung Hee University, Yongin-si, Korea Dong-Hun Lee, dhlee@khu.ac.kr

Kyung Hee University, Yongin, Korea

Geomagnetic ultra-low frequency (ULF) wave is one of the major energy transport mechanisms in the Earth's magnetosphere. Multi point satellite measurements have advanced our knowledge on the wave characteristics in the magnetosphere. However, in the ionosphere, spacecraft traverses different L-shells with considerably high speed, which results in the distortion of observed wave signals. We conduct three dimensional MHD wave simulations to investigate the Doppler effect of the ULF waves observed by low Earth orbit (LEO) satellites. A number of virtual spacecraft are imbedded in our model, which function as fast-moving observers in LEO. Our results show that transverse electric and magnetic field components exhibit latitude dependence in the arrival time and waveform, which is manifested when observed by fastmoving satellites. On the other hand, compressional components are insensitive to the latitude or the motion of the spacecraft. It is suggested that the Doppler effect of the LEO satellite observations can cause distinct discrepancies between ground-based and satellite measurements.

SPACE PLASMAS IN THE SOLAR SYSTEM, INCLUDING PLANETARY MAGNETOSPHERES (D)

ROLE OF NONTHERMAL DISTRIBUTIONS IN WAVE GENERATION, PARTICLE HEATING AND ACCELERATION IN SPACE PLASMAS (D3.3)

D3.3-0001-18 THE ROLE OF NON-THERMAL ELECTRON DISTRIBUTIONS IN SOLAR WIND ACCELERATION PROCESSES

Viviane Pierrard, viviane.pierrard@oma.be

Royal Belgian Institute for Space Aeronomy, Brussels, Belgium

Velocity distribution functions of plasma particles measured by spacecraft in the solar wind and many other space plasmas show enhanced suprathermal tails. Such distributions can be fitted by different velocity distribution functions such as a sum of two Maxwellians with different temperatures or, better, with Kappa distributions decreasing as a power law of the velocity. The presence of nonthermal populations in space plasmas, and in particular in the solar wind, has important consequences concerning particle acceleration and plasma heating. These effects are well described by the kinetic approach using non thermal distributions. A kinetic model of the solar wind has been developed and allows us to test the effects of enhanced populations of suprathermal electrons. We also show the evolution of the suprathermal particles with the radial distance as observed by different spacecraft and how wave-particle interactions can explain the main observed features.

D3.3-0002-18 SOLITONS AND SUPERSOLITONS IN MAGNETIZED PLASMAS WITH NONTHERMAL PARTICLE DISTRIBUTIONS

Manfred Hellberg, hellberg@ukzn.ac.za

University of KwaZulu-Natal, Durban, South Africa Frank Verheest, frank.verheest@ugent.be Universiteit Gent, Gent, Belgium

We present a brief overview of fully nonlinear, Sagdeev pseudopotential based investigations of solitons and related phenomena in magnetized fluid plasmas. We shall deal mainly with ion-acoustic structures, but also consider aspects of electron-acoustic solitons. Studies based on nonthermal velocity distributions such as the kappa and Cairns distributions will be discussed and compared. Care will be taken to point out limitations of the models, as a result of approximations underpinning the calculations. Finally, we shall draw attention to recent research that questions the existence of supersolitons in such models, because of the apparent presence of an inherent singularity in the pseudopotential.

D3.3-0003-18 SPECTROSCOPIC MEASUREMENTS OF THE ION VELOCITY DISTRIBUTION AT THE BASE OF THE FAST SOLAR WIND

Natasha Jeffrey, natasha.jeffrey@glasgow.ac.uk University of Glasgow, Glasgow, United Kingdom Michael Hahn, mhahn@astro.columbia.edu

Columbia University, New York City, New York, United States Daniel W. Savin, savin@astro.columbia.edu

Columbia University, New York City, New York, United States Lyndsay Fletcher, lyndsay.fletcher@glasgow.ac.uk

University of Glasgow, Glasgow, United Kingdom

In situ measurements of the fast solar wind reveal non-thermal distributions of electrons, protons and, minor ions extending from 0.3 AU to the heliopause. The physical mechanisms responsible for these non-thermal properties and the location where these properties originate remain open questions. Here we present spectroscopic evidence, from extreme ultraviolet spectroscopy, that the velocity distribution functions (VDFs) of minor ions are already non-Gaussian at the base of the fast solar wind in a coronal hole, at altitudes of < 1.1R0. Analysis of Fe, Si, and Mg spectral lines reveal a peaked line-shape core and broad wings that can be characteristed by a kappa VDF. A kappa distribution fit gives very small kappa indices off-limb of κ 1.9 2.5, indicating either (a) ion populations far from thermal equilibrium, (b) fluid motions such as non-Gaussian turbulent fluctuations or non-uniform wave motions, or (c) some combination of both. These observations provide important empirical constraints for the source region of the fast solar wind and for the theoretical models of the different acceleration, heating, and energy deposition processes therein. To the best of our knowledge, this is the first time that the ion VDF in the fast solar wind has been probed so close to its source region. The findings are also a timely precursor to the upcoming 2018 launch of the Parker Solar Probe, which will provide the closest in situ measurements of the solar wind at approximately 0.04 AU (8.5 solar radii).

D3.3-0004-18 WAVES AND INSTABILITIES IN SPACE PLASMAS MODELLED WITH KAPPA VELOCITY DISTRIBUTIONS

Richard Mace, macer@ukzn.ac.za

University of KwaZulu-Natal, Durban, South Africa

The primary advantage of the kinetic theory of waves based on the kappa velocity distribution is that it usually provides a more accurate statistical representation of collisionless space plasma environments than those based on Maxwellian types. Use of a kappa distribution model does not alter any microphysical processes, but it does change their probabilities of occurrence, which in turn affects important average quantities such as instability growth and wave damping rates. Additionally, dispersion relations can show features distinguishable from their Maxwellian counterparts, providing valuable signatures for out-of-equilibrium plasma behaviour.

A disadvantage of the approach, however, is that the mathematics arising from the use of kappa distributions is less familiar and often more complicated than that arising from the Maxwellian framework. It is perhaps because of the increased mathematical complexity that, in contrast to the Maxwellian case, the theories of wave propagation parallel and perpendicular to the magnetic field in plasmas with kappa distributions have developed separately, with no mathematically tractable theory of oblique propagation to connect them. The mathematics of each, while originating with the same linearised Vlasov-Maxwell system of equations, takes on quite a different form in each case.

This talk attempts to present a more unified approach to the problem of waves and instabilities in space plasmas modelled with kappa distributions. After briefly reviewing the traditional theoretical framework for kinetic studies of plasma waves, a modified approach that favours a more consistent treatment of the special cases of parallel and perpendicular propagation is suggested. Salient results from some of the investigations of waves and instabilities in plasmas modelled with kappa distributions carried out by the author and collaborators are discussed. Amongst others, these include studies of the whistler and EMIC instabilities driven by thermal anisotropy, as well as perpendicularly propagating electron and ion Bernstein waves. Finally, some recent results of 1D and 2D simulations of oblique waves in plasmas having a kappa distribution will be presented.

D3.3-0005-18 A MODEL FOR WEAK DOUBLE LAYERS AND COHERENT LOW-FREQUENCY ELECTROSTATIC WAVES IN THE SOLAR WIND

Gurbax Singh Lakhina, gslakhina@gmail.com

Indian Institute of Geomagnetism, Navi Mumbai, India Satyavir Singh, satyavir@iigs.iigm.res.in

Indian Institute of Geomagnetism, Navi Mumbai, India

A model based on ion-acoustic solitons and double layers is proposed for the weak double layers and coherent low-frequency electrostatic waves observed by Wind spacecraft in the solar wind at 1 AU. The model considers the solar wind plasma to consist of fluid hot protons, hot alpha particles streaming with respect to protons,and suprathermal electrons having kappadistribution. This plasma system supports two types of, slow and fast, ion-acoustic solitary waves. The fast ion-acoustic mode is similar to the ion-acoustic mode of proton-electron plasma, and can support only positive potential solitons. The slow ion-acoustic mode is a new mode that occurs due to the presence of alpha particles. This mode can support both positive and negative solitons and double layers. An increase of the kappaindex leads to an increase in the critical Mach number, maximum Mach number and the maximum amplitude of both slow and fast ion-acoustic solitons. The slow ion-acoustic double layer can explain the amplitudes and widths,but not shapes, of the weak double layers (WDLs) observed in the solar wind at 1 AU by Wind spacecraft.The Fourier transform of the slow ion-acoustic solitons/double layers would produce broadband low-frequency electrostatic waves having main peaks between 0.35 kHz to 1.6 kHz, with electric field in the range of E= (0.01 - 0.7) mV/m, in excellent agreement with the observed properties of the low-frequency electrostatic waves in the solar wind at 1 AU.

D3.3-0006-18 KINETIC SIMULATION OF SLOW MAGNETOSONIC WAVES AND QUASIPERIODIC UPFLOWS IN THE SOLAR CORONA

Jiansen He, jshept@pku.edu.cn Peking University, Beijing, China Wenzhi Ruan, 332480998@qq.com Peking University, Beijing, China Christian Vocks, cvocks@aip.de

Max-Plank-Institute for Solar System Research, Göttingen, Germany Linghua Wang, wanglhwang@gmail.com

Peking University, Beijing, China

Quasi-periodic disturbances of emission-line parameters are frequently observed in the corona. These disturbances propagate upward along the magnetic field with speeds of 100 km/s. This phenomenon has been interpreted as evidence of the propagation of slow magnetosonic waves or has been argued to be a signature of intermittent outflows superposed on the background plasmas. Here we aim to present a new "wave + flow" model to interpret these observations. In our scenario, the oscillatory motion is a slow-mode wave, and the flow is associated with a beam created by the wave-particle interaction owing to Landau resonance. With the help of a kinetic model, we simulate the propagation of slow-mode waves and the generation of beam flows. We find that weak periodic beam flows can be generated by to Landau resonance in the solar corona, and the phase with the strongest blueward asymmetry is ahead of that with the strongest blueshift by about 1/4 period. We also find that the slow wave damps to the level of 1/e after the transit time of two wave periods, owing to Landau damping and Coulomb collisions in our simulation. This damping timescale is similar to that resulting from thermal conduction in the MHD regime. The beam flow is weakened/attenuated with increasing wave period and decreasing wave amplitude since Coulomb collisions become more and more dominant over the wave action. We suggest that this "wave + flow" kinetic model provides an alternative explanation for the observed quasi-periodic propagating perturbations in various parameters in the solar corona.

D3.3-0007-18 MULTI-YEAR MEASUREMENTS OF RADIATION BELT ELECTRONS: ACCELERATION, TRANSPORT, AND LOSS

Daniel N. Baker, daniel.baker@lasp.colorado.edu

LASP / University of Colorado, Boulder, Colorado, United States

Extended studies of Van Allen Probes data show that "source" electrons (in a typical energy range of one to a few tens of keV energy) produced by magnetospheric substorms play a crucial role in amplifying the chorus waves in the magnetosphere. It is repeatedly observed that these chorus waves then rapidly heat and accelerate the tens to hundreds of keV seed electrons that are injected by substorms into the outer Van Allen zone. Thus, we often see that geomagnetic activity driven by strong solar storms (coronal mass ejections, or CMEs) almost inexorably leads to ultra-relativistic electron production through the intermediary step of intense magnetospheric substorms. In this presentation, we report observations of some of the largest geomagnetic storms of the last several years. Distinctive events that have had significant ring current development are discussed. We focus on storms that produced dramatic effects on the relativistic and ultra-relativistic electrons measured by the Relativistic Electron-Proton Telescope (REPT) sensors on board the Van Allen Probes spacecraft. This work describes the radiation belt acceleration, transport, and loss characteristics of these intense geomagnetic events. We emphasize features seen repeatedly in the data (3-belt structures, "impenetrable" barrier properties, radial diffusion signatures) in the context of acceleration and loss mechanisms. We especially highlight solar wind forcing of the ultra-relativistic (E 5 MeV) electron populations. We present pitch angle resolved data and energy-spectral analyses for key events. The presentation also includes animated segments portraying the mission-long time variability of the outer Van Allen belt emphasizing the remarkable dynamics of the system.

D3.3-0008-18 ON FORMATION OF ELECTRON KAPPA DISTRIBUTION FUNCTIONS

Peter Yoon, yoonp@umd.edu

University of Maryland, College Park, College Park, Maryland, United States

The solar wind electron distribution function is known to be composed of several components; the Maxwellian core, hot quasi isotropic halo, sometimes highly field-aligned strahl propagating in anti sunward direction, and highly energetic inverse power-law isotropic superhalo population. The highly energetic superhalo tail population is particularly well fitted with kappa distribution function. The present author developed a theory of a system of electrons and Langmuir turbulence that are in dynamical steady-state. In such a model, the kappa distribution function for the electrons emerges as a unique solution of the steady-state weak turbulence plasma kinetic equation. In view of the fact that the turbulent quasi equilibrium for Langmuir wave fluctuation and electron kappa distribution are derived in time asymptotic steady state, the question of whether finite collisionality may play a role for such a long time evolutionary state. Recently, a combined collisional and weakly turbulent collective theory is developed by the present author where collisional processes and wave turbulence is discussed within the rigorous framework. Making use of such a theory the generation process of electron kappa distribution is re-examined and it is shown that the Maxwellian core plus quasi inverse power law tail electron distribution may form at the corona base where the plasma is characterized by high collisionality. As the core-halo type of electron distribution travels outward the Langmuir turbulence process operates in order to maintain the core-halo-superhalo structure all the way to 1 AU.

Kappa functions describe particle distributions for the systems that are in stationary state but out of thermal equilibrium. The form of the kappa distribution consists of a Maxwellian core at low energies and a power law spectrum at high energies. Simultaneous determination of the parameters of kappa distributions in different space regions is important for understanding the role of different processes of particle acceleration and relaxation of kappa distribution functions to the Maxwellian ones. We study kappa distributions in different magnetospheric regions and magnetosheath, using the data of the Time History of Events and Macroscale Interactions during Substorms (THEMIS) mission. Problems of obtaining kappa approximations are connected with different sensitivity of devices measured particle fluxes in different energy ranges and pitch angles. Another difficulty is connected with frequently observed mixtures of plasmas of different origins. It was found, that in the regions, where distribution functions are formed due to mixing of two plasma populations, they can be described using bi-kappa distributions. Such feature permits to select the contribution of every plasma population in the whole one. We show that analyzing the space distribution of k-parameter it is possible to determine the location of the region of acceleration for a specific particle population. We try to evaluate the characteristic times of distribution function relaxation by analyzing measurements during different phases of auroral substorm.

D3.3-0010-18 ROLE OF KAPPA PARTICLE DISTRIBUTIONS IN GENERATING WHISTLERMODE WAVES IN SPACE PLASMAS

Danny Summers, dsummers@mun.ca

Memorial University of Newfoundland, St John's, Canada

Kappa particle distributions possess a high-energy power-law tail characterized by a spectral index kappa. Here we consider the role of both the bi-kappa and kappa-loss-cone distributions in the generation of whistler-mode waves in geospace plasmas. Comparisons between the whistler-mode wave linear growth rates corresponding to the bi-kappa and bi-Maxwellian distributions depend on the thermal anisotropy A. For anisotropies less than a critical value,the bi-kappa linear growth rate (for kappa = 2) dominates the bi-Maxwellian growth rate; for anisotropies greater than the critical value the opposite applies. Similar comparisons of the linear growth rates corresponding to the kappa-loss-cone distribution depend also on the losscone index. With respect to the threshold wave amplitude for nonlinear growth,comparisons between the bi-kappa and bi-Maxwellian distributions depend on both the anisotropy A and the wave frequency. For low anisotropy,we find that threshold wave amplitudes for the bi-kappa distribution can be much less than those for the bi-Maxwellian distribution. Similar conclusions regarding the threshold wave amplitudes corresponding to the kappa-loss-cone distribution also hold. Finally,we determine wave generation regions in (A,n)-parameter space, where n is the hot(energetic) electron number density. We find that such generation regions also depend crucially on the electron thermal momentum. For instance,for lower values of the electron thermal momentum,the extent of the wave generation region corresponding to the bi-kappa distribution exceeds that for the bi-Maxwellian distribution;for higher values of the electron thermal momentum,the reverse is true. Overall,we conclude that kappa distributions can significantly enhance whistler-mode wave generation in geospace plasmas,dependent on the values of the system parameters.

D3.3-0011-18 ELECTROSTATIC SOLITARY WAVES IN THE LUNAR WAKE PLASMA

Satyavir Singh, satyavir@iigs.iigm.res.in

Indian Institute of Geomagnetism, Navi Mumbai, India

R. Rubia, rubi.r92@gmail.com India

Gurbax Singh Lakhina, gslakhina@gmail.com

Indian Institute of Geomagnetism, Navi Mumbai, India

Electrostatic waves have been observed in the lunar wake during the first flyby of the Acceleration, Reconnection, Turbulence and Electrodynamics of Moon's Interaction with Sun (ARTEMIS) mission on 13 February 2010 [1]. An alternative mechanism for the evolution of these electrostatic waves in terms of slow and fast ion-acoustic and electron-acoustic solitons is proposed. The lunar wake is modelled by a four-component plasma system comprising of hot protons, hot heavier (He++) ions, electron beam and suprathermal electrons having a kappa distribution. Three modes, viz., slow and fast ion-acoustic modes and electron-acoustic modes exist. As all three modes exists simultaneously, the electric fields associated with all three modes taken together varies in the range (0.003-17) mV m-1 which matches perfectly with the observed electric field (5-15) mV m-1. The velocities of the solitons varying in the range (30-1300) km s-1 matches with the estimated phase velocities of the order 1000 km s-1. The Fast Fourier transform (FFT) of the soliton electric fields results in broadband spectra hav- ing peak frequencies in the range of (3-1800)Hz which corresponds to (0.001-0.56) fp that matches with the observed frequencies of (0.01-0.4) fpe, fpe is the electron plasma frequency (fpe= 3237.78 Hz).The theoretical plasma model very well explains the observed electrostatic waves in the lunar wake.

D3.3-0012-18 SOLITONS, DOUBLE LAYERS AND ROGUE WAVES IN PLASMAS WITH SUPERTHERMAL CHARGED PARTICLES

Nareshpal Singh Saini, nssaini@yahoo.com

Guru Nanak Dev University, Amritsar, India, Amritsar, India

Most of the space and astrophysical plasmas contain different types of charged particles with non-Maxwellian velocity distributions (e.g., nonthermal, superthermal, Tsallis). These distributions are commonly found in the auroral region of the Earth's magnetosphere, planetary magnetosphere, solar and stellar coronas, solar wind, etc. The observations from various satellite missions have confirmed the presence of superthermal particles in space and astrophysical environments. Over the last many years, there have been a much interest in studying the different kind of properties of the electrostatic nonlinear excitations (solitons, double layers, shocks, rogue waves etc.) in a multi-component plasmas in the presence of superthermal particles. It has been analyzed that superthermal distributions are more appropriate than Maxwellian distribution for the modeling of space data. It is interesting to study the dynamics of various kinds of solitary waves, Double layers, Shocks etc. in varieties of plasma systems containing different kind of species obeying Lorentzian (kappa-type)/Tsallis distribution. Talk has been focused on the study of large amplitude solitary structures (bipolar solitary structures, double layers etc.), modulational instability and rogue waves in multi-component plasmas. The Sagdeev pseudo-potential method has been employed to setup an energy balance equation, from which we have studied the characteristics of large amplitude solitary waves under the influence of superthermality of charged particles and other plasma parameters. The critical Mach number has been determined, above which solitary structures are observed and its variation with superthermality of electrons and other parameters has also been discussed. Double layers have also been discussed. Multiple scale reductive perturbation method has been employed to derive NLS equation. From the different kind of solutions of this equation, amplitude modulation of envelope solitons and rogue waves have been studied. It has been observed that various plasma parameters significantly influence the characteristics of different kinds of nonlinear structures. These findings may be of great importance to understand the underlying physics of different phenomena occurring in space and astrophysical environments.

D3.3-0013-18 SOLAR WIND DRIVEN WHISTLER INSTABILITY IN EARTH'S CUSP REGION

Muhammad Nouman Sarwar Qureshi, nouman_sarwar25@hotmail.com GC University, Lahore, Pakistan

One of the fundamental questions in space plasmas still not fully understood is how the energy is transported from solar wind to the Earth's magnetosphere. In the present study, we observe electron velocity distribution (EVD) functions in the Earth's magnetosphere using the CLUSTER data. The EVD functions are observed at different times, when the CLUSTER traversing the southern cusp region on 21-10-2001, such as when the electron density is very low typical of cusp values and when it suddenly increases due to some solar wind disturbances at the magnetopause. We found that the observed EVD functions are flat top distributions and have two populations; a cold bulk magnetospheric population and a hot solar wind tenuous population. Observed EVD functions are then fitted by generalized (r,q) distribution which is the generalized form of kappa and Maxwellian distribution functions and can be reduced to kappa and Maxwellian distributions in the limiting forms r=0,q=+1 and r=0,q→, respectively [Qureshi et al., 2004; 2014]. We derive the expressions of real frequency and damping/growth rates by employing generalized (r,q) distribution function and plot them using the observed plasma parameters and fitting values of spectral indices r and q. We found that during the time of increased density these shocked solar wind electrons have the same flat top distribution consisting of one population as earlier observed by various satellites downstream the Earth's bow shock. When such hot solar wind electrons with flat top distribution enter into the Earth's magnetosphere, we obtain growth causing the Whistler waves to grow and hence responsible for the transport of energy from solar wind to the magnetosphere.

D3.3-0014-18 MULTI-SPACECRAFT OBSERVATIONS OF WHISTLER-MODE WAVE-PARTICLE INTERACTIONS: TEMPORAL OR SPATIAL STRUCTURES?

James Roeder, james.roeder@aero.org

The Aerospace Corporation, Los Angeles, California, United States Joseph Fennell, joseph.f.fennell@aero.org

Wave-particle interactions that generate whistler-mode chorus emissions and modify energetic electron distributions are thought of as highly localized phenomena in both space and time. We will use data from the two satellite Van Allen Probe constellation to investigate such events. Individual chorus elements have very short time durations and interaction regions that span small distances at the magnetic equator. Recent observations by the Van Allen Probes satellites imply in contrast that the interactions sometimes form relatively long-lived signatures in both electrons and waves that drift past the satellites. Fennell et al. [GRL, 2014] described an event with upper-band chorus emissions that correlated well with simultaneously measured bursts of electron flux at 30 keV in narrow ranges of pitch angle. Both satellites, separated by 0.3 hours in the morning local time sector near L 6, observed similar quasiperiodic trains of correlated flux bursts and waves. Detailed comparison of the data from the two spacecraft shows that the sequence of wave and particle pulses match almost exactly if Probe A is shifted in time by two minutes relative to Probe B. This implies that the interactions produced a set of spatial structures that drifted from one satellite to the other at a speed of 25 km/s. The result is consistent with the idea of both waves and electrons propagating and being observed at distant locations. But the high correlation of waves and electrons at near-zero delay time at both locations is surprising since the waves and electrons nominally travel at different speeds. Several additional wave-particle interaction events observed by both Van Allen Probes are analyzed to provide additional information on the spatial scale size and propagation speed of wave emissions and particle features.

D3.3-0015-18 BGK ELECTRON HOLES IN NONTHERMAL SPACE PLASMAS

Bernstein, Greene, and Kruskal (BGK) have developed the theory for one-dimensional stationary nonlinear electrostatic waves in the Vlasov-Poisson framework of equations. Under the influence of electric potential, the theory gives localized BGK solutions characterized by a trapped population of electrons moving with the electron-hole (EH). Such structures are often detected by spacecrafts as a series of coherent bipolar electric field structures. In modeling these observed structures, most of the studies assume the space plasma in thermal equilibrium, described by the Maxwell distribution. However, several spacecraft observations reveal that the plasmas in space cannot be assumed to be in thermal equilibrium; instead, these plasmas are nonthermal and are best-modeled using generalized kappa distribution. Hence, the BGK theory for nonthermal plasma is an essential component to model EHs in space plasmas. We develop a first-ever one-dimensional model of EHs in nonthermal plasma keeping ions stationary in the electrostatic limit. We have derived the analytical expression for trapped electron density and distribution function of trapped electrons. We find a significant difference in the trapped electron density and distribution function. We find that the nonthermal plasma is more prone to trapping and as a result, the distribution function in nonthermal plasma found steeper and denser than the trapped distribution in thermal plasma. EHs formed in a nonthermal plasma are found to have a smaller size than the EHs formed in thermal plasma for same perturbation. The width and amplitude of perturbation play an important role in the development of stable EHs and deciding their characteristics. The analytical expression for width - amplitude inequality relation that decides the stability of EHs has been derived. We have observed that the parametric regime of amplitude and width of potential that supports stable BGK EH solutions in nonthermal plasma is less than that of weakly nonthermal plasma. We have applied the newly developed model to EHs observed by the FAST satellite, which operates in the auroral region where the nonthermal population dominant. bf

D3.3-0016-18 FLUID SIMULATION OF COHERENT ELECTRIC FIELD STRUCTURES IN THERMAL AND NON-THERMAL SPACE PLASMAS

Ajay Lotekar, ablotekar@gmail.com

Indian Institute of Geomagnetism, Navi Mumbai, India Amar Kakad, amar@iigs.iigm.res.in

Indian Institute of Geomagnetism, NAVI MUMBAI, India Bharati Kakad, bkakad9@gmail.com

Indian Institute of Geomagnetism, Panvel, India

The Earth's or any other planetary magnetospheres are rich in the variety of plasma wave processes. Numerous computer simulation codes are available in the literature to model these wave processes in thermal plasmas. In most of these model simulations, the plasma is considered to be in thermal equilibrium i.e. Maxwellian distributed plasmas. However, it is now well known that the space plasmas frequently contain particle components that exhibit high or superthermal energy tails with approximate power law distributions in velocity space. Such nonthermal distributions, with overabundances of fast particles can be better fitted for superthermal velocities by kappa distributions, than by Maxwellians or one of their variants. We developed a generalized one-dimensional multi-fluid code to study the plasma wave processes in thermal and nonthermal space plasmas. In this code, different species in the plasma can be represented with either fluid or non-thermal distribution. As an application of this code, we discussed a generation mechanism of the coherent electric field structures observed in the Earth's magnetosphere.

The solar wind can be considered as a collisionless turbulent magnetized plasma. Its low collisionality suggests that the kinetic approach would be more appropriate for a description of the turbulence properties than the fluid equations. Nevertheless, observations of velocity and magnetic field variations in the mHz range revealed a qualitative consistency of their behavior with MHD wave modes. It was shown that a compressive component of these fluctuations is rather minor and pressure balanced, whereas the Alfvenic component dominates. Since these features would be scale-dependent, the present contribution analyzes variations of the solar wind velocity that are computed from the Faraday cups of the Bright Monitor of the Solar Wind on board the Spektr-R spacecraft with a time resolution of 32 ms in the frequency range of 0.001-2 Hz. These observations are complemented with the 10 Hz Wind magnetic field measurements. A preliminary survey of about 10,000 of 20-minute intervals indicates that the variations are more compressive on the smaller scales, in agreement with theoretical predictions for the kinetic wave modes.

The magnetosphere of Saturn extends up to 20 Saturn radii and can act as a very large laboratory to study nonlinear waves. Various satellite (Pioneer11, Voyager-1, Voyager2 and Cassini) observations have confirmed the presence of H+, N+, O+, OH+, H2O+ ions in Saturn's magnetosphere with number densities and temperatures varying as a function of distance from Saturn. In addition, electron populations with two distinct temperatures (cold and hot) have also been observed at different radial distances of Saturn's magnetosphere. These electrons possesses high energy tail and can be well fitted with a kappa distribution function. These different species of ions and two temperature superthermal electrons under the influence of internally generated magnetic field (B 0.21 Gauss) of Saturn can lead to various kinds of nonlinear electromagnetic wave phenomena. Motivated by these observations, we propose the formation of nonlinear periodic (cnoidal) kinetic Alfven waves in the Saturn's magnetosphere. In order to study the cnoidal kinetic Alfven waves, the modified Kortewegde Vries (mKdV) equation has been derived. To perform the parametric analysis, we have used the observed values of physical parameters from Saturn's magnetosphere, such as kappa indices, temperatures, and number densities of both the cold and hot electrons. It is observed that the variation in these parameters significantly modifies the characteristics of cnoidal kinetic Alfven waves.

D3.3-0019-18 SELF-SIMILAR PLASMA EXPANSION DYNAMICS: THE ROLE OF SECONDARY IONS AND NONTHERMAL ELECTRONS

Ibrahem Elkamash, elkamashi@gmail.com

Queen's University Belfast, Belfast, United Kingdom Brian Reville, b.reville@qub.ac.uk

Queen's University Belfast, Belfast, United Kingdom Ioannis Kourakis, ioanniskourakissci@gmail.com Queen's University Belfast, Belfast, United Kingdom

We present an investigation of the self similar expansion of a multi-species ion plasma into vacuum via a multi-fluid model, adopting an adiabatic equation of state for each species. Our aim is to elucidate the effect of secondary ions on a plasma expansion front, in combination with energetic electrons in the background, modeled by a kappa-type distribution function. The plasma density, velocity and electric field profiles are obtained.

Energetic (suprathermal) electrons affect the velocity of the expansion front (shape, dynamics), thus enhancing the ion acceleration mechanism.

Various special cases are considered, as regards the relative magnitude of the ion mass and/or charge state.

Recent study of lunar wake plasma from ARTEMIS (Acceleration, Reconnection, Turbulence and Electrodynamics of Moon's Interaction with Sun) mission has revealed the presence of electrostatic waves. The lunar wake plasma is of solar wind origin. The linear analysis of electrostatic waves is carried in the lunar wake four-component unmagnetised plasma comprising of fluid protons, fluid He++, electron beam and suprathermal electrons following a kappa distribution.

Numerical analysis of the dispersion relation shows that there will be six roots corresponding to various plasma wave modes, namely, an electron acoustic mode in the positive direction (mode 1) and electron acoustic mode in the negative direction which is driven by electron beam (mode 6), fast ion acoustic mode in the positive direction (mode 2) and negative direction (mode 5) and slow ion acoustic mode in the positive direction (mode 3) and negative direction (mode 4). The electron beam mode (mode 6) and slow ion acoustic mode (mode 3) merge and forms an unstable region over certain wave number regime for normalized beam velocity of 4.3. Subsequent increase in the normalized beam velocity to 4.5 produces two unstable regions, where mode 6 merges with mode 3 in the lower wave number regime and with mode 2 in the higher wave number regime. For a beam velocity of 5.5-7.7, mode 6 merges with mode 2 only, and thereafter, merging of modes does not occur, thereby forming a stable region. The relevance of our model to explain the generation mechanism of electrostatic waves in the lunar wake will be discussed.

D3.3-0021-18 EVOLUTION OF NONLINEAR ELECTROSTATIC WAVES IN THE AURORAL ACCELERATION REGION

Rubia R, rubi.r92@gmail.com

Evolution of nonlinear electrostatic oscillations in a three-component magnetized plasma comprising of protons, oxygen ion beams and suprathermal electrons following -distribution has been analyzed. The nonlinear electrostatic waves are considered to be propagating at an oblique direction to the ambient magnetic field. A parametric study of the effect of initial driving electric field amplitude, wave Mach number, propagation angle, κ-index, number density and temperature of the constituent species on the evolution of nonlinear waves is carried out. The effect of these parameters on the frequency and the nature of electric field structures (sinusoidal, sawtooth or spiky) is also analyzed. The results from the model are compared with the satellite observations of spiky waveforms in the parallel electric field in the auroral acceleration region.

D3.3-0022-18 WHISTLER WAVES AT THE BOW SHOCKS VENUS AND EARTH: COMPARISON OF WAVE PROPERTIES

Hanying Wei, hwei@igpp.ucla.edu

Institute of Geophysics and Planetary Physics, University of California, Los Angeles, California, United States

C.T. Russell, ctrussell@igpp.ucla.edu

Robert J. Strangeway, strange@igpp.ucla.edu UCLA, Los Angeles, California, United States

When the solar wind encounters the magnetosphere of Earth and the ionosphere of Venus, a bow shock formed in the upstream of the planet where the solar wind decelerates from a superto sub-magnetosonic flow. Around the shock, there are many wave activities. In the upstream foreshock region, there is abundant wave activity generated by the shock or by the back-streaming ions and electrons from the shock. In the downstream magnetosheath region, there is also abundant wave activity either locally generated by the heated electrons or ions from the shock or transported from the shock or foreshock regions by the solar wind. Understanding these waves could improve our knowledge on the heating of electrons and ions across the shock ramp and the energy dissipation of supercritical shocks. The magnetometers of Venus Express and Magnetospheric Multiscale missions both occasionally record 128 Hz data in burst mode during their shock crossing, which allow us to analyze whistle waves around and above lower hybrid frequency. The MMS plasma measurements also could help us understand the sources of these waves. In this paper we examine and compare these waves at the bow shock of Venus and Earth.

Recent observations from the Energetic Particle Detector (EPD) instrument suite aboard the NASA Magnetospheric Multiscale (MMS) spacecraft show that energetic (greater than tens of keV) magnetospheric particle escape into the magnetosheath occurs commonly across the dayside. This includes a new signature that requires magnetic reconnection and the surprisingly frequent observation of magnetospheric electrons in the duskside magnetosheath. A statistical analysis of escape events identified in the 40 keV electron energy channel during the first MMS dayside season revealed strongly anisotropic pitch angle distributions indicating monohemispheric field-aligned streaming away from the magnetopause. Despite the extensive history of such research, these new observations provide a more comprehensive data set that includes unprecedented magnetic local time (MLT) coverage of the dayside equatorial magnetopause/magnetosheath. These data clearly highlight the common escape of energetic electrons along magnetic field lines concluded to have been reconnected across the magnetopause. While these streaming escape events agree with prior studies which show strong correlation with geomagnetic activity (suggesting a magnetotail source) and occur most frequently during periods of southward IMF, the high number of duskside events is unexpected and previously unobserved. Notably, the events reported here also exhibit pitch angle anisotropies indicative of streaming up to 200 keV, which could represent the magnetopause loss of >1 MeV electrons from the outer radiation belt.

During MMS traversals of the midnight to dusk local time regions energetic electron data often show clusters of electron injections we call microinjections because of their short duration signatures. These microinjections of 50 to >400 keV electrons have energy dispersion signatures indicating that they gradient and curvature drifted from earlier local times. We show detailed results from some microinjections taken with burst mode data. We will also show a case where the microinjections were observed simultaneous with and superimposed upon a classic substorm electron injection profile at 10-11 Re altitude near local midnight. These data show that the energy of the electrons in the microinjections exceed those of the classic injection and were trapped with predominantly field-aligned angular distributions. Drift calculations constrained by the observed electron dispersion times indicate the electrons had drifted from near the magnetopause hours earlier in local

time. The 2016 observations were limited to altitudes of 9 to 12 Re because the MMS apogee was 12 Re then. The MMS apogee was raised to 25 Re in March 2017 and we will show how these later microinjection observations compare to the earlier ones. These microinjection clusters are a new phenomenon in this region of the magnetosphere and with the higher orbit we will observe how close to the magnetopause they exist and possibly traverse the source regions. We will provide some statistics on the occurrence of the injections and discuss possible sources and implications.

D3.4-0003-18 ION VELOCITY DISTRIBUTIONS IN FLOW BURSTS DOWNSTREAM FROM THE QUASI-PARALLEL BOW SHOCK

Stephen Fuselier, sfuselier@swri.edu

Southwest Research Institute, San Antonio, United States Joey Mukherjee, joey@swri.org

Southwest Research Institute, San Antonio, Texas, United States James Burch, jburch@swri.edu

LASP, Boulder, California, United States Steven Petrinec, petrinec@spasci.com

Lockheed Martin Advanced Technology Lab, Palo Alto, California, United States

Ion flow bursts are observed in the magnetosheath downstream from the quasi-parallel bow shock. These flow bursts have anti-sunward velocities that are one to two hundred km/s faster than that in the turbulent downstream magnetosheath. This talk discusses a survey of the occurrence frequency of these bursts using the Magnetospheric Multiscale mission data set. The survey is used to investigate the possibility that flow bursts reach the magnetopause. Also, the ion velocity distributions in flow bursts are used to help identify the origin of these bursts and their dynamic evolution.

D3.4-0004-18 ORIGIN OF NONLINEAR DENSITY FLUCTUATIONS IN THE FORESHOCK REGION

Yasuhito Narita, yasuhito.narita@oeaw.ac.at

Space Research Institute, Austrian Academy of Sciences, Graz, Austria

T. Hada, hada@esst.kyushu-u.ac.jp Kyushu University, Fukuora, Japan

Density fluctuations appear in various space plasma environments, and are often accompanied by magnetic field fluctuations. The sense of the density fluctuations can be correlated to that of the magnetic field fluctuations like the fast magnetosonic mode, and also anti-correlated like the slow mode or mirror mode. The quasi-static approximation offers a unified view of the density fluctuation such that fast-mode correlation sense is realized in a low-beta plasma, and the slow-mode correlation sense in a high-beta plasma. The quasi-static approximation is tested against 34 events of the Cluster spacecraft encounter with the Earth foreshock region, in which large-amplitude Alfven waves are excited by the shock-reflected backstreaming ions. We obtain two major results from the test. First, in contrast to the expectation from the quasi-static approximation, most of the studied foreshock waves exhibit a correlated sense of fluctuations between the ion density and the magnetic field magnitude both in the low-beta and high-beta plasma events. Second, interestingly, multiple types or branches of correlations are found in the high-beta plasma events. The lesson from the observational test for the quasistatic approximation against the foreshock waves is that a simple or fluid-like treatment of the quasi-static approximation is only valid in the low-beta plasmas and not in the high-beta plasmas. Different wave modes likely co-exist in the high-beta foreshock waves. Also, a kinetic extension of the quasi-static approximation needs to be considered.

D3.4-0005-18 MAGNETOPAUSE FROMATION AND PARTICLE PENETRATION THROUGH THE MAGNETOPAUSE

Multiple studies of the solar wind flow under the bow shock, near and under the magnetopause made it possible to obtain a more or less accurate picture of such flow. However, the understanding of the processes of formation of magnetosheath turbulence and magnetopause are only at the first stages of extensive study. Such situation is connected to the use of the frozen-in condition and the approximation of the magnetopause as a rigid impenetrable surface during modeling the magnetosheath magnetic field and plasma flow. We analyze the reasons leading to the use of such approximations and show that it was connected to the insufficient attention to the conditions of pressure balance at the magnetopause and conditions leading to ion penetration through the magnetopause. These conditions are different in the cases of high and low shears of the magnetic field at the magnetopause. We studied the properties of the ion spectra in both sides of the magnetopause for the cases of low and high magnetic shears. We show that it is possible to observe high shear and low shear magnetopause crossings independently on the magnetic field direction in the solar wind, which is the natural consequence of the development of magnetosheath turbulence. Our studies also show that using bi-kappa approximation of ion spectra is the very effective tool for the study of ion penetration through the magnetopause. It was found that the fitting parameters of the ion spectra for high and low shears of the magnetic field differ significantly. We found that particle can freely penetrate through magnetopause when its gyroradius, determined by the value of the magnetic field under the magnetopause, is comparable with the magnetopause thickness. We analyzed the role of the change of magnetic field inside the magnetosphere in the change of the

magnetopause form and position. We also show that the value of plasma pressure under the magnetopause determines the configuration of currents inside the magnetosphere.

D3.4-0006-18 THE FLANK MAGNETOPAUSE: THEMIS OBSERVATIONS

Stein Haaland, stein.haaland@uib.no

Max-Planck Institute / BCSS, Gottingen, Germany Andrei Runov, arunov@igpp.ucla.edu

University of California, Los Angeles, Los Angeles, California, United States Anton Artemyev, aartemyev@igpp.ucla.edu

University of California, Los Angeles, Los Angeles, California, United States Vassilis Angelopoulos, vassilis@ucla.edu

University of California, Los Angeles, Los Angeles, California, United States

The magnetopause is the boundary that, to first order, shields the Earth's magnetosphere from the shocked solar wind and its embedded interplanetary magnetic field. In this presentation, we show observations from the THEMIS constellation of spacecraft, comparing dayside magnetopause crossings with flank crossings near the terminator. Macroscopic properties such as current density, current sheet thickness, motion and transport across the boundary are examined for a large number of magnetopause crossings. We find that the flank magnetopause current sheet is generally thicker than the dayside magnetopause current sheet, but due to less reconnection activity, there is less transfer of mass and momentum across it. There are also asymmetries between dawn and dusk flanks for a number of properties. Dusk flank crossings typically have more pronounced changes in plasma and field quantities and are therefore easier to detect in the observations.

D3.4-0007-18 SOLAR WIND DRIVERS IN THE MAGNETOSHEATH: LONG-TERM EVOLUTION

Tuija Pulkkinen, tuija.pulkkinen@aalto.fi Aalto University, Espoo, Finland

Antti Lakka, antti.lakka@aalto.fi Aalto University, Espoo, Finland

Andrew Dimmock, andrew.dimmock@irfu.se

Swedisch Institute of Space Physics, Uppsala, Sweden Emilia Kilpua, emilia.kilpua@helsinki.fi

University of Helsinki, Helsinki, Finland

We study the long-term variability of the solar wind - magnetosphere - ionosphere coupling using several coupling functions to describe the solar wind input. As all plasma entering the magnetosphere is processed through the bow shock, magnetosheath, and the magnetopause, the complex dynamics of the solar wind - magnetosphere coupling is affected by the properties of the boundaries at the shock and the magnetopause as well as the dynamics within the magnetosheath. Data from the THEMIS 5-spacecraft mission processed in the magnetosphere interplanetary medium reference frame are used to study the magnetosheath properties. We demonstrate that the magnetosheath dynamics exhibits long-term variability associated with solar cycle evolution, and show how it varies as function of solar wind parameters. Especially, we focus on the energy entering the magnetosphere through the magnetopause in the form of Poynting flux. The IMAGE magnetometer chain measurements are used to trace the corresponding effects in the ionosphere over the THEMIS period, and also in a longer-term solar cycle perspective. The GUMICS-4 global MHD simulation quantitative results of energy entry and of the coupling of the boundary processes to the polar cap are used to provide a context and reference for the statistical observations.

D3.4-0008-18 TOPOLOGY OF MAGNETIC FIELD AND MAGNETOSPHERIC BOUNDARY LAYERS UNDER RADIAL IMF CONDITION: OBSERVATION AND SIMULATION RESULTS

Gilbert Pi, gilbert.pi@mff.cuni.cz

Charles University, Faculty of Mathematics and Physics, Prague, Czech Republic Zdenek Nemecek, zdenek.nemecek@mff.cuni.cz

Charles University, Faculty of Mathematics and Physics, Prague, Czech Republic Jana Safrankova, jana.safrankova@mff.cuni.cz

Charles University, Faculty of Mathematics and Physics, Prague, Czech Republic Kostiantyn Grygorov, grigorov88@gmail.com

Charles University, Prague, Czech Republic

Magnetospheric boundary layers are frequently found near the magnetopause and the structure of the layers is highly dependent on the interplanetary magnetic field (IMF) orientations. During a radial IMF, the magnetosheath Bz component points to different polarities in both hemispheres. This asymmetry leads to a special structure of boundary layers in the low-latitude region. We investigate the magnetic field and boundary layer structures near the subsolar point recorded by THEMIS spacecraft in course of past few years. The main tool for our study of the structure of the boundary layers is the ion pitch-angle distribution. Both the observations and simulation results are consistent with the suggested scenario. The layers can be classified as: (1) the inner part of the low-latitude boundary layer (LLBL) lying on closed magnetic field lines; (2) the outer LLBL on open field lines; (3) the inner part of the magnetosheath boundary layer (MSBL) formed by dayside reconnection in the southern hemisphere; and (4) the outer MSBL resulting from lobe reconnection in the northern hemisphere.

D3.4-0009-18 MAGNETOSHEATH JETS: MODIFYING MAGNETOSHEATH PLASMA AND FIELDS, AND LINKING THE BOW SHOCK TO THE MAGNETOPAUSE

Ferdinand Plaschke, ferdinand.plaschke@oeaw.ac.at

Space Research Institute, Austrian Academy of Sciences, Graz, Austria

Jets in the magnetosheath are local enhancements in dynamic pressure over ambient magnetosheath plasma, typically due to increases in both density in velocity. Undulations or ripples of the quasi-parallel bow shock stemming from impinging foreshock structures seem to constitute a major source of these jets. As they are able to traverse the entire magnetosheath, jets link processes and structures from the foreshock and bow shock with the day side magnetopause, on which they frequently impact. Here, latest statistical results based on THEMIS and MMS multi-spacecraft observations are presented, showing: (1) the plasma flow structure within and around jets as they traverse the magnetosheath and (2) the change in magnetic field orientation within jets resulting from that flow.

(1) The high velocity core jet plasma pushes slower plasma ahead out of the way, thereby setting up a vortical plasma motion in the vicinity. Inside the jet, slower plasma is accelerated in jet propagation direction while being redirected around the core. Outside of the jet, the evasive plasma motion is complemented by a deceleration of plasma in jet propagation direction with respect to the typical magnetosheath plasma flow. (2) The fast motion of jet plasma through the slower magnetosheath leads also to a straightening of the magnetic field in the jet core region, evidenced by consistently lower angles between plasma velocity and magnetic field direction at times of highest plasma velocity.

D3.4-0010-18 EXTERNAL AND INTERNAL CONDITIONS THAT AFFECT THE DAYSIDE MAGNETOPAUSE RECONNECTION LOCATION

Lockheed Martin Advanced Technology Lab, Palo Alto, California, United States

Magnetic reconnection at the Earth's magnetopause is discussed and has been observed as anti-parallel and component reconnection. While anti-parallel reconnection occurs between magnetic field lines of (ideally) exactly opposite polarity, component reconnection (also known as the tilted X-line model) predicts the location of the reconnection line to be anchored at the sub-solar point and extend continuously along the dayside magnetopause, while the ratio of the IMF By/Bz component determines the tilt of the X-line relative to the equatorial plane. A reconnection location prediction model known as the Maximum Magnetic Shear Model combines these two scenarios. The model predicts that during dominant IMF By conditions, magnetic reconnection occurs along an extended line across the dayside magnetopause but generally not through the sub-solar point (as predicted in the original tilted X-line model). Rather, the line follows the ridge of maximum magnetic shear across the dayside magnetopause. The model predicts the reconnection location correctly for about 80% of the time. This investigation uses MMS observations to discuss cases where the combination of large dipole titles with specific IMF clock angles causes the actual component reconnection X-line to be deflected from its predicted location.

D3.4-0011-18 MMS OBSERVATIONS OF HALL CURRENTS AT THE BORDERS OF A CRATER FLUX TRANSFER EVENT

Lorenzo Trenchi, lorenzo.trenchi@esa.int ESA/ESRIN, Frascati (Roma), Italy John Coxon, j.coxon@soton.ac.uk

University of Southampton, Southampton, United Kingdom Robert Fear, r.c.fear@soton.ac.uk

University of Southampton, Southampton, United Kingdom

We present MMS observations of a Flux Transfer Event (FTE) detected on 27 October 2015, during a period of stable southward interplanetary magnetic field. Several reconnection jets were also observed during this period. The FTE is characterized by a clear signature in the magnetic field magnitude, with a maximum of the magnetic field intensity at the FTE centre, flanked by two local minima. This class of FTEs are called 'crater' FTEs, and have been suggested to be connected with an active reconnection X line. The MMS burst mode data allowed for the identification of intense fluctuations in the components of electron velocity and electric field parallel to the magnetic field at the borders of the FTE. In particular, the strong fluctuations of the parallel electron velocity at the borders of the FTE are an evident signature of encounters with magnetic separatrices and suggest that this FTE is connected with an active reconnection X line. This has important consequences for the FTE generation mechanism: in the original Russell and Elphic (1978) model, the FTE is not connected with an active reconnection site, and only in the extended X line models are the separatrices expected at the borders of the FTE. Our observations suggest a stratification of the particles inside the reconnection layer, in which electrons are flowing toward the X line along the separatrix, and flowing away from the X line along the adjacent reconnected field lines. More internally, ions and electrons are flowing away from the X line with comparable velocities, forming the observed reconnection jets.

D3.4-0012-18 DYING FLOW BURSTS AS GENERATORS OF THE SUBSTORM CURRENT WEDGE

Gerhard Haerendel, hae@mpe.mpg.de

Max-Planck-Institut fuer extraterrestrische Physik, Garching, Germany

Many theories or conjectures exist on the driver of the substorm current wedge, e.g. rerouting of the tail current, current disruption, flow braking, vortex formation, and current sheet collapse. Magnitude, spatial scale, and temporal development of the related magnetic perturbations suggest that the generator is related to the interaction of the flow bursts with the dipolar magnetosphere after onset of reconnection in the near-Earth tail. The question remains how much of the energy feeding the wedge current is derived from flow braking and how much is contributed by the internal energy of the arriving plasma. In this presentation I argue that after flow braking the plasma attaching to the outer magnetosphere still contributes to current generation. The generator current is the grad-B current at the outer boundary of high-beta plasma compressed by the contracting magnetic field. It needs the sequential arrival of several flow bursts to account for duration and magnitude of the ionospheric closure current.

D3.4-0013-18 PIC SIMULATION OF KELVIN-HELMHOLTZ INSTABILITY AT THE DAYSIDE MAGNETOSPHERE

Eunjin Choi, eunjin.choi(at)nasa.gov NASA/GSFC, Greenbelt, Maryland, United States Kyoung-Joo Hwang, jhwang@swri.edu

Southwest Research Institute, San Antonio, Texas, United States David Sibeck, david.g.sibeck@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States

Kelvin-Helmholtz instability is one of the most important physical processes operating on the dayside magnetopause. It has been widely investigated within the MHD framework, however, importance of kinetics increases when the thickness of the velocity shear layer becomes comparable to the ion gyroradius. Several observational studies indicate the existence of a thin velocity shear layer at the subsolar region with a thickness on the order of an ion gyroradius. To consider the effects of particle kinetics, we run particle-in-cell (PIC) simulations and investigate how the Kelvin-Helmholtz instability is excited along such a thin dayside magnetopause. Our simulations show dramatic differences in the development phase of Kelvin-Helmholtz instability depending on the relative direction of ion gyromotion to the vortices. We compared multiple simulation cases by changing parameters such as the magnitude of shear velocity and the density ratio obtained from in-situ observations.

D3.4-0014-18 MMS OBSERVATIONS AND PARTICLE-IN-CELL SIMULATIONS OF TRIPOLAR OUT-OF-PLANE MAGNETIC FIELD PERTURBATIONS DURING KELVINHELMHOLTZ WAVES

Stefan Eriksson, eriksson@lasp.colorado.edu

Austrian Academy of Sciences, Graz, Austria David Newman, david.newman@colorado.edu

University of Colorado at Boulder, Boulder, United States

We present new MMS observations of tripolar BM guide magnetic field perturbations associated with Kelvin-Helmholtz (KH) waves which are supported by in-plane Hall-like electron current loops. Tripolar BM observations were reproduced by Hall-like current loops in a 3D PIC simulation of vortex-induced driven reconnection during a limited phase of the KH evolution. MMS observations of a significant BN deflection and a strong axial current within a BL=0 plateau are consistent with a small-scale flux rope within one of the current sheets. We explore similarities and differences across several such KH-associated current sheets when MMS recorded a tripolar guide field perturbation.

Space Research Institute, Austrian Academy of Sciences, Graz, Austria

When the interplanetary magnetic field (IMF) is strongly northward, a boundary layer that contains a considerable amount of plasma of solar wind (magnetosheath) origin is often observed along and earthward of the low-latitude magnetopause. Such a pre-existing boundary layer, with a higher density than observed in the adjacent magnetosphere, reduces the local Alfvén speed and allows the Kelvin-Helmholtz (KH) instability to grow more strongly. We employed a large-scale three-dimensional fully kinetic simulation to model an event observed by the Magnetospheric Multiscale (MMS) mission in which the spacecraft detected (i) substantial KH waves between a pre-existing boundary layer and the magnetosheath during strong northward IMF and (ii) small-scale reconnection signatures such as electron-scale energy dissipations and ion-scale reconnection exhausts within the observed KH waves. The simulation successfully demonstrated these reconnection signatures within the non-linearly developed KH vortex, which are in quantitative agreement with the observed signatures. The simulation further demonstrated that a turbulent evolution of this vortex-induced reconnection (VIR) process leads to a large-scale plasma transport across the magnetopause and resulting rapid formation of the new mixing layer along the magnetopause. The VIR also produces a strong parallel electron heating within the new mixing layer. In this presentation, we will show the detailed comparisons between the simulation and the MMS observation, and discuss how the mass and energy transfer occurs near the magnetopause during strong northward IMF.

D3.4-0016-18 SOLAR WIND TRANSPORT INTO THE DUSK MAGNETOPAUSE CAUSED BY KELVIN-HELMHOLTZ VORTICES AS THE RESPONSE TO NORTHWARD TURNING OF THE INTERPLANETARY MAGNETIC FIELD

Guang Qing Yan, gqyan@spaceweather.ac.cn

National Space Science Center, Chinese Academy of Sciences, Beijing, China Lei Dai, ldai@spaceweather.ac.cn

National Space Science Center, Chinese Academy of Sciences, Beijing, China Forrest Mozer, forrest.mozer@gmail.com

Chunlin Cai, clcai@nssc.ac.cn

Center for Space Science and Applied Research, Chinese Academy of Sciences, Beijing, China

Two spacecraft encountered the magnetopause and the low latitude boundary layer (LLBL) periodically with fluctuations of plasma features at the dusk magnetopause when the interplanetary magnetic field (IMF) turned northward abruptly. Although few features of the highvelocity-low-density were found in the plasma flows, the rotation features in the bulk velocity observations adjacent to the magnetopause, the distorted magnetopause as the results of minimum variance analysis (MVA), and the magnetic field deviations indicate the generation of the rolled-up Kelvin-Helmholtz (KH) vortices at the dusk magnetopause. In the KH vortices, the mixtures of the ions from magnetosheath with those from the magnetosphere were observed in the energy spectrum. The plasma flows were more periodic at the upstream spacecraft while more mixed than at the downstream one, suggesting that the plasma transport could occur significantly during the KH wave propagation from the upstream spacecraft to the downstream one. Under new criteria, the typical portrait of the plasma entry into the magnetosphere was made based on the observations of the electron and ion energy spectrums.

D3.4-0017-18 REMOTE SENSING OF A BOW SHOCK AT COMET 67P: THEORY, ICA OBSERVATIONS AND HYBRID MODELLING

Markku Alho, markku.alho@aalto.fi Aalto University, Espoo, Finland Hans Nilsson, hans.nilsson@irf.se

Swedish Institute of Space Physics, Kiruna, Sweden Esa Kallio, esa.kallio@aalto.fi

Aalto University, Espoo, Finland

Cyril Simon Wedlund, c.s.wedlund@fys.uio.no University of Oslo, Oslo, Norway

Riku Jarvinen, riku.jarvinen@aalto.fi Aalto University, Espoo, Finland

Tuija Pulkkinen, tuija.pulkkinen@aalto.fi Aalto University, Espoo, Finland

No direct observational evidence of the cometary bow shock around comet 67P/ChuryumovGerasimenko has been presented during the ESA/Rosetta mission. The Rosetta probe, during its escort phase, performed a lengthy dayside excursion up to a cometocentric distance of approximately 1500 kilometers, but no bow shock crossing was observed, implying either a distant bow shock or no bow shock formation at all. However, modelling studies at low heliocentric distances and high outgassing rates consistently predict the formation of a cometary bow shock within several thousands of kilometres of 67P's nucleus.

The Ion Composition Analyzer ICA, of the Rosetta Plasma Consortium, a top-hat ion spectrometer aboard Rosetta, measured solar wind and cometary ion distribution functions during the escort phase. As the length scales of the heavy cometary pickup ions exceed those of the predicted bow shock standoff distance by a factor of two up to an order of magnitude, the pickup ions could provide a remote sensing diagnostic of the cometary environment. A bow shock would present a significant increase in plasma heating and turbulence, leading to a modified acceleration environment for freshly ionized cometary particles and a modulation of the pickup ion energy spectra at the nucleus.

In this work, we summarily present a potential bow shock observation using energy dispersion of cometary ions observed by ICA and provide an interpretation of the observations with a self-consistent, numerical hybrid plasma model. We describe simulated observations of ions from two cometary plasma environments, one shock-producing and one non-shocked, and give guidelines on how the bow shock could be inferred remotely from in-situ observations.

D3.4-0018-18 SOLAR WIND PLASMA/PARTICLE ENTRY DURING NORTHWARD IMF AND ITS RELATED AURORAL ACTIVITIES

Quanqi Shi, sqq@pku.edu.cn

Shandong University at Weihai, Weihai, China Et Al., sqq@sdu.edu.cn

China

During quiet times when the interplanetary magnetic field (IMF) is northward, using Cluster multi-spacecrafts observation between August to October each year from 2002 to 2004, Shi, et al. [2013] reported an unexpected discovery observation of regions of solar wind entry into the Earth's high-latitude magnetospheric lobes where the solar wind plasmas may penetrate into magnetosphere through the mechanism of high-latitude magnetic reconnection. From statistical analysis, they found that the IMF Bx component may influence the solar wind entry into the magnetosphere by changing the occurring conditions of high-latitude magnetic reconnection. Based on their studies, in this paper we use another period Cluster data which is between January to April each year from 2001 to 2006 to do a further study. As a result, the influence of the IMF Bx component is consistent with the results from [Shi, et al. 2013]. We find that the IMF By component influenced affects the events along with the IMF Bx component, which is consistent with the Parker Spiral of the IMF. We also present some transpolar arc observations occurring in correlation with the solar wind entry events. The properties of entry plasma, electron and ion properties associated with aurorae and correlations with IMF conditions are examined using multiple spacecraft data (Cluster, TIMED, DMSP, IMAGE, POLAR). The time evolution and asymmetries between two hemispheres for these transpolar arcs are studied as well. Using multi satellite, we have studied the geospace effect of the solar electron release. In several events, the electron flux enhanced in different regions of the magnetosphere after some solar electrons arrived at the vicinity of the earth. The entry mechanism of these high energy electrons is discussed.

D3.4-0019-18 STATISTICAL STUDY OF INFLUENCE OF THE ULF WAVES ON EARTH FORESHOCK PLASMA PROPERTIES

Jaroslav Urbar, jaroslav.urbar@gmail.com

Charles University, Faculty of Mathematics and Physics, Prague, Czech Republic Zdenek Nemecek, zdenek.nemecek@mff.cuni.cz

Charles University, Faculty of Mathematics and Physics, Prague, Czech Republic Jana Safrankova, jana.safrankova@mff.cuni.cz

Charles University, Faculty of Mathematics and Physics, Prague, Czech Republic Lubomir Prech, lubomir.prech@mff.cuni.cz

Charles University, Faculty of Mathematics and Physics, Prague, Czech Republic

The parameters of the solar wind plasma are modified upstream the Earth,s bow shock, in the ion foreshock region, which is typically observed at quasi-parallel bow shock. Associated ULF waves are created due to the interaction of the solar wind plasma with the ions reflected at the bow shock where they generate fast magnetosonic waves with an in-phase relationship between the ion flux and magnetic field fluctuations. Using multipoint observations from the THEMIS spacecraft fleet located in the foreshock, we present statistical maps of a modification of solar wind parameters due to foreshock processes (solar wind heating and deceleration, enhancements of electric and magnetic field fluctuation levels associated with specific ULF waves, etc.). Special attention is devoted to intervals of the radial interplanetary magnetic field that creates the foreshock upstream of a whole dayside bow shock.

D3.4-0020-18 A STUDY OF SPONTANEOUSLY HOT FLOW ANOMALIES AND CORRESPONDING UPSTREAM CONDITIONS

Gilbert Pi, gilbert.pi@mff.cuni.cz

Charles University, Faculty of Mathematics and Physics, Prague, Czech Republic Zdenek Nemecek, zdenek.nemecek@mff.cuni.cz

Charles University, Faculty of Mathematics and Physics, Prague, Czech Republic Jana Safrankova, jana.safrankova@mff.cuni.cz

Charles University, Faculty of Mathematics and Physics, Prague, Czech Republic

Hot flow anomalies (HFAs) are usually formed by the interaction of a solar wind tangential discontinuity with the bow shock but they can also be found without the tangential discontinuity. This kind of HFAs is named spontaneous HFAs (SHFAs). SHFAs are formed by the interaction of particles reflected from the bow shock with the ambient solar wind. Nevertheless, the upstream IMF conditions should also contribute to the formation of SHFAs. In this study, we investigate the SHFAs recorded by Time History of Events and Macroscale Interactions during Substorm (THEMIS) satellites from 2007-2009 and corresponding upstream solar wind conditions monitored by Wind and ACE. The study provides us further information on the SHFA formation.

D3.4-0021-18 SPATIAL DISTRIBUTION OF MAGNETIC FIELD AND PLASMA PARAMETERS IN THE MAGNETOSHEATH DURING PERIODS OF A RADIAL IMF

Mychajlo Hajos, hayosh@ufa.cas.cz

Institute of Atmospheric Physics, Prague, Czech Republic Zdenek Nemecek, zdenek.nemecek@mff.cuni.cz

Charles University, Faculty of Mathematics and Physics, Prague, Czech Republic Jana Safrankova, jana.safrankova@mff.cuni.cz

Charles University, Faculty of Mathematics and Physics, Prague, Czech Republic Gilbert Pi, gilbert.pi@mff.cuni.cz

Charles University, Faculty of Mathematics and Physics, Prague, Czech Republic

The solar wind is slowed down at the bow shock and diverted around the magnetopause creating the magnetosheath. Spatial profiles of the plasma parameters within the magnetosheath were studied theoretically in a gasdynamic approximation under assumptions of the frozen-in interplanetary magnetic field (IMF). Later, global MHD models revealed importance of the IMF orientation in a magnetosheath formation but none of these approaches can reflect kinetic processes connected with the presence of beams of particles accelerated at the bow shock and penetrating into the magnetosheath. These effects would be even more important during intervals of a radial IMF that facilitates a penetration of the energetic particles into the whole magnetosheath. The study uses a huge amount of Cluster and THEMIS magnetosheath observations for a determination of typical profiles of the density, velocity, and temperature as well as the direction and magnitude of the magnetic field in the dayside low-latitude magnetosheath. In order to account for the changing solar wind conditions, the study uses dimensionless quantities normalized to corresponding upstream parameters. Magnetopause and bow shock models reflecting the magnetopause expansion during intervals of the radial IMF serve for a determination of the magnetosheath coordinates. The results obtained for the radial IMF are compared with a similar study of the magnetosheath profile for the strongly northward IMF and with the MHD model.

The solar wind dynamic pressure is a principal factor controlling the magnetopause location and a relation between them is usually described by a power-law form but values of suggested indices vary from 1/4.8 to 1/6.6 in magnetopause models developed in course of last years. However, solar wind parameters are modified inside the magnetosheath and this modification depends on the orientation of the interplanetary magnetic field (IMF), thus a relation between the upstream pressure and magnetopause location would be a function of the IMF orientation. On the other hand, the magnetospheric magnetic field that opposes the upstream pressure is affected by a number of processes that, in turn, depend on upstream parameters like the IMF orientation or solar wind velocity. The paper analyzes several thousands of THEMIS dayside magnetopause crossings observed in a broad range of upstream pressures (0.2-20 nPa) and under various IMF orientations with a motivation to validate the power-law form for a description of variations of the magnetopause stand-off distance with the upstream pressure and to determine the factors that furthermore influence an actual value of the power-law index.

D3.4-0023-18 ION RAMPS OF BOW SHOCKS AND INTERPLANETARY SHOCKS: DIFFERENCES AND SIMILARITIES

Fast forward shocks driven by coronal mass ejections or by interaction of fast and slow solar wind streams can be encountered in the interplanetary space, whereas the bow shock is a standing fast reverse shock formed by an interaction of the supersonic solar wind with the Earth magnetic field. Both types of shocks are responsible for a transformation of a part of the energy of the directed solar wind motion to plasma heating and acceleration of reflected particles to high energies. These processes are closely related to the shock front structure. In the present paper, we compares fast forward interplanetary shocks registered in the solar wind by the DSCOVR, WIND, and ACE with bow shock crossings observed by the Cluster, THEMIS, MMS, and Spektr-R spacecraft with the Alfvén Mach number lower than the first critical Mach number in the small plasma beta (<1) regime. An application of the high-time resolution data facilitates a further discussion on formation mechanisms of both types of shocks and their associated structures.

D3.4-0024-18 GAS-DYNAMIC INTERPRETATION OF STRUCTURES IN THE MAGNETOSHEATH ON THE BASIS OF THEMIS AND CLUSTER MEASUREMENTS

Polya Dobreva, polya2006@yahoo.com

Institute of Mechanics, Bulgarian Academy of Sciences, Sofia, Bulgaria Monio Kartalev, m.kartalev@yahoo.com

Institute of Mechanics, Bulgarian Academy of Sciences, Sofia, Bulgaria

Our purpose is to analyze structures and processes in the Earth's magnetosheath on the basis of both theoretical modeling and data from recent spacecraft missions. In our investigation we apply plasma measurements, taken onboard the THEMIS and Cluster satellites. The numerical gas-dynamic magnetosheath-magnetosphere model is used as a theoretical tool. For a given solar wind state, the model self-consistently determines the positions of the bow shock and the magnetopause. It also provides the distribution of plasma parameters in the magnetosheath and distribution of magnetic field in the magnetosphere, the latter calculated via a magnetospheric magnetic field model. WIND and ACE data are used as a solar wind monitoring. The capabilities of the model in describing the features of the terrestrial magnetosheath are discussed.

D3.4-0025-18 SPACE WEATHER - TECHNOLOGY, RESEARCH, AND EDUCATION CENTER (SWX-TREC)

Daniel N. Baker, daniel.baker@lasp.colorado.edu

LASP / University of Colorado, Boulder, Colorado, United States
Jeffrey Thayer, jeffrey.thayer@colorado.edu

United States

Thomas Berger, thomas.berger@colorado.edu

University of Colorado at Boulder, Boulder, Colorado, United States

SWx-TREC is a new Center at the University of Colorado - Boulder initiated under a grant intended to create a center of gravity for the many units at CU working on space weather topics. TREC will be in the College of Engineering and Applied Science and the Laboratory for Atmospheric and Space Physics (LASP). It will be able to work across the usual academic boundaries to better develop and integrate space weather models, missions, and data that will have a direct benefit to the operational forecasting offices. TREC will also be the focal point for creating undergraduate, graduate, and professional courses in space weather. TREC is currently making strategic investments in research-to-operations (R2O) projects such as an improved full-physics model of Low-Earth-Orbit satellite and debris drag, as well as operationsto-research (O2R) projects including improvements to solar magnetic field measurements and models that form the basis of operational solar wind forecasting models. In addition, TREC will host a "space weather data portal" and a forecast center "test bed", enabling close interaction between operational forecasters and researchers from around the nation and the world. In short, TREC is a new academic research and technology center dedicated to helping bridge the gap between space weather research and operations, and to educating the space science workforce, from undergraduates to industry professionals. TREC will work with national and international operational forecast centers, industry, other academic groups, and NSF and NASA centers such as the NASA/NSF CCMC, to develop and transition new models and tools that improve space weather forecasting and nowcasting. TREC will also be focusing significant effort on its educational mission in alignment with CU's mission as a leading space science university.

The NASA Magnetospheric Multiscale (MMS) mission uses four closely-spaced spacecraft to investigate magnetic reconnection in the boundary regions of the Earth's magnetosphere by measuring charged particles and electric and magnetic fields at the electron scale for the first time in space. Magnetic reconnection involves the conversion of magnetic energy to heat and charged particle kinetic energy. Particle energization is manifested in several different ways including jets of ions streaming away from X lines, electron jets streaming both toward and away from X lines, out-of-plane flows of electrons accelerated by the reconnection electric field, and high-energy ions and electrons produced by induced electric fields and Fermi acceleration. MMS encounters both asymmetric reconnection at the dayside magnetopause and symmetric reconnection in the magnetotail. Particle densities are much lower in the tail so that the available magnetic energy per particle is much higher than on the day side. The sources of accelerated electrons are also different being primarily magnetosheath

electrons on the day side and neutral-sheet electrons on the night side. Meandering, Speiser-type trajectories are important in both regions, which allows for cross-field acceleration by the reconnection electric field. Detailed comparisons are made of various particle acceleration mechanisms in symmetric and asymmetric reconnection, and an overall budget of particle and magnetic energy is derived in order to make better estimates of the reconnection rate.

D3.5-0002-18 ON THE FORMATION OF SATURN'S ELECTRON RADIATION BELTS BY Z-MODE WAVE ACCELERATION

Saturn's electron radiation belt is most intense just outside the ring system. It consists of high-energy electrons of energies up to several MeV which are accelerated inside the planetary magnetic field. It has long been thought that inward transport and conservation of the first two adiabatic invariants is responsible for the acceleration. Here we show that in-situ acceleration through wave particle interactions, which initial studies dismissed as ineffectual at Saturn, is in fact a vital part of the energetic particle dynamics at Saturn. We present evidence from numerical simulations based on careful modelling of data from the Cassini spacecraft that a particular class of plasma waves, known as Z-mode waves, accelerates electrons to MeV energies inside 4 RS (1 RS = 60,330 km). The acceleration takes place via Doppler shifted cyclotron resonance in regions of low plasma density. Our results show that Z-mode waves propagating almost along the planetary magnetic field are much more effective at electron acceleration than obliquely propagating waves, or O-mode waves. We show that the resulting electron energy spectrum closely approaches that observed, even without transport effects. The results suggest that electron acceleration by Z mode waves plays a major role in the formation of Saturn's electron radiation belt.

D3.5-0003-18 THE STRUCTURE AND PROPERTIES OF MARTIAN MAGNETOSPHERE AT 70° SOLAR-ZENITH ANGLE IN MSE COORDINATES AS OBSERVED ON MAVEN SPACECRAFT

Results of measurements on MAVEN spacecraft during its 44 passes through dayside solar wind-Mars interaction region are analyzed in MSE coordinate system, arranged by the angle between electric field vector and the projection of spacecraft position radius vector in the YZ plane E. All passes were divided into 3 angular sectors near 0°, 90° and 180° E angles in order to estimate the role of IMF direction in plasma and magnetic properties of dayside Martian dayside magnetosheath and magnetosphere. The observations were performed from January 17 through February 4, 2016 when MAVEN was crossing the dayside magnetosphere at SZA 70°. Magnetosphere as the region with prevailing energetic planetary ions was always found between the magnetosheath and the ionosphere. Magnetic barrier forms in ionosheath in front of the magnetosphere with strong magnetic field and continues within magnetosphere. Magnetopause was defined at the steep increase of the ration of N(O+) + N(O2+)/Np from 0.1 to 1. The number densities of O+ and O2+ ions increase from magnetopause to the interface with ionosphere by the factor of 100 -1000. Within each angular sector of magnetic coordinates there are typical profiles of the magnetosheath, the magnetic barrier and the magnetosphere and relative magnetic field magnitudes in these two domains vary. Plume ions frequently dominate the ion flow in magnetosheath and magnetosphere in the northern MSE sector (E 0-300) where motion electric field is directed from the planet. The high flux of plume protons disturbs the structure of magnetosphere and magnetic barrier. In the equatorial sector (E 60°-120°) magnetic barrier, magnetopause and magnetosphere are very irregular and triple crossings of magnetopause are observed, magnetic barrier has small thickness. Velocity-dispersed ion beams are observed in the magnetosphere. The southern sector (E 160°-180°) is characterized by small scale and small magnitude magnetic barrier. Magnetosheath proton flux weakens but usually keeps the same energy distribution at the magnetopause. Magnetic field magnitude has a minimum at magnetopause. The gradient of planetary ions is steeper at magnetopause than in other sectors. The average height of the boundary with ionosphere is 530 km and the average height of the magnetopause is 730 km. The heights of magnetopause and the interface of magnetosphere with ionosphere in the southern sector are about by 150 km higher than ones in other sectors.

D3.5-0004-18 CRUCIAL CONTRIBUTION OF RAPID INJECTIONS FROM THE TAIL TO RADIATION BELT FORMATION

Hee-Jeong Kim, heekim@atmos.ucla.edu UCLA, LA, California, United States Larry Lyons, larry@atmos.ucla.edu

UCLA, Los Angeles, California, United States Chih-Ping Wang, cat@atmos.ucla.edu

University of California, Los Angeles, Los Angeles, California, United States

Analysis of the radiation belt measurements by the Van Allen Probes reveals evidence that rapid, direct injection of relativistic electrons from the plasma sheet can make a crucial contribution to formation of the outer radiation belt. Simultaneous, prompt, large increases of electron flux, often over a large radial extent, are seen not only at the 10s-100s keV energies that have been suggested to be injected from the plasma sheet and serve as a source population for local acceleration to relativistic energies, but also for MeV electrons. We will show that electrons at MeV energies are frequently injected in association with strong substorm dipolarizations. To recognize these injections, it is necessary to properly take into account how observation of this prompt injection depends on the location of spacecraft and the crucial loss of electrons by magnetopause shadowing at the larger radial distances. For electron enhancement events that have good conjunction with THEMIS and/or MMS spacecraft in the nightside, propagation of the dipolarization front from the tail can be unambiguously identified, and comparison of phase space densities for fixed adiabatic invariant shows the existence of enough population in the plasma sheet to produce the observed enhancement of MeV electrons in the radiation belt. Furthermore, examination of detailed time evolution of relativistic electron intensities reveals that significant electron enhancements are often intermittent rather than continuous, with the timings of identified intermittent flux increases closely matching substorm dipolarization manifested in the magnetic fields and electric fields measurements by the EFW and EMFISIS instruments onboard the Van Allen probes. As a process solely related with substorm activity, the significant contribution of direct injection of MeV electrons is observed regardless of the strength of geomagnetic storm disturbance, and operates in addition to the more gradual effects of wave-driven electron energization and radial diffusion.

D3.5-0005-18 ROLE OF ENERGETIC HEAVY IONS DYNAMICS ON THE RING CURRENT LOSSES

Kateryna Yakymenko, kyakymenko@lanl.gov

Los Alamos National Laboratory, Los Alamos, New Mexico, United States Vania Jordanova, vania@lanl.gov

Los Alamos National Laboratory, Los Alamos, New Mexico, United States

During geomagnetic storms, magnetic field in the equatorial plane can weaken and deviate from the dipole approximation. Such conditions may cause an onset of nonadiabatic motion of energetic ions and their precipitation into the atmosphere; the effect is expected to be especially profound for heavier ions. The nonadiabatic motion results in diffusion of energetic ions into the loss cone, the phenomenon known as field-line curvature scattering. We explore how this effect influences ion losses in the ring current during disturbed geomagnetic conditions. The ring current decay typically happens in two stages with initial rapid decay followed by a period of slower ring current dissipation. Observations indicate that heavy oxygen ions are preferentially removed during the process, however an exact mechanism causing this decay is a question of ongoing debate. Simulations with a state-of-the-art ring current-atmosphere interactions model with self-consistent magnetic field (RAM-SCB) fail to reproduce correctly the ring current decay. We show that the situation significantly improves when the field-line curvature scattering is taken into account in the RAM-SCB model. In the presentation we also show that for heavy energetic ring-current ions, even for conditions of slight nonadiabaticity, the loss cone shifts from zero-degree pitch angle and we provide a simple way to compute the modification of the loss cone.

D3.5-0006-18 NEW RESULTS CONCERNING PARTICLE ENERGIZATION IN EARTH'S VAN ALLEN RADIATION BELTS

Daniel N. Baker, daniel.baker@lasp.colorado.edu

LASP / University of Colorado, Boulder, Colorado, United States

The energy distribution, spatial extent and particle species makeup of the Van Allen belts has been explored by several space missions. However, recent observations by the NASA dualspacecraft Van Allen Probes mission have revealed wholly unexpected properties of the radiation belts, especially for electrons at highly relativistic (E > 2 MeV) and ultra-relativistic (E > 5 MeV) kinetic energies. In this presentation we show using high spatial and temporal resolution data from the Relativistic Electron-Proton Telescope (REPT) experiment on board the Van Allen Probes that multiple belts can exist concurrently and that an exceedingly sharp inner boundary exists for ultra-relativistic electrons. Using additionally available Van Allen Probes data, we demonstrate that these remarkable features of energetic electrons are driven by strong solar and solar wind forcings. The comprehensive Van Allen Probes data show more broadly and in many ways how extremely high energy particles are accelerated, transported, and lost in the magnetosphere due to interplanetary shock wave interactions, coronal mass ejection impacts, and high-speed solar wind streams. The new data have in many ways rewritten our understanding about the radiation belts as a key space weather threat to human technological systems.

LASP / University of Colorado, Boulder, Colorado, United States

The NASA Van Allen Probes have opened a new window on the dynamics of ultra-relativistic electrons in the Van Allen radiation belts. Under different solar wind forcing the outer belt is seen to respond in a variety of apparently diverse and sometimes remarkable ways. For example, sometimes a third radiation belt is carved out (e.g., September 2012), or the belts can remain depleted for 10 days or more (September 2014). More usually there is a sequential response of a strong depletion, sometimes even total extinction on hour timescales, followed by a re-energization, the latter increasing outer belt electron flux by orders of magnitude on hour timescales during some of the strongest storms of this solar cycle (e.g., March 2013, March 2015). Such dynamics also appear to be often bounded at low-L by an apparently impenetrable barrier at L 2.8 through which ultra-relativistic electrons do not penetrate. Many studies in the Van Allen Probes era have sought explanations for these apparently diverse features, often incorporating the effects from multiple plasma waves. In contrast, we show how this apparently diverse behaviour can instead be explained by one dominant process: ULF wave radial transport. Once ULF wave transport rates are accurately specified by observations, and coupled to the dynamical variation of the outer boundary condition at the edge of the outer belt, the observed

diverse responses can all be explained. However, in order to get good agreement with observations, the modeling reveals the importance of very fast loss in the main phase which results in an almost total extinction of the belts and decouples preand post-storm ultra-relativistic electron flux on hour timescales, and we show how this can be explained by losses to the last closed drift shell. Similarly, varying source populations at the outer edge of the belt, which might include effects from local acceleration, are seen to be of critical importance such that near-tail dynamics play a crucial role. Nonetheless, simple models incorporating accurate transport rates derived directly from ULF wave measurements are shown to provide a single natural, compelling, and at times elegant explanation for such previously unexplained and apparently diverse responses to solar wind forcing.

D3.5-0008-18 LONG-TERM CORRELATION OF EMIC WAVE ACTIVITY AND RADIATION BELT FLUX VARIATIONS

Maria Usanova, maria.usanova@lasp.colorado.edu University of Colorado, Boulder, Colorado, United States Alexander Drozdov, adrozdov@ucla.edu

UCLA, Los Angeles, California, United States Ian Mann, imann@ualberta.ca

University of Alberta, Edmonton, Canada Yuri Shprits, shprits@gmail.com

German Research Centre for Geosciences, Potsdam, Germany

Electromagnetic ion cyclotron (EMIC) waves are transverse electromagnetic waves generated in the equatorial magnetosphere that are believed to play an important role in the dynamics of the most energetic, a few MeV radiation belt electron population. We expand on the study by Usanova et al. [2014] demonstrating a clear correlation between ground EMIC wave activity and modulation of ultra-relativistic electron pitch-angle distributions. We will present analysis of long-term (several months) simultaneous radiation belt flux measurements and electron pitchangle distributions observed by the REPT instrument onboard the Van Allen Probes together with ground measurements of EMIC wave power by the CARISMA magnetometer array.

D3.5-0009-18 OBSERVATIONAL EVIDENCE OF ULTRARELATIVISTIC ELECTRON SCATTERING FROM THE EARTH'S RADIATION BELTS

German Research Centre for Geosciences, Potsdam, Germany Irina Zhelavskaya, irina.zhelavskaya@gmail.com

Helmholtz Centre Potsdam, GFZ German Research Centre for Geosciences, Potsdam, Germany

The process of pitch-angle scattering of ultrarelativistic electrons (multi-MeV energies) from the radiation belts into the Earth's atmosphere by electromagnetic ion cyclotron (EMIC) waves is imprinted in the time-history of radial profiles of electron phase space densities (PSD). Resonating with electrons in a narrow region of space, EMIC waves can leave signatures of deepening minimums in PSD as a function of the third adiabatic invariant. In this work, we use Van Allen Probe measurements to calculate PSD profiles and detect local minimums. We show that the occurrence of the minimums coincides with ground observations of EMIC waves, and in situ observations of narrowing electron pitch angle distributions. We use the Versatile Electron Radiation Belt (VERB) code to simulate the radiation belt dynamics, and further support our findings by analyzing the modeling results.

D3.5-0011-18 DETAILED DISTRIBUTION OF EMIC WAVE EVENT LOCATIONS IN THE VICINITY THE MAGNETOPAUSE

Institute of Atmospheric Physics, Prague, Czech Republic

Wave particle interactions play an important role in the magnetosphere dynamics. ElectroMagnetic ion cyclotron (EMIC) waves are one of the kind of plasma waves involved in these interactions. After the first in situ observations of EMIC waves close to the plasmapause, many statistical studies pointed out that the dayside magnetosphere region close to the magnetopause is the place where the EMIC occurrence rate is the highest. In this region the EMIC wave occurrence is related to magnetosphere compression events, in relation with solar wind kinetic pressure increases. The presentation of the EMIC occurrence rate is usually made with respect to the L-shell value of the observations (the L-shell value of a location in the magnetosphere being the distance to the Earth (in Earth radii), in the magnetic equatorial plane, of the magnetic field line passing through this location). The L-shell value of the region adjacent to the magnetopause can vary by few Earth radii in respect with the solar pressure. In the present study we propose to represent the EMIC wave occurrence in the dayside magnetosphere with respect to the distance from the magnetopause. This provides a new insight of the EMIC wave distribution in this region and a better understanding of the magnetosphere compression influence on the EMIC wave onset. The THEMIS mission offers the best data set for this: THEMIS instruments observed EMIC emissions in this region and the the orbits of the spacecraft (THEMIS/C, D, E and to a lower extent A) often cross the region of interest, including the magnetopause. The magnetopause position is estimated with the Shue et al. model (1998) and compared to the observed position, when possible. We propose here to present in detail our method and the EMIC occurrence rate in function of their distance to the magnetopause. Our study is based on EMIC waves events by Usanova et al. (2012) based on Flux Gate Magnetometers measurements onboard THEMIS spacecraft. The influence of the solar wind pressure is also discussed.

D3.5-0012-18 COMPETITION BETWEEN PROMPT INJECTION AND LOSS DUE TO INWARD MOTION OF THE MAGNETOPAUSE FOLLOWING CME-SHOCK DRIVEN STORM SUDDEN COMMENCEMENT

Prompt enhancement followed by loss of relativistic electron flux has been reported from Van Allen Probes measurements associated with strong interplanetary shock compression of the dayside magnetopause, for example 8 October 2013, 15 March 2015, 16 July 2017 and 6 September 2017. Acceleration by up to 1 MeV is inferred on less than a drift time scale when magnetopause compression launches a magnetosonic azimuthal electric field impulse tailward. This impulse propagates from the dayside around the flanks accelerating electrons in drift resonance at the dusk flank. Such longitudinally localized acceleration events produce a drift echo signature which is seen with time dispersion corresponding to drift energy. An immediate local response to ULF waves generated by the shock compression is also evident without energy dispersion.

These injection events out-run the magnetopause compression initially, but rarely persist as the magnetopause moves inward, and outward radial diffusion due to enhanced ULF wave power produces loss. MHD-test particle simulations of sample injection events reproduce observed drift echo periods and pitch angles. Competing losses at higher energy and lower L values due to EMIC waves are also examined for the 22 June 2015 storm.

The flux enhancement is short-lived during the Van Allen Probes era because no shock compressions have reached the magnitude of the March 1991 and the Halloween 2003 storms which transported electrons into the slot region (Blake et al., GRL, 1992; Looper et al, GRL, 2005). Prompt acceleration on a drift time scale is contrasted with radial diffusion which smooths out peaks in phase space density resulting from both local heating and drift time scale radial transport.

Looper, M. D., J. B. Blake, and R. A. Mewaldt (2005), Response of the inner radiation belt to the violent Sun-Earth connection events of October-November 2003, Geophys. Res. Lett., 32, L03S06, doi:10.1029/2004GL021502.

University of Iowa, Iowa City, Iowa, United States

It is well known that interplanetary (IP) shocks can result in rapid injection and energization of energetic electrons. One of the strongest of such an interaction occurred during March 1991 with electrons energized to ultra-relativistic energies and being injected into the inner zone. More recently, during September of 2017 two IP shocks in rapid succession impacted the magnetosphere. We report here detailed observation made by the Relativistic Electron and Proton Telescope and the Magnetic Electron and Ion Sensors on board NASA's Van Allen Probes. The resulting rapid response of the energetic electrons showed shock-induced energization as well as drift echoes in the L range of 4 to 5. Increased electron fluxes were seen to energies up to

>5 MeV with moderate spectral hardening post injection. We also discuss Van Allen Probes observations of solar energetic protons energized by the IP shock.

D3.5-0014-18 SIMULATION STUDY ON THE PROMPT ACCELERATION OF RELATIVISTIC ELECTRONS ASSOCIATED WITH THE SOLAR WIND PRESSURE PULSE

Yoshizumi Miyoshi, miyoshi@isee.nagoya-u.ac.jp

Institute for Space-Earth Environmental Research, Nagoya University, Nagoya, Japan Shinji Saito, ssaito(at)nict.go.jp

NiCT, Japan

Yosuke Matsumoto, ymatumot@chiba-u.jp Chiba University, Chiba, Japan

Takanobu Amano, amano@eps.s.u-tokyo.ac.jp University of Tokyo, Tokyo, Japan

Relativistic electron fluxes of the outer radiation belt rapidly change associated with enhancement of solar wind dynamic pressure. Fast mode waves associated with the solar wind pressure pulse produe the fast mode waves through the compression of the dayside magnetopause, and the fast mode wave propagation from dayside to night side are observed. In order to investigate this process in detail, we conduct a code-coupling simulation using the GEMSIS-RB test particle simulation (Saito et al., 2010) and the GEMSIS-GM global MHD magnetosphere simulation (Matsumoto et al., 2010). The results indicate that the fast mode waves propagates from the dayside to nightside, interacting with drifted-electrons. Through the interactions between the fast-mode waves and drifted electrons, rapid accelerations of MeV electrons are observed. The energy spectrum showed that the accelerations occur at wide energy range. We derived theoretically the minimum energy for the acceleration that is determined from the propagation speed of the fast mode waves and the speed of drifted electrons. In the simulation, we observed the electron accelerations above the minimum energy, which is consistent with the theoretical estimation.

D3.5-0015-18 GLOBAL TEST PARTICLE SIMULATIONS OF THE RING CURRENT EVOLUTION DURING 17 MARCH 2013 STORM

Aleksandr Ukhorskiy, ukhorskiy@jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, United States Kareem Sorathia, kareem.sorathia@jhuapl.edu

Maryland, United States

Viacheslav Merkin, slava.merkin@jhuapl.edu JHU/APL, Laurel, Maryland, United States Mikhail Sitnov, mikhail.sitnov@jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, United States John Lyon, lyon@tinman.dartmouth.edu

Dartmouth College, United States

During geomagnetic storms a large volume of ions is transported from the magnetotail deep into the inner magnetosphere leading to ion acceleration to the energies of tens to hundreds keV. Energized ions become the dominant source of plasma pressure in the inner magnetosphere. Pressure gradients drive the ring current system that couples the inner magnetosphere and the ionosphere. Ion acceleration and transport from the tail into the inner magnetosphere can occur at different spatial and temporal scales ranging from global quasi-steady convection to localized impulsive injection events. The goal of this study is to investigate mechanisms and properties of the plasma pressure buildup during 17 March 2013 large magnetic storm. For this purpose we use a global three-dimensional test-particle tracer (CHIMP) integrated into a coupled magnetospheric and ring current model (LFM-RCM). LFM-RCM will be used to compute storm-time electromagnetic fields and plasma flows. Then, global test-particle simulations, initialized in the magnetotail with the properties of computed plasma flows, will be used to analyze ion transport into the inner magnetosphere and to derive the buildup and evolution of storm-time plasma pressure. Specifically, we will address the following science questions: How deep into the inner magnetosphere can localized ion injections penetrate? What are their properties (spatial extent, maximum energy, ion composition)? What are the relative roles of the adiabatic and non-adiabatic mechanisms in the acceleration of different ion species (H, He, O)? How does plasma pressure evolution derived from full-particle trajectories compare with the results of global RCM simulations constrained by the slow-flow and adiabaticity assumptions.

D3.5-0016-18 TRANSIENT FLUXES OF HIGH-ENERGY ELECTRONS IN RADIATION BELTS: RESULTS OF MEASUREMENTS ON "VERNOV" AND "LOMONOSOV" SATELLITES

Mikhail Panasyuk, panasyuk@sinp.msu.ru

Moscow State University, Skobeltsyn Institute of Nuclear Physics, Moscow, Russia

The report presents an overview of the results on measurements of short-time, milliseconds - second duration, electron fluxes of relativistic and subrelativistic energies in various regions of the Earth's radiation zones and outside the area of stable trapping (Transient Relativistic Electrons Precipitation - TREP), the nature of which is associated with both the acceleration processes and the losses of these particles in the inner magnetosphere. The polar LEO satellites «Vernov» and «Lomonosov», launched in 2014 and 2016 respectively, were equipped with various instruments for measuring high-energy radiation, which have a sufficiently good time resolution and sensitivity for measuring radiation fluxes and doses during events of the TREP type. The results of measurements of hot plasma in the geostationary orbit (Eletro -2 satellite) were used to analyze data on TREP in the auroral zone. Along with possible physical models relevant to the nature of the TREP, various effects from both the effects of the TREP on the Earth's atmosphere and the materials and on-board satellite systems are discussed.

D3.5-0017-18 GLOBAL MHD/TEST PARTICLE SIMULATIONS OF RADIATION BELT DYNAMICS DURING EXTREME SPACE WEATHER EVENTS

Ravindra Desai, ravindra.desai@imperial.ac.uk Imperial College London, London, United Kingdom

Jonathan Eastwood, jonathan.eastwood@imperial.ac.uk Imperial College London, London, United Kingdom Lars Mejnertsen, lars.mejnertsen10@imperial.ac.uk

Blackett Laboratory, Imperial College, London, United Kingdom Joe Eggington, j.eggington17@imperial.ac.uk

Blackett Laboratory, Imperial College, London, United Kingdom

The Van Allen radiation belts respond dynamically to solar wind conditions and present specific difficulties to Space Weather modelling efforts due to the range of scales involved. For example, radiation belt populations can be strongly affected by kinetic effects which can in turn be driven by large-scale magnetospheric compressions and reconfigurations. Extreme magnetospheric behaviour also results in the diffusion theory currently used to model the radiation belts, rapidly diverging from the observed physical processes. To address this challenge, we employ the 3D MHD simulation code, Gorgon (Mejnertsen et al., 2018), coupled to a test particle simulation code. The MHD setup is used to represent the global magnetosphere through the implementation of a dipole field subjected to inflowing plasma, parametrised according to upstream solar wind measurements. Large numbers of test-particles are then spawned and traced through the time-dependent MHD fields to directly model radiation belt behaviour. We present results on the evolution of these simulated populations during scenarios representative of extreme Space Weather events where one or more Interplanetary Coronal Mass Ejections impact upon the magnetosphere. These studies inform how non-diffusive processes can lead to large flux dropouts and the rapid formation of new radiation belt populations.

D3.5-0018-18 ON THE PARAMETERS AFFECTING OBSERVATIONS OF ELECTRON FLUX OSCILLATIONS IN RESPONSE TO BROADBAND ULF WAVES

Theodore Sarris, tsarris@ee.duth.gr

Democritus University of Thrace, Xanthi, Greece Xinlin Li, lix@lasp.colorado.edu

University of Colorado Boulder, Boulder, Colorado, United States

We investigate the parameters affecting the appearance and amplitudes of electron flux oscillations, which appear under the effect of Ultra Low Frequency (ULF) fluctuations in the magnetosphere. To this direction, particle tracing simulations are conducted through a parametric study. It is found that the width in energy of electron energy channels are a critical parameter, with narrower energy channels enabling the observation of higher amplitude flux oscillations; this could explain why such features were not routinely observed before the Van Allen Probes era, except for large-amplitude drift echoes following a storm or substorm, as past spacecraft missions generally had lower energy resolution. Flux oscillations are also governed by the local gradient of the Phase Space Density, with steeper gradients leading to higher flux oscillations. A third parameter is the power of ULF wave electric and magnetic fluctuations, with higher field amplitudes leading to higher flux oscillations. Finally, the effects of azimuthal wave number, field power spectrum and ULF wave azimuthal localization are investigated. Such effects are quantified and parameterized.

D3.5-0019-18 RESONANT AND NON-RESONANT WAVE-PARTICLE ENERGIZATION IN EARTH'S RADIATION BELTS

Frederick Menk, fred.menk@newcastle.edu.au

University of Newcastle, Australia, New South Wales, Australia Colin Waters, colin.waters@newcastle.edu.au

University of Newcastle, Australia, NSW, Australia Asif Shah, asif.shah@uon.edu.au

University of Newcastle, Australia, Callaghan, Australia Murray Sciffer, murray.sciffer@newcastle.edu.au University of Newcastle, New South Wales, Australia

Earth's Van Allen radiation belts were discovered almost six decades ago and are responsible for much of what we call space weather. However, their formation, dynamics and consequences are still not clearly understood. A critical question concerns how radiation belt electrons and ions are accelerated to energies which may damage satellites and other infrastructure. Several satellite missions and many modelling efforts have been devoted to this problem. It seems clear the Ultra-low Frequency (ULF) plasma waves play an important role. Here we describe a model of ULF wave propagation in Earth's magnetosphere, incorporating realistic ionosphere boundary conditions, interacting with test particles in the radiation belt. Our model parameters are referenced to actual in situ particle and wave observations, and incorporate off-equatorial particle dynamics. We find that internal energization of equatorially mirroring electrons via non-resonant and resonant interactions with low wave number ULF waves can explain these observations. The amount of energization depends upon the ionospheric conductance and wave parameters such as the frequency, wave mode and wave number. Such non-resonant interactions and ionospheric boundary conditions have not been considered previously but play an important role in particle energization.

D3.5-0020-18 SPATIAL CHARACTERIZATION OF RELATIVISTIC ELECTRON ENHANCEMENTS IN THE EARTH'S OUTER RADIATION BELT DURING THE VAN ALLEN PROBES ERA

Using data from the Van Allen Probes ECT-REPT instrument we have identified 76 relativistic electron enhancement events in the outer radiation belt that occurred between 2012 and 2017 at different L values between L = 2.5 and L = 6.0. We have classified the events according to their characteristic radial propagation, temporal evolution, and flux response at different energy channels ranging from 1.8 MeV to 6.3 MeV and found that enhancement events can be grouped by the "shape" of their spatiotemporal evolution. Using OMNI data, we have studied the solar wind parameters for the events and we have found that, when grouped, events in a group share similar properties in the evolution of fluxes and characteristic solar wind parameters, suggesting that different physical mechanisms play predominant roles for different events. To supplement our study, we have used > 2 MeV electron fluxes at geostationary orbit as measured by the GOES 13 and 15 Energetic Particle Sensor (EPS) instrument to compare our results with the geostationary orbit. We discuss the conditions under which GOES data might be used to predict fluxes at the hearth of the radiation belt and vice-versa.

D3.5-0021-18 RELATIVISTIC ELECTRON FLUXES AND MAGNETOSPHERIC MAGNETIC FIELD DYNAMICS DURING STRONG GEOMAGNETIC STORMS IN 2015

Solar wind pressure pulses and interplanetary magnetic field variations play the crucial role in the outer Earth's radiation belt dynamics. Unfortunately, the physical mechanisms that control the loss and acceleration of the magnetospheric energetic electrons are still not quite understood. In this study we compared and contrasted some features of relativistic electron flux dynamics during two largest geomagnetic storms in 2015 (17-18 March and 22-23 June) having the similar Dst-variations profiles and amplitudes (200 nT) but accompanied by different conditions in the interplanetary space. Analysis of experimental data from Van Allen Probes (RBSP), GOES, Electro-L, POES, Meteor-M, SAC-D and Jason-2 satellites was combined with magnetic field measurements on-board RBSP satellites and calculations on the base of the A2000 model of the magnetosphere. Multi-satellite observations at GEO and LEO show the dramatic changes in the MeV electron populations during the main phase of the magnetic storms. We have found that solar wind and IMF variations are responsible for large-scale magnetospheric current system changes that reveal themselves in the different dynamics of the relativistic electron fluxes during two major storms occurring in 2015.

D3.5-0022-18 MEASUREMENTS OF ENERGETIC ELECTRONS AND PROTONS ABOARD A CUBESAT ON LOW EARTH ORBIT: AALTO-1 / RADMON

Rami Vainio, rami.vainio@utu.fi University of Turku, Turku, Finland Aalto-1/RADMON

H.-P. Hedman, E. Hæggström, A. Ilmanen, M. Lindroos, M. Määttänen, P. Niemelä, J. Peltonen, J. Pentikäinen, J. Pesonen, J. Praks, A. Punkkinen, R. Punkkinen, T. Säntti, R. Vainio,

E. Valtonen

Aalto-1, a three-unit CubeSat launched to Sun-synchronous Low Earth Orbit on 23 June 2017, is Finland's first satellite in orbit. It carries a payload consisting of three state-of-the-art instruments: a hyperspectral camera, a Plasma Brake for deorbiting demonstration, and a radiation monitor (RADMON) measuring the charged particle radiation in orbit. RADMON is sensitive to >10 MeV protons and >2 MeV electrons. As Aalto-1 spacecraft is still in a tumbling mode, RADMON is rapidly scanning directions in the sky allowing one to generate an omni-directional flux measurement from the counting rates of the detector.

We will present an overview of the first months of RADMON measurements in space. In addition to stably trapped electrons and protons in the Earth's radiation belts, RADMON observes quasi-trapped electron populations, which have been scattered to the drift loss cone and are en route to be precipitated in the atmosphere. In the first half of September, RADMON also observed a solar proton event, which was among the strongest ones in the present solar activity cycle and led to several space weather effects in orbit, including spontaneous reboots of the on-board computer of Aalto-1. During the late phase of the solar event, RADMON also observed a relativistic electron precipitation event, where the disturbed magnetospheric conditions led to loss of trapped electrons to the atmosphere.

D3.5-0023-18 OBSERVATION ON IMPULSE ELECTRIC FIELD INDUCED BY INTERPLANETARY SHOCK

Wenlong Liu, liuwenlong@buaa.edu.cn Beihang University, Beijing, China Dianjun Zhang, diandian@buaa.edu.cn Beihang University, Beijing, China

We investigate the characteristics of impulsive electric field in Earth's magnetosphere associated with induced by interplanetary shocks based on Van Allen Probes measurements from January 2013 to July 2016. Our results show that the electric field impulse is induced by the global compression by the shock and mostly in the azimuthal direction. The amplitude of the initial electric field impulse is positively correlated with the jump of dynamic pressure across the shock in the dayside. The rising time of the impulse is likely related to the changing rate of dynamic pressure of the solar wind, Pd and SYM-H index. It is thus suggested that the first period of the impulse is likely directly controlled by the external solar wind parameters instead of any internal eigen-period of the magnetosphere, and finite changing rate of Pd should be considered in the study of the interaction between solar wind and magnetosphere.

D3.5-0024-18 THE CONTRIBUTION OF ULF-VLF WAVE MECHANISMS TO THE APPEARANCE OF RELATIVISTIC ELECTRONS IN THE OUTER RADIATION BELT DURING MAGNETIC STORM AND WITHOUT IT

Vladimir Belakhovsky, belakhov@mail.ru

Polar Geophysical Institute, Russian Academy of Sciences, Apatity, Russia Viacheslav Pilipenko, pilipenko_va@mail.ru

Mark Engebretson, engebret@augsburg.edu

Augsburg College, Minneapolis, Minnesota, United States

In this study we estimate a possible contribution of ULF and VLF mechanisms to the electron acceleration up to relativistic energies. We analyze storm and non-storm periods during high solar wind streams. GOES satellites data are used to describe the electron fluxes (from 40 keV to > 2 MeV), and magnetic field variations. To characterize the magnetospheric wave activity in the Pc5 frequency range (1-7 mHz) the ground ULF index is used. The VLF data from RBSP satellite and Halley Bay station (Antarctica) are used as the chorus proxy in the magnetosphere. Analysis of several typical events demonstrates that the rate of the electron flux increase does not depend on the geomagnetic storm intensity and a substantial increase can occur even without geomagnetic storm. Two necessary conditions for the substantial intensification of relativistic electron fluxes have been found: an occurrence of high-speed solar wind stream and a prolong substorm activity. A good correspondence between the periods with the high solar wind speed and growth of the relativistic electron fluxes with a 1-2 days delay confirms the notion on important role of the electron drift resonance with ULF waves in electron energization. This resonant interaction leads to a preliminary electron acceleration up to sub-relativistic energies upon the radial diffusion deep into the magnetosphere. According to the RBSP satellite data a substantial growth of magnetospheric VLF activity occurs during approximately one day after the injection of seed electrons (50-100 keV). Supposedly, VLF emissions energize pre-accelerated electrons to relativistic energies.

D3.5-0025-18 MULTIPOINT SPACECRAFT OBSERVATIONS OF LONG-LASTING PC4 PULSATIONS IN THE DAYSIDE MAGNETOSPHERE: THE PARTICLES SIGNATURES

Galina Korotova, gkorotov@umd.edu

University of Maryland, College Park, United States David Sibeck, david.g.sibeck@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States Rob Redmon, rob.redmon@noaa.gov

NOAA National Geophysical Data Center, Boulder, Colorado, United States Vassilis Angelopoulos, vassilis@ucla.edu

University of California, Los Angeles, Los Angeles, California, United States

We use magnetic field and plasma observations from the Van Allen Probes spacecraft to study the spatial and temporal characteristics of long-lasting Pc4 pulsations during six orbits in the dayside magnetosphere. We investigated the nodal structure of the waves. When they exhibit a strong compressional component, the spacecraft observe meridional sloshing of the node. When the node's motion attains maximum amplitude, spacecraft off the equator observe one peak while spacecraft at the equator observe two compressions per cycle. The particles observed by Van Allen Probes, THEMIS A and GOES 13 and 15 over a broad range of energies from tens of eV to 2 MeV exhibit regular periodicity with periods corresponding to the ULF magnetic field waves. We attribute the Pc4 pulsations to a drift bounce resonance mechanism.

D3.5-0026-18 THE DYNAMICS OF RELATIVISTIC ELECTRON IN THE SLOT REGION BETWEEN THE VAN ALLEN RADIATION BELTS

XiaoChao Yang, yxc@nssc.ac.cn

Chinese Academy of Sciences, Beijing, China

Using multi-satellite measurements, the dynamics of relativistic electrons in the slot region are investigated from 2000 to 2011. The dependences of relativistic electron enhancements in the slot region on interplanetary and magnetospheric conditions are researched. It is resulted that the relativistic electron enhancements in the slot region occurred under remarkable interplanetary and magnetospheric conditions. A uniquely strong and long-lived relativistic electron slot region refilling event from November 2004 to January 2005 is studied especially. Both empirically modeled and observationally estimated plasmapause locations demonstrate that the plasmasphere eroded significantly prior to the enhancement phase of this event. The estimated diffusion coefficients indicate that the radial diffusion due to ULF waves is insufficient to account for the observed enhancement of slot region electrons. However, the diffusion coefficients evaluated using the distribution of chorus wave intensities derived from low-altitude POES electron observations indicate that the local acceleration induced by chorus could account for the major feature of observed enhancement outside the plasmapause. When the plasmasphere recovered, the refilled slot region was enveloped inside the plasmapause. In the plasmasphere, while the efficiency of hiss scattering loss increases by including unusually low frequency hiss waves, the interaction with hiss alone cannot fully explain the decay of this event, especially at higher energies, which suggests that EMIC waves contribute to the relativistic electron loss process at such low L-shells for this refilling event.

D3.5-0027-18 SUPRATHERMAL FE+ DISCOVERED IN AND NEAR EARTH'S MAGNETOSPHERE

Applied Physics Laboratory Johns Hopkins University, Laurel, Maryland, United States

Suprathermal (87-212 keV/e) singly charged iron, Fe+, has been observed in and near Earth's equatorial magnetosphere using long-term (1995-2015) Geotail/STICS data. Fe+ is rare compared to dominant suprathermal solar wind and ionospheric origin heavy ions, appearing to be positively associated with both geomagnetic and solar activity. The relevance of four candidate sources are compared: charge exchange of nominal solar wind Fe+ 7, solar wind transported inner source pickup Fe+, outflow of ionospheric Fe+ (observed at up to 1000 km), and/or lunar pickup Fe+. Using 26% of low-to-moderate geomagnetic activity level magnetospheredominated data, we show that during those times solar wind Fe charge exchange secondaries are not an obvious Fe+ source. Earth flyby and cruise data from Cassini/CHEMS, a nearly identical instrument, indicate that inner source pickup Fe+ is not present at suprathermal energies. Our observations indicate lunar components, but no lunar Fe+. Therefore, it appears that ionospheric Fe+ constitutes at least an important portion of Earth's suprathermal Fe+, comparable to our observations at Saturn where suprathermal Fe+ has also been observed.

D3.5-0028-18 RELATIVISTIC OUTER RADIATION BELT ELECTRONS OUTWARD DIFFUSED DUE TO ULF WAVES IN THE PC5 FREQUENCY RANGE OBSERVED DEEP IN MAGNETOSPHERE.

Livia Alves, liviarib@gmail.com

INPE - National Institute for Space Research, Sao Jose Dos Campos, Brazil INPE Radiation Belt group and collaborators

Paulo Ricardo Jauer, Ligia Alves da Silva, Graziela B. D. da Silva, Jose P. Marchezi, Vitor M. Souza, Marlos R. da Silva, Marcelo B. de Padua, Claudia Medeiros, David G Sibeck, Shrikanth G Kanekal, John R Wygant

Field line resonances in the magnetic pulsations frequency range named Pc 5 are known to be oscillations of magnetospheric field lines. It is observed as a combination of three fundamental modes, namely poloidal, toroidal and compressional. Such a disturbance may have their energy sources arising from external high dynamic pressure solar wind pulsation that induces waves in the day-side sector magnetosphere. Also, low-frequency instabilities of the ring current ions are candidates to promote ultra-low frequency (ULF) waves in the Pc5 frequency range. The toroidal mode is mainly due to upstream solar wind disturbances and it is observed in the dawndusk flanks, while compressional and poloidal modes can be originated from local disturbances and they can be observed everywhere in the night side sector. On July 19, 2016, at 2309 UT, the ground magnetometers registered a sudden impulse due to an interplanetary coronal mass ejection (ICME) shock arrival. The solar wind parameters registered by ACE satellite showed a sharp increase in the density and velocity, reaching 40 cm-3 and 450 km/s, respectively. GOES15(13) satellite that was at noon-to-dusk (dusk-to-midnight) sector noted a major (minor) increase in the magnetic field, followed by oscillations in the horizontal magnetic field. Data from plasma parameters measured by the Themis-D satellite agreed that the geomagnetic field was compressed, the results from empirical models lead to magnetospheric stand-off position compressed to 6.5 Re. In the following, results from the instruments on board the Van Allen Probes A, which traveled from midnight to dawn sector observed a relativistic electron flux dropout two orders of magnitude long, occurred throughout 3 hours following the shock arrival. The ULF waves in a Pc5 frequency range are observed both at the location of the satellite and on the ground, the different magnetometers show that ULF waves reached midi-to-low latitudes with considerable power spectral densities. Regarding the ULF waves are known to contribute with relativistic particles outward diffusion in the Van Allen belts, including through magnetopause shadowing events, we investigate the ability of the different solar wind parameters to be energy sources to generate Pc5 frequency waves in different modes deep inside the magnetosphere.

D3.5-0029-18 OBSERVATION OF ION INJECTION TRIGGERED EMIC WAVES IN THE EARTH'S MAGNETOSPHERE

We present a case study and statistics of electromagnetic ion cyclotron (EMIC) waves triggered solely due to substorm injected anisotropic ions using Van Allen Probes observations from 2015. We discuss in detail the EMIC wave event that occurred on 09 August 2015. The EMIC wave onset was associated with the arrival of anisotropic ions along with a dip in the magnetic field. The time at which the injected ions are observed directly corresponds to the onset of EMIC waves at the location of the Van Allen Probe A (L=5.5 and 18:06 MLT). The GOES and LANL geosynchronous spacecraft observed the injected and westward (eastward) drifting ions (electrons) at various local times. Using the observed arrival times of dispersive injections at the LANL and GOES spacecraft, we trace the particles back in a dipolar magnetic field to their injection location centered near 20:00 MLT. GOES and ground magnetometer responses confirm substorm onset at approximately the same local time. The arrival of anisotropic ions together with the concurrent and co-located decrease in the magnetic field favored the growth of the EMIC wave instability based on quasi-linear theory analysis. Further, statistical analysis will give deeper insight on the magnetic field and particle behavior during these events and their local time distribution.

D3.5-0030-18 THE JOINT AND COMPETITIVE EFFECTS OF WHISTLER MODE WAVES AND FAST MAGNETOSONIC WAVES ON RADIATION BELT ELECTRONS

Liuyuan Li, lyli_ssri@buaa.edu.cn Beihang University, Beijing, China Jiang Yu, 924831347@qq.com Beihang University, Beijing, China

Using the Van Allen Probe long-term (2013-2015) observations and quasi-linear simulations of wave-particle interactions, we examine the joint and competitive effects of whistler mode waves (chorus and hiss) and magnetosonic (MS) waves on energetic (<0.5 MeV) and relativistic (>0.5 MeV) electrons inside and outside the plasmasphere. Although whistler mode chorus waves and MS waves can singly or jointly accelerate electrons from the hundreds of keV energy to the MeV energy in the low-density trough, most of the relativistic electron enhancement events are best correlated with the chorus wave emissions outside the plasmapause. Inside the plasmasphere, intense plasmaspheric hiss can cause the net loss of relativistic electrons via persistent pitch angle scattering, regardless of whether MS waves were present or not. The intense hiss waves not only create the energy-dependent electron slot region but also remove a lot of the outer radiation belt electrons when the expanding dayside plasmasphere frequently covers the outer zone. Since whistler mode waves (chorus or hiss) can resonate with more electrons than MS waves, they play dominant roles in changing the outer radiation belt and the slot region. However, MS waves can accelerate the energetic electrons below 400 keV and weaken their loss inside the plasmapause. Thus, MS waves and plasmaspheric hiss generate different competing effects on energetic and relativistic electrons in the high-density plasmasphere.

D3.5-0031-18 SOLAR CELL DEGRADATION OF THE ARASE SATELLITE IN THE PROTON RADIATION BELT

Japan Aerospace Exploration Agency (ISAS/JAXA), Kanagawa, Japan

Solar cells mounted on any satellites are susceptible to effect of abundant space radiations. Solar cells on the Arase satellite orbiting in the inner magnetosphere degrade due to trapped protons with energies of more than 6 MeV. The Arase satellite was launched on December 20, 2016 for studying the radiation belt dynamics. However, it observes ions with energies of less than 180 keV, and no MeV ions are measured. In the current study, we try to deduce spatial distribution of the radiation belt protons from analysis of output variation of the SAP (Solar-cell Array Panel) of the Arase satellite. The Van Allen Probes measure no energetic protons between 1 and 20 MeV and our analysis gives a unique information of radiation belt protons around 8 MeV. Analysis of the SAP data showed a clear degradation that could be attributed to trapped MeV protons. Radiation dosage was determined from Voc (Open circuit voltage) variation of the solar cells and we made comparison with those expected from various distribution models (AP8MAX, AP9MEAN and CRRESPRO quiet) of trapped protons. We found a little difference in expected radiation dosage from the model calculations. We introduce modified models to minimize the difference and discuss the spatial distribution of trapped MeV protons.

D3.5-0032-18 ON THE EFFECT OF GEOMAGNETIC STORMS ON RELATIVISTIC ELECTRONS IN THE OUTER RADIATION BELT: VAN ALLEN PROBES OBSERVATIONS

Pablo Moya, pablo.moya@ug.uchile.cl Universidad de Chile, Santiago, Chile Victor Pinto, victor.pinto@gmail.com

UCLA, Los Angeles, California, United States David Sibeck, david.g.sibeck@nasa.gov

LASP / University of Colorado, Boulder, Colorado, United States

Using Van Allen Probes Energetic Particle, Composition, and Thermal Plasma-Relativistic Electron-Proton Telescope (ECT-REPT) observations, we performed a statistical study on the effect of geomagnetic storms on relativistic electrons fluxes in the outer radiation belt for 78 storms between September 2012 and June 2016. We found that the probability of enhancement, depletion, and no change in flux values depends strongly on L shell and energy. Enhancement events are more common for 2 MeV electrons at L 5, and the number of enhancement events decreases with increasing energy at any given L. However, considering the percentage of occurrence of each kind of event, enhancements are more probable at higher energies, and the probability of enhancement tends to increases with increasing L shell. Depletion are more probable for 4-5 MeV electrons at the heart of the outer radiation belt, and no-change events are more frequent at $L <$ 3.5 for E 3 MeV particles. Moreover, for $L > 4.5$ the probability of enhancement, depletion, or no-change response presents little variation for all energies. Because these probabilities remain relatively constant as a function of radial distance in the outer radiation belt, measurements obtained at geosynchronous orbit may be used as a proxy to monitor $E \geq 1.8$ MeV electrons in the outer belt.

D3.5-0033-18 CHARGED PARTICLE NONLINEAR BEHAVIOR IN ULTRALOW FREQUENCY WAVES

Xuzhi Zhou, xuzhi.zhou@gmail.com Peking University, Beijing, China

In Earth's inner magnetosphere, electromagnetic waves in the ultralow frequency (ULF) range are believed to play an important role in accelerating and diffusing charged particles via a resonant process named drift resonance. In the conventional drift resonance theory, a linearization approach is used to assume a small wave-particle energy exchange so the particle trajectories remain unperturbed. For ULF waves with large amplitudes and/or long durations, however, the conventional theory becomes less accurate since the particle trajectories can be highly modified by the waves. Here we extend the conventional drift resonance theory into the nonlinear regime, and predict from the extended theory the observable signatures of nonlinear wave-particle interactions such as rolled-up structures in the particle energy spectrum. After considering its manifestation in particle data with finite energy resolution, we compare these predicted signatures with observations from Van Allen Probes. The good agreement between them validates the nonlinear theory, and therefore provides an improved understanding of particle dynamics and interactions with ULF waves in the inner magnetosphere.

The solar structures that eventually reach the Earth, causing intense geomagnetic storms, modify the geomagnetic field where the electrons are trapped in the Van Allen radiation belts. The way in which intense geomagnetic storms may affect the variability of the relativistic electron fluxes in the radiation belts is not completely understood, and here we address this point. We used data from

the Relativistic Electron-Proton Telescope (REPT) instrument aboard NASA's twin Van Allen Probes. To identify and quantize the intensity of storms we used the symmetric index, SYM-H, and to identify the cause of the geomagnetic storms, we used data from the solar wind: speed, dynamic pressure and magnetic field as measured by the Advanced Composition Explorer (ACE), and Deep Space Climate Observatory (DSCOVR) satellites, which are orbiting the gravitational balance point between the Sun and the Earth. The comparison of electron fluxes in the outer radiation belts with Interplanetary Medium data showed the importance of the interplanetary magnetic field (IMF) Bz component (in Geocentric Solar Magnetospheric - GSM - coordinates) on the trapped electron flux during the occurrence of geomagnetic storms. Negative values of the IMF Bz component interconnect the interplanetary and geomagnetic fields, allowing particles to escape throughout the magnetosphere to the solar wind, causing decreases in the electron flux in periods that coincide with negative IMF Bz values. This suggests that the particles' flux in the radiation belts depends on the IMF Bz component the same way it does for the occurrence of intense geomagnetic storms. It is necessary a deeper investigation to understand the contribution of the different mechanisms of the internal and external phenomena of the Earth's magnetosphere to fully understand and describe the behavior of trapped particles.

D3.5-0035-18 MATHEMATICS OF IONIC CHARGE STATE DISTRIBUTIONS IN THE EARTH'S RADIATION BELTS

Walther Spjeldvik, wspjeldvik@weber.edu

Weber State University, Ogden, Utah, United States Inacio Martin, martin@ita.br

Instituto Tecnologico de Aeronautica, Sao Jose Dos Campos, Brazil Anatoly Gusev, ganso@pochta.ru

Space Research Institute of the Russian Academy of Sciences (IKI), Moscow, Russia

From a mathematical point of view there are at least two operational techniques for theoretically assessing the distribution over charge state for ionic species confined in the Earth's radiation belts: [1] Direct computation via coupled ionic distribution functions (e.g., Spjeldvik and Fritz, 1978; Spjeldvik, 1979) and [2] Recursive computation via normalized ionic distributions coupled with an overall summed ionic/isotopic species equation, thus yielding an over-determined system of equations (e.g., Spjeldvik, 1990). The latter technique held the promise of usefulness for any ionic species. However, in applications a numerical instability has been discovered which at first threatened the useability of the method. This paper reports an approximate method by which the numerical stability is restored, and it amounts to an alternate approximate evaluation of the charge state averaged radial diffusive transport coefficient. The mathematical algorithm is reviewed and the stability restoring approximation is explored. Application is made in the adiabatic invariant formulation of the radiation belt source/transport/loss description. [References: Spjeldvik and Fritz, J. Geophys. Res., 83, 1583-1594; Spjeldvik, Sp. Sci. Rev., 23, 499-538, 1979; Ann. Geophys., 8, 59-68, 1990].

D3.5-0036-18 ENERGETIC PARTICLE DYNAMICS NEAR CALLISTO

Lucas Liuzzo, lucas.liuzzo@eas.gatech.edu

Georgia Institute of Technology, Atlanta, Georgia, United States
Sven Simon, sven.simon@eas.gatech.edu

Georgia Institute of Technology, Atlanta, Georgia, United States

Callisto's magnetic environment is characterized by a complex admixture of induction signals from its conducting subsurface ocean, the interaction of corotating Jovian magnetospheric plasma with the moon's ionosphere and induced dipole, and the non-linear coupling between these effects. In contrast to other Galilean moons, ion gyroradii near Callisto are comparable to its size, requiring a kinetic treatment of the interaction region near the moon. This is especially true for energetic particles, whose gyroradii may exceed Callisto's radius by orders of magnitude. We therefore use electromagnetic fields calculated by a hybrid (kinetic ions, fluid electrons) model to investigate energetic particle dynamics and loss processes, as well as their effect on Callisto's environment. From this, we are able to provide a map of global energetic particle precipitation onto Callisto's surface, which may be an important contribution to the generation of its atmosphere.

D3.5-0037-18 CHARGE STATES OF KEV AND MEV HEAVY IONS CONFINED IN THE EARTH'S MAGNETOSPHERE

Walther Spjeldvik, wspjeldvik@weber.edu

Weber State University, Ogden, Utah, United States Inacio Martin, martin@ita.br

Instituto Tecnologico de Aeronautica, Sao Jose Dos Campos, Brazil
Anatoly Gusev, ganso@pochta.ru

Space Research Institute of the Russian Academy of Sciences (IKI), Moscow, Russia

Heavy ions are present throughout the Earth's magnetosphere in measurable quantities. The question about their origin has long been fairly open, but in a recent paper in JGR-blue, Christon et al. (JGR-blue, Nov. 2017) using S/C Geotail data obtained over a 21-year time span in the outer magnetosphere (where 9 Re R 30 Re) argue that ions of iron most likely stem from the Earth's upper atmosphere where they have their origin in the vaporized meteor metallic gas. Earlier in the space era, Spjeldvik and Fritz (1978a,b) presented Helium ion observations that could have their origin either from interplanetary space (e.g., the sun), and Spjeldvik and Fritz (1978c) computed charge state distributions of ionized atomic oxygen assuming either a solar source (thus with the ion source mostly in the sixth ionic charge state) or an atmospheric source (with the ions source mostly in the first ionic charge state), and they demonstrated that given enough residence (magnetic confinement) time in the magnetosphere - collisional processes tends to redistribute the oxygen ions amongst the available charge states yielding an equilibrium charge state distribution that is fairly independent of the ion source charge state; similar physics also likely works on other ion species. In this work, ions of carbon and iron are considered from an overall distribution evolution point of view at radial distance considered for stable confinement, at geomagnetic L-shells 7, and like the situation from magnetically confined oxygen ions, carbon and iron ions in that inner region also evolve towards radiation belt distributions that obscure the charge state characteristics of their sources. Classic diffusion theory is applied in adiabatic invariant space yielding fluxes of carbon and iron ions distributed over ionic charge states, magnetic moment (first adiabatic invariant), and radial locations from the Earth; the results are also converted to energy spectra. Boundary conditions for the numerical simulations are taken from different spacecraft measurements, and the computed ion distributions at KeV and MeV energies are presented for representative extended quiescent geophysical conditions. The simulations technique can be made time-dependent, and so extended to simulate ion injection events during geomagnetic disturbances, such as magnetic storms, as has earlier been done by the present author for Hydrogen ions.

D3.5-0038-18 MULTI-SATELLITE MEASUREMENTS OF THE OUTER RADIATION BELT DURING GEOMAGNETIC STORMS: VAN ALLEN PROBES AND PROBA-V OBSERVATIONS

Graciela López Rosson, graciela.lopezrosson@uclouvain.be

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States Viviane Pierrard, viviane.pierrard@oma.be

Royal Belgian Institute for Space Aeronomy, Brussels, Belgium

The response of the inner magnetosphere to geomagnetic activity and solar wind conditions is still not fully understood. For example, electron fluxes in the outer radiation belt can be enhanced or depleted depending on the energy of the particles, and the phase or driver of a geomagnetic storm, and solar wind conditions. The Van Allen Probes Relativistic Electron-Proton Telescope (REPT), and the Energetic Particle Telescope (EPT) on board the ESA satellite PROBA-V together provide simultaneous high-resolution measurements of the relativistic electrons of the outer radiation belt at different orbits. Here we analyze MeV electron differential and integrated fluxes measured by the Van Allen Probes and PROBA-V spacecraft at the same L-shell during geomagnetic storm events occurred during 2014 and 2015, comparing similar measurements at different orbit altitudes.

D3.5-0039-18 EXTREME ELECTRON FLUXES DURING SPACE WEATHER EVENTS IN THE RADIATION BELTS AND SOUTH ATLANTIC ANOMALY: EXTREME VALUE ANALYSIS USING DATA FROM THE ARGENTINE SAC-D SPACECRAFT

Vanina Lanabere, vaninalanabere@gmail.com Universidad de Buenos Aires, Argentina, Argentina Sergio Dasso, sdasso@iafe.uba.ar

Instituto de Astronomía y Física del Espacio (IAFE), Buenos Aires, Argentina

The van Allen radiation belts are regions in the terrestrial space environment that present ions and energetic electrons trapped by the geomagnetic field. Since the geomagnetic field in the South Atlantic Anomaly (SAA) region is relatively weakest over the western South Atlantic Ocean, trapped energetic particles of the radiation belts can reach closer distances to the Earth than energetic particles in other regions. The electron population in the outer radiation belt can reach energies mainly in a range from some keV to tens of MeV. During a geomagnetic storm, the population of energetic particles in the radiation belts can significantly increase. The increase of fluxes of these energetic particles has a major interest for Space Weather, mainly because the impact on satellites and human activities in space. The specific effects and impacts will depend upon satellite orbit and the energy of the energetic particles. A detailed knowledge of the highest energies reached as well as the extreme fluxes and frequencies, is essential for the specific design of satellites and for the development of satellite technologies. The main purpose of the present work is to study the extreme electron fluxes in the terrestrial outer radiation belt (L 3-6) and in the SAA, for an energy range between 0.249 MeV and 1.192 MeV at 660 km of altitude above the Earth surface, using measurements made by the detector ICARE-NG/Carmen-1 on board the polar Argentinean satellite SAC-D. A statistical analysis based on the peaks over threshold approach was implemented for the daily average electron fluxes, and we present results of its cumulative probability distribution function, showing that it likely has a finite upper limit for a wide range of energies and in different regions.

SPACE PLASMAS IN THE SOLAR SYSTEM, INCLUDING PLANETARY MAGNETOSPHERES (D)

MAGNETOTAIL DYNAMICS AND SUBSTORMS DURING STORM AND NON-STORM TIME (D3.6)

D3.6-0001-18 SUBSTORM ONSET: A SWITCH ON THE SEQUENCE OF TRANSPORT FROM DECREASING ENTROPY TO INCREASING ENTROPY

Chuxin Chen, chuxin@ustc.edu.cn

University of Science and Technology of China, Hefei, China

In this study, we propose a scenario about the trigger for substorm onset. In a stable magnetosphere, entropy is an increasing function tailward. However, in the growth phase of a substorm, a later born bubble has lower entropy than earlier born bubbles. When a bubble arrives at its final destination in the near-Earth region, it will spread azimuthally because of its relatively uniform entropy. The magnetic flux tubes of a dying bubble, which cause the most equatorward aurora thin arc, would block the later coming bubble tailward of them, forming an unstable domain. Therefore, an interchange instability develops, which leads to the collapse of the unstable domain, followed by the collapse of the stretched plasma sheet. We regard the substorm onset as a switch on the sequence of transport, i.e., from a decreasing entropy process to an increasing entropy process. We calculated the most unstable growth rates and the wavelengths of instability, and both are in agreement with observations.

D3.6-0002-18 RESPONSE OF PLASMASPHERIC CONFIGURATION TO SUBSTORMS REVEALED BY CHANG'E 3

Han He, hehan@nao.cas.cn

National Astronomical Observatories, Chinese Academy of Sciences, Beijing, China Team for Chang'e-3/EUVC scientific data analysis

Huaning Wang (National Astronomical Observatories, China), Chao Shen (Harbin Institute of Technology Shenzhen Graduate School, China), Xiaoxin Zhang (National Center for Space Weather, China), Bo Chen (Changchun Institute of Optics, Fine Mechanics and Physics, China), Jun Yan (National Astronomical Observatories, China), Yongliao Zou (National Astronomical Observatories, China), Chunlai Li (National Astronomical Observatories, China), Anders M. Jorgensen (New Mexico Institute of Mining and Technology, USA), Fei He (Institute of Geology and Geophysics, China), Yan Yan (National Astronomical Observatories, China), Xiaoshuai Zhu (National Astronomical Observatories, China), Ya Huang (National Space Science Center, China), Ronglan Xu (National Space Science Center, China)

The Moon-based Extreme Ultraviolet Camera (EUVC) of the Chang'e 3 mission provides a global and instantaneous meridian view (side view) of the Earth's plasmasphere. The plasmasphere is one inner component of the whole magnetosphere, and the configuration of the plasmasphere is sensitive to magnetospheric activity (storms and substorms). However, the response of the plasmaspheric configuration to substorms is only partially understood, and the EUVC observations provide a good opportunity to investigate this issue. By reconstructing the global plasmaspheric configuration based on the EUVC images observed during 20-22 April 2014, we show that in the observing period, the plasmasphere had three bulges which were located at different geomagnetic longitudes. The inferred midnight transit times of the three bulges, using the rotation rate of the Earth, coincide with the expansion phase of three substorms, which implies a causal relationship between the substorms and the formation of the three bulges on the plasmasphere. Instead of leading to plasmaspheric erosion as geomagnetic storms do, substorms initiated on the nightside of the Earth cause local inflation of the plasmasphere in the midnight region.

D3.6-0003-18 SOLAR-WIND MAGNETOSPHERE COUPLING: A GLOBAL PERSPECTIVE OF SUBSTORM ONSET

Miles Bengtson, mibe4496@colorado.edu

University of Colorado Boulder, Boulder, Colorado, United States Katariina Nykyri, nykyrik@erau.edu

Embry-Riddle Aeronautical University, Daytona Beach, Florida, United States Vassilis Angelopoulos, vassilis@ucla.edu

University of California, Los Angeles, Los Angeles, California, United States

We present a case study of the 25 December 2015 substorm which occurred between 08:15 and 08:45 Universal Time. A fortuitous and unique alignment of several independent spacecraft missions near the Earth-Sun line together with ground based measurements, allows a comprehensive and global analysis of the substorm onset. During this interval, fast particle flows and field geometry consistent with magnetic reconnection were detected in the mid-tail region. An ejected plasmoid was observed by the lunar-orbiting ARTEMIS probes and a corresponding dipolarization signature was observed by the THEMIS spacecraft earthward of the reconnection site, which was determined to be approximately -33 RE. Ground signatures indicative of substorm activity were also observed by the THEMIS ground-based observatories during this interval. The MMS probes, which were in the dayside magnetosheath, detected a strong fluctuation in Bz, with a minimum near -35 nT, at 08:00 UT, consistent with the time delay required for propagation from the magnetosheath to the mid-tail. We analyze and discuss these fluctuations and propose that this strong southward component of Bz in the magnetosheath is possibly associated with the substorm trigger. We simulate the entire magnetosphere for this event using the SWMF/BATS-R-US model with a special, high-resolution grid. The simulations qualitatively agree with the observed substorm flows. The results of this work will be highly relevant to future solar wind observation missions, global-scale space weather models, and the ongoing effort to understand how solar wind energy is coupled to the space environment in near-Earth and at lunar distances.

It is known that magnetic field disturbances often appear in the night-side magnetosphere associated with the magnetic dipolarization. The disturbances carry significant energy which is considered to be released by the global configuration change of the magnetosphere, The energy normally directs to the earth in the inner magnetosphere at the several Re distance from the earth. It suggests that the disturbances are generated in the near-earth magnetotail region, presumably about 10 Re distance from the earth. However, it is not still very clear how the magnetic field disturbances are excited and affect the particle motion in the inner magnetosphere.

The Arase (ERG) satellite was launched on December 20, 2016, to investigate the plasma physics in the inner magnetosphere. The energy exchange between particles and fields is one of the major subjects of the Arase project. We are studying the magnetic dipolarization and associated disturbances observed by Arase. The characteristics (compressibility, polarization, propagation direction, and so on) are investigated for typical events to limit the generation mechanism of the disturbances. Very close investigation of the disturbances should lead to the future statistical study, occurrence ratio, distribution and relation with the particle signature.

D3.6-0005-18 GROUND MAGNETIC PERTURBATIONS ASSOCIATED WITH SUBSTORMS, PSEUDO-BREAKUPS, AURORAL STREAMERS AND OMEGA BANDS

Mike Henderson, mghenderson@lanl.gov

Los Alamos National Laboratory, Los Alamos, United States Jesse Woodroffe, jwoodroffe@lanl.gov

Los Alamos National Laboratory, Los Alamos, New Mexico, United States Steven Morley, smorley@lanl.gov

Los Alamos National Laboratory, Los Alamos, New Mexico, United States

Strong magnetic perturbations on the ground are a prime cause of Geomagnetically-Induced Currents (GICs) that can have catastrophic effects on a number of engineered technological systems like power grids, communication lines, railways, and pipelines. In recent years we have learned that the strongest dB/dt signals may be confined to relatively localized regions. We also know that a number of localized auroral phenomena occur during highly disturbed intervals including substorms, pseudo-breakups, auroral streamers, torches and omega bands. Here we examine which of these types of disturbances are most related to the localized dB/dt signals associated with harmful GIC events. Preliminary results indicate that many of the auroral disturbances are capable of producing strong, localized dB/dt. However, during storms and long-lived substorms, the repetitive quasi-periodic evolution of PBIs into streamers, torches and omega bands has the potential to result in sustained long-lived production of strong localized dB/dt. A major implication of this finding is that we need to be able to model flow bursts in the tail in a reasonable way in order to capture much of the strong localized dB/dt activity during storms and substorms.

D3.6-0006-18 INVESTIGATION OF LOW-LATITUDE PI2 PULSATIONS USING CONJUGATE OBSERVATIONS FROM LONGITUDINALLY DISTRIBUTED GROUND NETWORK AND SWARM SATELLITES

Neethal Thomas, neethalmariyathomas@gmail.com

Institute for Space-Earth Environmental Research, Nagoya University, Nagoya, Japan Kazuo Shiokawa, shiokawa@nagoya-u.jp

Institute for Space-Earth Environmental Research, Nagoya University, Nagoya, Aichi, Japan Geeta Vichare, geeta@iigs.iigm.res.in

Indian Institute of Geomagnetism, Navi Mumbai, India

Pi2 pulsations are the ultra-low frequency oscillations of the Earth's magnetic field with frequency 6.6 - 25 mHz, and are commonly observed in association with substorm. At the onset of substorm expansion phase, Pi2s are often observed over a wide range of longitude sector, including daytime at low-latitudes. In the present study, low-latitude Pi2 oscillations are investigated using conjugate observations from Swarm satellites in the topside ionosphere and a dense network of ground stations (within 50° magnetic latitude) distributed over all local time

(LT) sectors. This distinct data set comprising satellite and ground observations from different LT sectors provide a unique opportunity to simultaneously observe day and night Pi2 oscillations from both space and ground. The magnetic field data represented in H, D, Z components (geomagnetic coordinates) at ground and the residual magnetic field at Swarm satellites (obtained by subtracting CHAOS5 geomagnetic field model) represented in compressional, toroidal and poloidal components (field-aligned coordinates) are used in this study. Present study reports the identification of coherent Pi2 oscillations in all the three magnetic field components at satellite and ground during nighttime, with analogous magnetic field components (compressional - H and toroidal - D) observed above and below the ionosphere found to have identical phase relations. The characteristic features of daytime Pi2s were found to be different from that of night time ones, indicating different source mechanism responsible for day and night Pi2s. Present study proposes that, the low-latitude Pi2 pulsations are the manifestation of the dynamical coupling of the ionosphere-magnetosphere system through substorm currents, with oscillating substorm current wedge FACs (field-aligned currents) in the night side and the ionospheric currents in the dayside as the possible source mechanism responsible for low-latitude Pi2 oscillations observed at night and day LTs respectively. The observations will be presented and discussed in view of this model.

D3.6-0007-18 KINETIC FEATURES OF EXPLOSIVE ENERGY CONVERSION AND DISSIPATION IN MAGNETOTAIL DIPOLARIZATIONS

Mikhail Sitnov, mikhail.sitnov@jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, United States Viacheslav Merkin, slava.merkin@jhuapl.edu

Johns Hopkins Applied Physics Laboratory, Laurel, Maryland, United States Barry Mauk, barry.mauk@jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, Maryland, United States

The Earth's magnetosphere is a unique natural laboratory of fully collisionless plasmas. Its magnetotail is particularly significant because it accumulates the energy of the solar wind/magnetosphere interaction and then releases it in the form of substorms, pseudobreakups, bursty bulk flows and dipolarization fronts. The Magnetospheric MultiScale (MMS) mission provides for the first time a critical opportunity to investigate energy conversion in these dipolarization processes in collisionless plasmas, because it enables measurements of 3D vectors of electric and magnetic fields, ion and electron bulk flow velocities, pressure tensor components, and, crucially, their spatial derivatives. However, dissipation in collisionless plasmas cannot be described by the standard resistive MHD parameter, the Joule heating rate, because that fluid parameter cannot distinguish between ion and electron dissipation. Here, using 3D PIC simulations of the magnetotail current sheet, we describe plasma dissipation accompanying tail dipolarization in terms of new kinetic measures different for ions and electrons: the pressure dilatation, as well as the double contraction of deviatoric pressure tensor and traceless strain-rate tensor. Simulations show signatures of dissipation both near new X-lines and near dipolarization fronts, which may form before the magnetic topology change. Dissipation patterns are different for ions and electrons and they reveal characteristic striation features on the scales of the lower hybrid drift instability. We also discuss manifestations of these theoretically predicted features in MMS observations.

D3.6-0008-18 PROPERTIES AND ORIGIN OF RAPID FLUX TRANSPORT EVENTS IN THE MAGNETOTAIL

Andrei Runov, arunov@igpp.ucla.edu

University of California, Los Angeles, Los Angeles, California, United States Vassilis Angelopoulos, vassilis@ucla.edu

University of California, Los Angeles, Los Angeles, California, United States Anton Artemyev, aartemyev@igpp.ucla.edu

Peking University, Beijing, China

It has been noticed that the magnetotail flux transport response to a steady solar wind driving is impulsive. The pulses of magnetic flux transport at rates exceeding 2 mV/m are known as rapid flux transport (RFT) events. We statistically studied earthward RFT events observed by THEMIS probes in the near-Earth plasma sheet at radial distances 7 < R < 25 RE and tailward RFT events observed by ARTEMIS probes in the magnetotail at distances R 60 RE. We compared average plasma parameters such as density, ion and electron temperatures and pressures, their dependencies on magnetic and electric fields, and average energy spectra at both locations. We found that the ion average temperatures and spectral slopes within RFTs at R 60 RE are close to those in RFTs observed at 15 < R < 25 RE. Assuming the plasma sheet pressure balance, the average RFT ion temperature corresponds to the lobe field BL 20 nT. This leads us to suggest that the ion population within the RFTs originated in the mid-tail plasma sheet at R 30 RE. Whereas particle populations in earthwrard RFTs observed at R < 15 RE gain energy from being convected towards the dipole, particles in tailward RFTs propagated to the ARTEMIS location without undergoing energy changes.

D3.6-0009-18 PARTICLE BEHAVIOR NEAR THE DIPOLARIZATION FRONT

Suiyan Fu, suiyanfu@pku.edu.cn Peking University, Beijing, China Duo Zhao, zhaoduo@pku.edu.cn Peking University, Beijing, China Weijie Sun, weijiesun@pku.edu.cn Peking University, Beijing, China Xuzhi Zhou, xzzhou@pku.edu.cn Peking University, Beijing, China Shaojie Zhao, zsj1450@pku.edu.cn Peking University, Beijing, China George Parks, parks@ssl.berkeley.edu

Space Sciences Laboratory, UC Berkeley, Berkeley, California, United States Qiugang Zong, qgzong@gmail.com

Peking University, Peking, China

Dipolarization front (DF) is known as the leading edge of earthward high-speed flow with sharp enhancement in the northward magnetic field. Since it is often related with the tail activities, the particle behavior and waves near the front are of great interest. It is shown that not only protons could be reflected at the front, as many researchers have predicted, oxygen ions also follow the similar processes, however, due to their heavy mass and large gyro radius, they also shown some interesting features different from that of protons. Electron are found having the so-called flat-top distributions near the front and also associated with some whistler mode wave activities. Several case studies will be shown and the implications of the particle behaviors will be discussed.

D3.6-0010-18 OSCILLATORY BRAKING OF FAST FLOWS IN THE NEAR-EARTH PLASMA SHEET AND INWARD SPREADING OF PI2 PULSATIONS

Evgeny Panov, evgeny.panov@oeaw.ac.at

Space Research Institute, Austrian Academy of Science, Graz, Austria Rumi Nakamura, rumi.nakamura@oeaw.ac.at

Space Research Institute, Austrian Academy of Sciences, Graz, Austria Wolfgang Baumjohann, baumjohann@oeaw.ac.at

Space Research Institute, Austrian Academy of Sciences, Graz, Austria

Braking and rebound of earthward reconnection outflows in the Earth's magnetotail can be theoretically approximated as buoyancy oscillations of depleted flux tubes. Spacecraft observations reveal that being a local disturbance, these oscillations launch Pi2 pulsations in parallel and perpendicular B-field directions throughout the night-side inner magnetosphere and down to the ionosphere. In this talk we review examples of oscillatory braking in the near-Earth plasma sheet and discuss initiated by the braking wave modes with their damping mechanisms.

D3.6-0011-18 USING AN EVENT FITTED MAGNETIC FIELD MODEL WITH RAM-SCBE TO REPRODUCE MAGNETOSPHERIC CONFIGURATIONS DURING DISTURBED INTERVALS

The relationships between the magnetotail configuration and plasma flows from the tail are essential in understanding the development and behavior of storms and substorms. We investigate these relationships by using a state-of-the-art ring current model with a self-consistent, force balanced, magnetic field and self-consistent electric field (RAM-SCBE). Previous work using this model relied on setting the magnetic boundary using empirical models or coupling with the Space Weather Modeling Framework (SWMF). While this approach has been successful in modeling a number of events it is limiting in both modes of operation. When running standalone, the outer boundary is constrained to empirical magnetic field models and when coupled to SWMF we lose the ability to guide the overall solution via data ingestion. Both of these methods prove to be insufficient at capturing the individual storm dynamics and configurations. To solve this issue we have implemented a novel approach for dealing with the boundary conditions and data ingestion problems that offers optimal solutions in both stand-alone and SWMF-coupled modes. This event fitted model uses data from a number of satellites to adjust the input parameters for the TS04 model so that the model field better matches observations for the given time. This new model is expected to reproduce inner magnetospheric configurations with unprecedented accuracy even during highly disturbed intervals. We present preliminary results obtained with RAM-SCBE driven by this event fitted model during a range of active time periods. As a method of model validation we compare our results with measurements from RBSP, focusing primarily on the transport and dispersion of flux through the system.

Both observations and simulations indicate that the Earth's magnetotail dynamics often invoke multi-scale physical processes. The Cluster mission has emphasized multi-scale processes occurring throughout the Earth's magnetosphere since 2000. The MMS mission, launched in 2015, has unraveled, in particular, the electron-scale processes with unprecedented time-resolution measurements of particles and fields. The Cluster and MMS, constituting two tetrahedral configurations, have provided us with an opportunity to capture a micro-to-macroscopic picture of the important magnetotail dynamics including magnetic reconnection, geomagnetic storm and substorm. Here we inspect MMS and Cluster observations of magnetic reconnection and the mid-tail and near-Earth magnetotail topology related to the storm/substorm event as well as using ARTEMIS/Wind/ACE as solar wind inputs. We focus on multi-scale processes embedded in the magnetotail dynamics preconditioning the sudden change of the global magnetic field topology. These dynamics are key to the magnetosphere-ionosphere coupling and Earth's global current system, which will ultimately improve our ability in space weather forecasts under a variety of external interplanetary conditions and structures.

The Arase (ERG) satellite was launched in December, 2016, and started its regular observation from end of March, 2017. The Arase satellite is equipped with six particle instruments to cover wide energy ranges both for electrons and ions, as well as two field/ wave instruments. Orbit of the Arase satellite is highly elliptic, whose apogee and perigee altitudes are 32,000km and 450km, respectively. The inclication of the orbit is rather high (31deg). Therefore, the satellite can reach high latitude (approx. 30-40deg) plasma sheet (at most L 10) near the plasma sheet boundary when the satellite goes outside the outer radiation belt. Since the regular observation started, Arase encountered several magnetic storms driven by CIR and CMEs, and phenomena related to the transportation / energization and loss of particles, such as energy-dispersed and dispersionless sudden flux enhancements, are observed depending on the geomagnetic activities. In this presentaion, we will present key features of instuments onboard Arase and initial results of Arase observations at the near-Earth magnetosphere.

D3.6-0014-18 THIN CURRENT SHEETS IN THE EARTH'S AND PLANETARY MAGNETOSPHERES

Lev Zelenyi, lzelenyi@iki.rssi.ru

Space Research Institute of RAS, Moscow, Russia

Current sheets (CSs) are the important objects in space plasma as they separate the regions with different magnetic characteristics, accumulating magnetic energy and releasing it via magnetic reconnection. Numerous observations of the CSs in the Earth's magnetotail provide much information on their spatial structure and evolution. It was revealed that very often the structure of the CS signicantly differs from the simple isotropic Harris CS model. Multipoint spacecraft observations demonstrated that the CSs often exhibit complicated multilayered structure in which a thin and intense current layer is embedded in a thicker layer(s) having a smaller current density. To describe these features the quasi-adiabatic approach is more effective than the classical MHD approximation. With the development of the quasi-adiabatic theory in the last two decades, the existence of a number of new thin current sheet features, such as embedding, asymmetry of the current density spatial profiles, metastability, has been predicted and subsequently confirmed "in situ" observations. The role of individual particle populations in the formation of the CS fine structure has also been investigated. Somewhat counterintuitive but CSs observed in different objects of space plasma (e.g. in the terrestrial and Martian magnetospheres, in the solar wind) exhibit very similar characteristic features in their spatial structures, despite the drastic difference in the formation mechanisms and local plasma characteristics. This phenomenon can be explained by the universal mechansm of their formarion in different natural conditions. Once CS has been formed, then it should be self-consistently supported by the internal coupling of the total current carried by particles in the CS and its magnetic conguration, and as soon as the system achieved the quasi-equilibrium state, it "forgets" the mechanisms of its initial formation, and its emerging structureis controlled only by the general principles of plasma kinetics described by Vlasov-Maxwell equations.

During periods where the interplanetary magnetic field has a southward component, reconnection on the dayside magnetopause leads to a build up of magnetic flux in the magnetotail lobes, and the magnetotail acts as a reservoir of plasma and energy. During a substorm this energy is explosively released, leading to the deposition of large quantities of energy into the polar ionospheres and leading to the bright and dynamic substorm aurora. Auroral substorm onset is observed at the equatorward edge of the auroral oval, suggesting that at least some of the processes which play an important role in energy release occur on closed magnetic field lines. Recent work has highlighted that auroral beads embedded within the substorm onset arc grow exponentially through onset, which indicates the action of a plasma instability in this near-Earth region.

We use state of the art auroral measurements from the MOOSE (Multi-spectral Observatory Of Sensitive EM-CCDs) imagers to construct an observational dispersion relation of the plasma sheet instability responsible for the beading signature in the aurora. Informed by in-situ measurements of the plasma parameters in the magnetotail and magnetic field modelling, we extend theory to a high beta regime in the near-Earth plasma sheet. The solutions of the warm plasma dispersion relation in this regime show that

a shear Alfvén wave instability with small perpendicular scales is consistent with the dispersion relation obtained from auroral observations.

D3.6-0016-18 MAGNETOTAIL DYNAMICS IN AND NEAR THE ELECTRON DIFFUSION REGION

We have been using a combination of a global magnetohydrodynamic (MHD) simulation of the interaction between the solar wind, magnetosphere and ionosphere system and a large scale kinetic simulation (iPic3D) to investigate magnetic reconnection in the magnetotail during substorms. First we run a MHD simulation using observed solar wind input and they run the PIC code on the resulting magnetotail configuration. Magnetotail reconnection is very dynamic and structured. We find that multiple simultaneous neutral lines form and the location of reconnection can move across the tail rapidly. In this study we have examined the structure and dynamics in and near the electron diffusion region (EDR). The reconnection is characterized by large (100s km/s) earthward and tailward electron flows and comparable shear flows in the azimuthal (YGSM) direction. The shear flows form in the EDR. The region of shear flow contains structures in which the work done by the electromagnetic fields on the plasma (J•E′) where J is the current density and E ′is the electric field in the electron frame alternates between positive and negative. These changes in J•E′ mainly come from changes in E ′. This suggests instabilities other than just reconnection may be occurring. A number of studies have investigated instabilities in this region under idealized magnetotail configurations. We are investigating this under more realistic conditions. In our simulation this signature is consistent with a long wavelength variant on the lower hybrid drift instability. Since it is associated with very large shear we also are investigating shear instabilities such as the Kelvin-Helmholtz instability. In the talk we will evaluate the possible instabilities.

D3.6-0017-18 INTERNAL PLASMA SOURCE REQUIREMENT FOR GEOSPACE STORMS

NASA GSFC, Greenbelt, Maryland, United States

In our legacy nomenclature, a substorm, consisting of a cycle of stretch and relaxation of the magnetotail, is a necessary but insufficient element of a full-fledged geomagnetic storm. This dates to Davis and Parsatharathy's 1960s finding that the Dst index is well-approximated by integrating the AE index, with a superposed decay rate. Since the disturbance currents clearly exist in space around the Earth rather than inside it where the geomagnetic field originates, the term "geospace" may replace "geomagnetic". But is a geospace storm guaranteed by a sufficiently rapid series of "substorms", or as Feynman [1980 JGR], Kamide [1992 JGR], and Gonzalez [1994 JGR] suggested, must the magnetotail enter a different mode of behavior to develop a full fledged storm time ring current? In this talk, we return to and further explore the observations [Daglis et al., 1999 RG] and a hypothesis [Moore et al., 2001 SSR] that the key element of a geospace storm is a substantial internal source of plasma in a magnetosphere. Models suggest that a storm ring current also forms in response to strong steady magnetospheric convection without any need for substorms [Stephens et al. 2013 JGR]. Thus, a series of substorms does not appear uniquely causal of storms, while the transfer of enhanced mass density from the ionosphere to the magnetosphere may be essential. In the case of Mercury, with a much smaller internal source of plasma than Earth or other planets with magnetospheric ring currents, a magnetosphere has been found to lack a storm time response [Rong et al., 2018 JGR]. In the case of Earth, observations from Geotail [Nosé et al. 2005 JGR], and Cluster [Kistler et al., 2010 JGR] have noted an association of ionospheric source ions with storm time activity. The mechanisms of this association will be considered, with prospects for further exploration by the MMS mission.

D3.6-0018-18 TRANSPORT OF KEV ELECTRONS IN THE NIGHT-SIDE EARTH'S MAGNETOSPHERE DURING SUBSTORMS

Brian Swiger, swigerbr@umich.edu

University of Michigan, Ann Arbor, Michigan, United States Natalia Ganushkina, natalia.ganushkina@fmi.fi

Finnish Meteorological Institute, Helsinki, Finland

Low energy (< 200 keV) electrons from the magnetotail plasma sheet comprise the majority of the source of inner magnetosphere relativistic electrons, and their distribution is critically important for radiation belt dynamics. The electron flux at keV energies varies significantly with geomagnetic activity driven by the solar wind, especially during substorms. Meanwhile, the exact physical processes of electron transport in the magnetotail and their variations at different distances are still far from being completely understood. We present the results of an investigation of the chain of physical processes starting with the analysis of solar wind driving of the source population in the plasma sheet; and then, transport and acceleration of low energy electrons from the plasma sheet to inner regions during substorms. We analyze the THEMIS ESA and SST data in the plasma sheet in the vicinity of the equatorial plane on the night-side at distances from 6 to 10 RE. All time intervals selected for the analysis are linked with the corresponding solar wind and IMF measurements obtained from ACE and DSCOVER spacecraft, and a statistical pattern of the variations of keV electron fluxes during periodic and isolated substorms is developed.

D3.6-0019-18 NEW INSIGHTS ON ENERGETIC PARTICLE INJECTIONS AND SUBSTORM ACTIVITY FROM NASA'S MAGNETOSPHERIC MULTISCALE (MMS) AND VAN ALLEN PROBES MISSIONS

Los Alamos National Laboratory, Los Alamos, United States

Related to substorm activity, energetic particle injections from Earth's magnetotail into the inner magnetosphere ($L < 10$) occur frequently (several per day under normal magnetospheric conditions) and are considered important to source processes of ring current ions and radiation belt electrons. Here, we present a series of new results from multipoint studies using NASA's Magnetospheric Multiscale (MMS) and Van Allen Probes missions plus supplementary data from THEMIS, Geotail, GOES, and LANL-GEO. We focus on new insights gleaned from the recently available microscopic (MMS) and macroscopic (all missions) multipoint capabilities. In particular, we highlight: 1) new results concerning the size (in MLT) and extent (in L-shell and pitch angle space) of the injection region for energetic particles using the unprecedented energy, angular, and temporal resolutions afforded by the MagEIS and FEEPS instruments on Van Allen Probes and MMS, respectively; 2) the relationship between small-scale, localized injections associated with bursty bulk flows and dipolarizing flux bundles and larger-scale more global injections associated with the development of the substorm current wedge; 3) and how energetic particle injections play a critical role in enhancements of Earth's outer radiation belt.

D3.6-0020-18 COMPARING AND CONTRASTING DISPERSIONLESS INJECTIONS AT GEOSYNCHRONOUS ORBIT DURING A SUBSTORM EVENT

Kyiv Taras Shevchenko University, Kyiv, Ukraine

Particle injections are responsible for the transport of energy in the magnetosphere. In this study we consider generation mechanisms, acceleration processes and propagation of "dispersionless" injections, namely, those with simultaneous increase of the particle flux over a wide energy range. We take advantage of multisatellite constellation which simultaneously monitor Earth's magnetospheric dynamics from the tail toward the radiation belts and ground-based observations during a substorm event. We show that dispersionless injections are associated with instabilities in the plasma sheet during the growth phase of the substorm, with a dipolarization front at the onset and with magnetic flux pileup during the expansion phase. The injections show different spatial spread and propagation characteristics. Injection associated with the substorm onset does penetrate into the radiation belts while others not. At geosynchronous orbit (6.6 RE), the electron distributions show a bump on tail centered on about 120 keV during the injections associated with dipolarization. However, electron distributions in the magnetotail (13 RE) do not show such a signature during the injections. We surmise that a resonant acceleration acts in between these locations. We link the acceleration mechanism to the electron drift resonance with ultralow frequency waves localized in the inner magnetosphere.

D3.6-0021-18 MMS OBSERVATIONS OF MAGNETIC RECONNECTION ASSOCIATED WITH KELVIN-HELMHOLTZ WAVES DURING NORTHWARD IMF CONDITIONS

Stefan Eriksson, eriksson@lasp.colorado.edu

University of Colorado at Boulder, Boulder, Colorado, United States

The four Magnetospheric Multiscale (MMS) spacecraft recorded the first direct evidence of reconnection exhausts associated with Kelvin-Helmholtz (KH) waves at the duskside magnetopause on 8 September 2015, which allows for local mass and energy transport across the flank magnetopause. This period provides the first direct evidence of equatorial plane ion exhausts at 22 of 42 compressed KH-related current sheets as well as one of the first electron-diffusion region encounters in a significant guide magnetic field. MMS observed an equal probability of inward and outward directed ion exhausts along the magnetopause. MMS also recorded asymmetric Hall magnetic and electric fields consistent with a strong guide-field and a weak density asymmetry. Finally, we explore whether the 20 current sheets without a clear ion exhaust instead support a presence of electron exhausts as would be expected in a region closer to a reconnection X-line.

D3.6-0022-18 THE STATISTICS OF TRIGGERING EFFECTS FOR MAGNETOSPHERIC SUBSTORMS

Dana Saxonbergova, jdanka25@yahoo.com

Institute of Atmospheric Physics AS CR, Prague, Czech Republic
Zoltan Voeroes, zoltan.voeroes@oeaw.ac.at

Space Research Institute, Austrian Academy of Science, Schmiedlstrasse 6,, Graz, Austria

For understanding the magnetospheric substorm onset it is necessary to find out whether substorm onset is always externally triggered or sometimes is a result of internal processes, which can be observed for example during northward oriented interplanetary magnetic field i.e. in the time when there is no significant flux transfer. Large directional changes in the solar wind flow, especially observed during the northward oriented interplanetary magnetic field, can result in large-scale windsock motion of magnetotail. It can lead to current sheet thinning and force magnetic reconnection in magnetospheric tail, which consequently can lead to substorm onset. We analysed concurrent observations in the solar wind OMNI and Geotail data of distant tail's response. We present here a statistical study of the temporal resposes of magnetotail to the vertical directional changes in the solar wind flow.

D3.6-0023-18 PLASMA PRESSURE DISTRIBUTION IN THE GEOMAGNETOSPHERE

Pavel Sedykh, pvlsd@iszf.irk.ru

Institute of Solar-Terrestrial Physics SB RAS, Irkutsk, Russia

Direct observations of plasma distribution in the magnetosphere are faced with large difficulties, because pressure must be known everywhere in the plasma sheet at high resolution, which in situ satellites have been unable to provide. The equations of the two-fluid or one-fluid magnetohydrodynamics with isotropic or anisotropic pressure are as a rule applied to describe collisionless magnetospheric plasma. In this case any dissipative processes in the system are considered inessential. This statement is usually valid for ohmic loss and loss by radiation. However, particles (and energy) also escape from the magnetospheric plasma into the atmosphere through open ends of flux tubes. This type of loss can be very substantial and should be taken into account. The combined action of plasma convection and pitch-angle diffusion of electrons and protons lead to the formation of plasma pressure distribution in the magnetosphere. Specifying the initial pressure at the boundary, we can find the resultant pressure at any point on the flux line. In such a way, the field of plasma pressures in the entire magnetosphere is calculated. We are unique research team in our country, which has developed the original method of plasma pressure distribution calculation (3D). The others only copy our ideas, and unfortunately without references on my papers. The projection (mapping) of the plasma pressure distribution onto the ionosphere corresponds to the form and position of the auroral oval. This projection, like the real oval, executes a motion with a change of the convection electric field, and expands with an enhancement of the field. Steady bulk currents are connected to distribution of plasma pressure. The divergence of these bulk currents brings about a spatial distribution of field-aligned currents, i.e. magnetospheric sources of ionospheric current systems. The problem of compatibility of field-aligned currents generated in the magnetosphere, and of field-aligned currents, which are produced as a result of a spatial inhomogeneity of conductivity (and to a lesser extent, of the electric field), that is, as if they were "generated" in the ionosphere, is part of the problem of ionosphere-magnetosphere coupling. The problem of ionosphere-magnetosphere coupling primarily implies that it is necessary to solve the question as to how the magnetospheric producer of current and power "adjusts itself" to the ionospheric consumer.

D3.6-0024-18 DEPENDENCE ON THE ION MASS AND CHARGE OF A FERMI-LIKE ACCELERATION MECHANISM IN THE EARTH'S MAGNETOTAIL

Abstract Energetic particles with energies from tens of keV to a few hundred keV are frequently observed in the Earth's magnetotail, but the mechanism that can generate such heated particles is not fully understood. Here we study, by means of a test particle numerical simulation, the acceleration of different ion species (H+, He+, He++, and On+ with n = 1 -6) in the presence of transient electromagnetic perturbations. The equilibrium magnetic and electric field configuration is obtained from the generalized Harris solutions, and the 3-D time-dependent electromagnetic perturbations are superimposed. We injected 104 particles for each run, varying parameters like the ion mass, the ion charge, the initial energy, and the perturbation size. The efficiency of the acceleration process has a parametric dependence on the initial energy and on the perturbation size, while the dependence on the ion charge and mass is not affected by the particular initial condition. All the considered ions develop power law tails at high energies, except for O+ ions. This is strongly correlated to the time that the particle spends in the current sheet, where they frequently interact with the perturbations. Ion acceleration is found to be proportional to the charge state, while it grows in a weaker way with the ion mass. We find that O5+/6+ can reach energies higher than 500 keV. These results may explain the strong oxygen acceleration observed in the magnetotail.

D3.6-0025-18 VORTEX, ULF WAVE AND AURORA AFTER SOLAR WIND DYNAMIC PRESSURE CHANGE: THEMIS OBSERVATIONS AND SIMULATIONS FOR A GLOBAL VIEW

Quanqi Shi, sqq@pku.edu.cn

Shandong University at Weihai, Weihai, China Et Al., sqq@sdu.edu.cn

China

We will summarize our recent study and show some new results on the Magnetosphere and Ionosphere Response to Dynamic Pressure Change/disturbances in the Solar Wind and foreshock regions. We study the step function type solar wind dynamic pressure change (increase/decrease) interaction with the magnetosphere using THEMIS satellites at both dayside and nightside in different geocentric distances. Vortices generated by the dynamic pressure change passing along the magnetopause are found and compared with model predictions. ULF waves and vortices are excited in the dayside and nightside plasma sheet when dynamic pressure change hit the magnetotail. The related ionospheric responses, such as aurora and TCVs, are also investigated. We compare Global MHD simulations with the observations. We will also show some new results that dayside magnetospheric FLRs might be caused by foreshock structures.

D3.6-0026-18 INFLUENCE OF THE IMF CONE ANGLE ON INVARIANT LATITUDES OF POLAR REGION FOOTPRINTS OF FACS IN THE MAGNETOTAIL: CLUSTER OBSERVATION

Zhengwei Cheng, zwcheng@spaceweather.ac.cn

State Key Laboratory of Space Weather, Center for Space Science and Applied Research, Chinese Academy of Sciences, Beijing, China

Jiankui Shi, jkshi@nssc.ac.cn

National Space Science Center, CAS, Beijing, China Jichun Zhang, jichun.zhang@unh.edu

University of New Hampshire, Durham, New Hampshire, United States

The influence of the interplanetary magnetic field (IMF) cone angle (the angle between the IMF direction and the Sun-Earth line) on the invariant latitudes (ILATs) of the footprints of the field-aligned currents (FACs) in the magnetotail has been investigated. We performed a statistical study of 542 FAC cases observed by the four Cluster spacecraft in the northern hemisphere. The results show that there are almost no FACs when the IMF cone angle is less than 10º, and there are indications of the FACs in the PSBLs being weak under the radial IMF conditions. The footprints of the large FAC (>10 nA/m2) cases are within ILATs <71º and mainly within IMF cone angles >60º, which implies that the footprints of the large FACs mainly expand equatorward with large IMF cone angle. The equatorward boundary of the FAC footprints in the polar region decreases with increasing IMF cone angle (and has a better correlation for northward IMF), which shows that the IMF cone angle plays an important controlling role in FAC distributions in the magnetosphere-ionosphere coupling system. There is almost no correlation between the poleward boundary and the IMF cone angle for both northward and southward IMF. This is because the poleward boundary movement is limited by an enhanced lobe magnetic flux. This is the first time a correlation between FAC foot prints in the polar region and IMF cone angles has been determined.

D3.6-0027-18 INTENSE CURRENT STRUCTURES OBSERVED AT ELECTRON SCALES DURING DIPOLARIZATION AND SUBSTORM CURRENT WEDGE FORMATION

We study multiscale magnetic structures in 14 substorm-related prolonged dipolarization events in the near-Earth magnetotail by using data from the Cluster Inner Magnetosphere Campaign. The dipolarizations were associated with the arrival and braking of multiple Bursty Bulk Flows and Dipolarization Fronts (DFs). The very small separation (electron inertia length) between Cluster-3 and Cluster-4 permits, for the first time, the observation of strong magnetic gradients at electron scales. These structures were transiently (2s) observed during prolonged dipolarization growth at the leading and trailing edges of DFs. The values of magnetic gradients observed at electron scales are several dozen times larger than the corresponding values of magnetic gradients simultaneously detected at ion scales. These nonlinear features in magnetic field gradients denote the formation of intense and localized (a few electron inertia lengths) current structures during the dipolarization and substorm current wedge formation. These observations highlight the importance of electron-scale processes in the formation of a 3D substorm current system.

St. Xavier's College, Maitighar, Kathmandu, Kathmandu, Nepal

Phenomena like solar energetic particles, geomagnetically induced currents and ionospheric disturbances that can cause frequent radio and radar scintillations, failure of power grids, disruption of navigation by magnetic compass and auroral displays at much lower latitudes than normal in the earth are associated with geomagnetic storms. Substorm occurs more frequently during a geomagnetic storm and one substorm may follow the previous before its completion. The geomagnetic Northward component (X) Field of the four stations in the equatorial and low latitude region was taken to study their variations during super substorm events of April 05 2010, August 24 2005 and November 24 2001. The location of stations extends from Asia to South America across Africa. We studied the storm time (Dst) variations in the Northward component (X) of the geomagnetic field at low latitude stations during super substorm events and to substantiate the results, wavelet transform and cross-correlation techniques were used. We checked the correlation of Northward component (X) with Dst, SYM-H, Bz, X, Y and Ey individually to show that geomagnetic effect during the super substorm events at low latitude is significant. The power regions with the maximum fluctuation were analyzed using the continuous wavelet transform.

D3.6-0029-18 PRINCIPAL COMPONENTS OF RESIDUAL GEOMAGNETIC FIELD VARIABILITY IN THE NORTHERN HEMISPHERE

Kingsley Okpala, kingsley.okpala@unn.edu.ng University of Nigeria, Nsukka, Nigeria, Nsukka, Nigeria

The residual magnetic field (Hand Z-component) from 15 geomagnetic observatories have been subjected to principal component analysis (PCA). The technique has been used in other to identify dominant sources of residual field across different latitudes and the influence of solar activity on these residual fields on annual and semi-annual scales.The first three principal components: PC1, PC2 and PC3, accounted for 93-97% of the variances in the monthly mean and the PC1for H-component showed semiannual variation associated with the ring current with two peaks in April and October/November particularly in the midand lowlatitudes. The Z-components semiannual variation equally exhibited the same trend especially in the mid and low latitudes with negative peaks in April/May and September/October. The PC1 for the yearly mean residual of the H-component revealed solar activity dependence in the mid-latitudes and low-latitudes. The physical mechanisms involved in the residuals of the Z component are yet to be fully understood.These finding have important implications for our present understanding of the North-South migration of the ring current and the role of solar activity in modulating the geomagnetic field strength.

D3.6-0030-18 MESOSCALE FLOW CHANNELS AND FIELD ALIGNED CURRENT STRUCTURES IN A GLOBAL MAGNETOHYDRODYNAMIC SIMULATION OF A SUBSTORM

Mostafa El-Alaoui, mostafa@igpp.ucla.edu

Boston University, Boston, Massachusetts, United States

The dynamics of flow channels and dipolarizations complicate the field aligned current pattern during substorms. We have used a global magnetohydrodynamic simulation to investigate how meso-scale magnetotail structures determine the substorm current configuration. We have extensively analyzed a substorm event for which we have observations from THEMIS spacecraft. The available data include an extensive network of all sky cameras and ground magnetometers that establish the times of various auroral and magnetic events. The simulation of this event shows a sequence of fast flows and dipolarization events similar to what is seen in the data, though not at precisely the same times or locations. Both earthward and tailward flows were found in both the observations and the simulations. Fast earthward flows have convoluted paths that are diverted or reflected as they reach the inner magnetosphere. We will use our simulation results combined with the observations to investigate the global convection system and current sheet structure during this event. Our study includes determining the location, timing and strength of several current wedges and expansion onsets during an eight-hour interval.

DARK ENERGY AT 20 (E1.1)

E1.1-0001-18 DARK ENERGY AND MODIFIED GRAVITY

Claudia De Rham, c.de-rham@imperial.ac.uk Imperial College London, London, United Kingdom

The recent direct detections of gravitational waves represent a direct manifestation of the propagating degrees of freedom of gravity. While the recent detections have been successfully used to examine the basic properties of these gravitational degrees of freedom and set an upper bound on its mass and constrain its speed of propagation with unprecedented accuracy, I will explore the possibility for this mass to be sufficiently small to pass current tests of gravity and yet sufficiently large to have deep potential implications on our observable Universe and particularly for dark energy and the cosmological constant problem.

E1.1-0002-18 COSMOLOGY RESULTS FROM THE DARK ENERGY SURVEY

Elisabeth Krause, ekrause@caltech.edu

California Institute of Technology, Pasadena, California, United States

This talk presents cosmology constraints from a combined analysis of galaxy clustering and weak gravitational lensing, using 1321 deg2 of griz imaging data from the first year of the Dark Energy Survey (DES Y1). The analysis combines (i) the cosmic shear correlation function of 26 million source galaxies in four redshift bins, (ii) the galaxy angular autocorrelation function of 650,000 luminous red galaxies in five redshift bins, and (iii) the galaxy-shear cross-correlation of luminous red galaxy positions and source galaxy shears. These three measurements yield consistent cosmological results, and provide constraints on the amplitude of density fluctuations (S8 = 0.794+0.029-0.027) and dark energy equation of state (w = -0.80+0.20-0.22) that are competitive with those from Planck cosmic microwave background measurements. I will describe the validation of measurements and modeling from catalogs to cosmology, and highlight cosmology constraints from the combination of DES Y1 with external data sets. Based on DES Collaboration 2017 (1708.01530) and supporting papers.

E1.1-0003-18 DARK ENERGY RESULTS FROM PLANCK

Martin Kunz, martin.kunz@unige.ch University of Geneva, Geneva, Switzerland

The ESA Planck satellite provides the currently best measurements of the anisotropies of the cosmic microwave background, and of its gravitational lensing, on large and intermediate scales. This data set provides important constraints on cosmology at early and late times. In my talk I will specifically focus on what we have learned from Planck, alone and when combined with observations of the late-time universe like weak lensing and redshift space distortions, about dark energy and modified gravity models

E1.1-0004-18 DARK ENERGY RESULTS FROM KIDS

Hendrik Hildebrandt, hendrikhildebrandt@gmail.com

Argelander Institute for Astronomy of University of Bonn, Bonn, Germany

Cosmic shear tomography yields cosmological insights complementary to other probes like the cosmic microwave background (CMB). Ongoing wide-field imaging surveys exploit this to come up with competitive constraints on important cosmological parameters like the matter density, the amplitude of the matter power spectrum, and the dark energy equation-of-state. In this talk I will concentrate on results from the ongoing European KiDS (Kilo Degree Survey) project and its infrared complement VIKING (VISTA Kilo Degree Infrared Galaxy Survey). This unique combination of an optical and an infrared imaging survey over hundreds of square degrees on the sky allows us to reach an unprecedented accuracy in the redshift calibration of the sources used in the weak lensing measurement. In combination with the well-calibrated KiDS shape measurements this will reveal whether the recently reported tension between Planck CMB measurements and KiDS optical-only cosmic shear results (Hildebrandt et al. 2017) still holds in this improved analysis. I will further discuss constraints on possible extensions to the standard model of cosmology, including massive neutrinos, non-zero curvature, and evolving dark energy. Combined with Planck, the first KiDS results showed some mild preference for an evolving dark energy component, and in this extended model the tension between Planck and KiDS was alleviated. With the greater systematic accuracy of the KiDS+VIKING data set we will revisit this model and put even tighter constraints on the dark energy equation-of-state.

E1.1-0005-18 FIRST-YEAR COSMOLOGICAL RESULTS FROM THE SUBARU HYPER SUPRIMECAM SURVEY

Hironao Miyatake, hironao.miyatake@iar.nagoya-u.ac.jp Nagoya University, Nagoya, Japan

Hyper Suprime-Cam (HSC) is the newly developed wide-field prime focus camera on the Subaru Telescope, which provides a 1.77 sq. degree field-of-view with superb image quality (0.6" seeing FWHM) and large light-gathering power enabled by the 8.2-m primary mirror. HSC started the wide, deep optical/near infrared imaging survey in 2014 that covers 1,400 sq. degree of the sky down to the i-band limiting magnitude of i 26. The primary goal of the HSC survey is constraining the nature of cosmic acceleration through the measurement of structure growth using weak gravitational lensing. In this talk, we will present our cosmological results based on our first-year galaxy shape catalog which consists of six distinct fields that cover 170 sq. degrees in total with full color and full depth. We first describe details of the shape catalog production including systematic tests and simulation-based calibrations. We then present our cosmological results from our cosmic shear measurement and joint measurements of galaxy-galaxy lensing and auto-correlation of galaxies. For the latter, we use a spectroscopic sample of galaxies taken from the SDSS to cross-correlate the distribution with shapes of background HSC galaxies, which enables us to resolve uncertainties in galaxy bias and nonlinear clustering.

E1.1-0006-18 RESULTS FROM BOSS

Shirley Ho, shirleysurelyho@gmail.com

Lawrence Berkeley National Laboratory, Berkeley, California, United States

The SDSS-III's Baryon Oscillation Spectroscopic Survey (BOSS) mapped the spatial distribution of luminous red galaxies (LRGs) and quasars to detect the characteristic scale imprinted by baryon acoustic oscillations in the early universe. Sound waves that propagate in the early universe, like spreading ripples in a pond, imprint a characteristic scale on cosmic microwave background fluctuations. These fluctuations have evolved into today's walls and voids of galaxies, meaning this baryon acoustic oscillation (BAO) scale (about 150 Mpc) is visible among galaxies today. BOSS presents a one per cent measurement of the cos- mic distance scale from the detections of the baryon acoustic oscillations in the clustering of galaxies. Our results come from the Data Release 11 (DR11) sample, containing nearly one million galaxies and covering approximately 8500 square degrees and the redshift range 0.2<z<0.7. Assuming a concordance CDM cosmological model, the sample covers a volume of 13 (Gpc/h) 3 and is the largest region of the Universe ever surveyed at this density. We measure the correlation of field reconstruction of the baryon acoustic oscillation (BAO) feature. Our measurements of the distances cal.

E1.1-0007-18 DIRECT DETECTION OF DARK ENERGY IN THE SOLAR SYSTEM

Eric Huff, eric.m.huff@jpl.nasa.gov

JPL, Pasadena, California, United States

Dark energy remains one of the most profound mysteries of our time and a major focus of observational investigation and theoretical modeling. However, to date all the evidence for cosmic acceleration is indirect, relying on information from the expansion history of the universe as a whole and measurements of the cosmic structure on scales that are a significant fraction of the observable universe. In the meantime, the theoretical fine-tuning problems associated with the baseline cosmological constant model have motivated significant work on extensions to General Relativity and alternative models of gravity. The opening of the theory space in combination with the limits of the current observational program suggest that we should take a new look at local, experimental constraints on the nature of gravity. In this talk I will review some current prospects for constraints on the nature of gravity and dark energy models from laboratory and solar system tests.

E1.1-0008-18 TESTING COSMOLOGICAL GRAVITY ON ALL SCALES

Jeremy Sakstein, sakstein@sas.upenn.edu

University of Pennsylvania, Philadelphia, Pennsylvania, United States

One popular explanation for the acceleration of the cosmic expansion—dark energy—is that general relativity is modified on large scales. Modern cosmologically relevant theories of gravity predict novel dynamics for astrophysical objects including stars, galaxies, and clusters. In this talk, I will review how different astrophysical objects can be used to test different theories of cosmological gravity and discuss the possible constraints that could be placed.

E1.1-0009-18 THE MICROSCOPE MISSION: FIRST CONSTRAINTS ON THEORIES OF MODIFIED GRAVITY.

Martin Pernot-Borras, martin.pernot_borras@onera.fr ONERA, Chatillon, France

Joel Berge, joel.berge@onera.fr ONERA, Chatillon, France

Philippe Brax, philippe.brax@ipht.fr

Institut de Physique Théorique, Gif-sur-Yvette, France Emilie Hardy, emilie.hardy@onera.fr

ONERA, Châtillon, France

Gilles Metris, gilles.metris@oca.eu

Université Côte d'Azur, Observatoire de la Côte d'Azur, CNRS, IRD, Géoazur, VALBONNE, France

Pierre Touboul, pierre.touboul@onera.fr ONERA, PALAISEAU, France

Jean-Philippe Uzan, uzan@iap.fr

Institut d'Astrophysique de Paris, Paris, France

MICROSCOPE is a French space mission developed by ONERA and CNES, launched on the 25th of April 2016, which aims to improve the test of the Weak Equivalence Principle (WEP)

by two orders of magnitude and reach a level of 10–15 on the Eötvos parameter. The experiment is based on testing the WEP's experimental manifestation known as the Universality of Free

Fall, with an ultrasensitive accelerometer composed of two test masses of different composition. Although not a cosmology experiment, MICROSCOPE can provide constraints on dark energy complementary and directly related, to those obtained by large scale surveys.

Indeed, the results of the mission should have implications on alternatives theories of gravity, designed to solve the dark energy problem and/or unify gravity with quantum physics. Scalartensor theories represent a class of such theories that could be constrained by MICROSCOPE: they introduce a new scalar field to Einstein's gravity, which by coupling to matter gives rise to a 5th force that can violate WEP. A simple example is the string-theory-inspired dilaton, a light scalar field which couples with a different strength to each component of matter. Another model that MICROSCOPE should also be able to constrain is the Chameleon model. This scalar field was proposed as a dark energy candidate that could satisfy local gravity constraints through a screening mechanism: due to such a mechanism, the dynamics of the field is

highly coupled to the local density of matter, therefore effectively hiding the field from on-ground experiments. Being in a less dense environment, MICROSCOPE was expected to be able to provide a smoking gun for the existence of a chameleon.

A first result with a sample of the data collected by MICROSCOPE has been published in December 2017, and has shown that the WEP is still valid at a level of 2 10−14, improving the previous constraint put on ground by one order of magnitude. In this talk, after introducing the

MICROSCOPE mission, I will present its first constraints on such models as the dilaton (the limits on its coupling parameters and its range are already improved by an order of magnitude) and the chameleon scalar fields.

E1.1-0010-18 COSMOLOGY WITH COSMIC VOIDS

Alice Pisani, apisani@astro.princeton.edu

Princeton University, Princeton, New Jersey, United States

Modern surveys allow us to access to high quality measurements on large areas in the sky and at high redshift - thus sampling the galaxy distribution in detail also in the emptier regions, voids. Void cosmology is hence becoming an increasingly active sector of galaxy clustering analysis: by measuring void properties, such as the abundance or the density profiles, it is possible to constrain cosmological parameters.

The void perspective is particularly promising to better understand dark energy: voids being by definition devoid of matter, their dominant component is dark energy and the effects of this component are expected to be more evident on voids. However another possibility to justify current observations is to consider a modification of the laws of General Relativity. Cosmic voids constitute a sweet spot where the effects of modifications of General Relativity would be more prominent.

In this talk I briefly illustrate the use of cosmic voids as a tool for cosmology, I present recent developments on the field and discuss on the constraining power of voids that will be observed by upcoming surveys such as the NASA's Wide Field Infrared Survey Telescope (WFIRST) and the ESA's Euclid space mission.

E1.1-0011-18 DARK ENERGY WITH THE SIMONS OBSERVATORY

Nicholas Battaglia, nb572@cornell.edu

Cornell University, Ithaca, New York, United States

The Simons Observatory (SO) is a next generation cosmic microwave background (CMB) experiment optimized to make precise measurements over frequencies spanning 30-300 GHz. The observatory will be built with a combination of 6 meter class and 0.4 meter class telescopes located in the Atacama Desert and will make unprecedented measurements of secondary anisotropies in the CMB. I will present forecasts that illustrate SO's potential to constrain properties of Dark Energy using CMB lensing cross-correlations, galaxy cluster abundances selected by their thermal Sunyaev-Zel'dovich (SZ) signal, and thermal and kinetic SZ statistics.

E1.1-0012-18 FINDING THE UNEXPECTED: THE DISCOVERY OF THE ACCELERATING EXPANSION

Saul Perlmutter, saul@lbl.gov

Lawrence Berkeley National Laboratory, Berkeley, California, United States

In the 1990s, several groups studying the expansion of the universe found an astonishing result. Rather than the expansion slowing down due to gravity, the rate of expansion was accelerating, implying the need for new physics. This unexpected result points to a universe that is dominated by a mysterious phenomenon called dark energy. I'll describe the personal journey that led to this discovery and how we are looking to create the ultimate dark energy experiments in the coming decade.

E1.1-0013-18 THE EUCLID MISSION

Stefanie Wachter, wachter@ipac.caltech.edu Caltech JPL, Pasadena, California, United States

In the early 2020s the Euclid space telescope will be launched. From the second Lagrangian point in far Earth orbit, it will survey the full extragalactic sky. The mission's goal will be nothing less than understanding the dark universe. This talk will overview Euclid's main scientific goals. It will review the tools we are building that will enable us to probe the expansion history of our universe as well as the nature of gravity. As a Stage IV dark energy mission, Euclid will no longer be limited by statistics as much as it will be challenged by systematics. This talk will discuss some of those challenges and present some recent updates on how these challenges are being tackled. Finally, it will present the most up-to-date forecasts for some of the main cosmological parameters that we will use to constrain our cosmological model.

E1.1-0014-18 DARK ENERGY IN THE ERA OF LSST

Chihway Chang, chihway@kicp.uchicago.edu University of Chicago, Chicago, Illinois, United States

The Large Synoptic Survey Telescope (LSST) will provide us with an unprecedented view of the Universe. During the 10 years of operation, it will map out half of the visible sky every three days, reaching a median redshift of 1.2. Exploiting the information one can extract from this data set may give us the key to understanding the nature of Dark Energy and open up windows for new physics. In this talk I will introduce the various venues LSST will be able to constrain Dark Energy and some of the effort in the LSST Dark Energy Science Collaboration (DESC) where we prepare ourselves for the start of the survey in 2021.

E1.1-0015-18 DARK ENERGY WITH DESI

Andreu Font-Ribera, a.font@ucl.ac.uk

University College London (UCL), London, United Kingdom

The study of the large scale structure of the Universe can answer some of the most important and challenging questions in physics: the nature of the dark energy causing the acceleration of the Universe; the inflationary origin of the density fluctuations; the physical properties of the dark matter component; and the number of neutrino species and their mass.

In particular, one of the most powerful and robust cosmological probes is the measurement of Baryon Acoustic Oscillations (BAO) in the distribution of matter. In the last few years, the Baryon Oscillation Spectroscopic Survey (BOSS) has provided a 1% measurement of the scale of these oscillations at intermediate redshifts (z=0.6), using a catalog of over a million galaxy redshifts. BOSS also measured the oscillations in the distribution of neutral hydrogen at a much higher redshifts (z=2.4), using a phenomenon known as the Lyman alpha forest.

Starting in 2019, the Dark Energy Spectroscopic Instrument (DESI) will increase these datasets by an order of magnitude, and it will provide an exquisite measurement of the expansion over cosmic time. These BAO measurements will be very complementary to other cosmological probes, like weak lensing, supernovae distances or the fluctuations in the cosmic microwave background.

E1.1-0016-18 WFIRST AS A PROBE OF DARK ENERGY

David N. Spergel, dns@astro.princeton.edu

Princeton University, Princeton, New Jersey, United States

WFIRST will be a highly capable telescope for studying dark energy. The WFIRST mission has been optimized to minimize systematic errors in dark energy measurements and to use multiple techniques to probe the growth of structure and the geometry of the universe. WFIRST will be able to trace the geometry of the universe through both supernova observations and baryon acoustic oscillation measurements. WFIRST will be able to measure the growth rate of the structure through lensing observations and measurements of the evolution of clustering.

E1.1-0017-18 DARK ENERGY WITH HIRAX 21CM INTENSITY MAPPING

Kavilan Moodley, moodleyk41@ukzn.ac.za University of KwaZulu-Natal, Durban, South Africa

Observations of redshifted 21-cm emission of neutral hydrogen over a wide range of radio frequencies allow us to access redshifts that encompass a vast comoving volume, including the era of dark energy. In this talk I will present the HIRAX project, which is a proposed 21cm intensity mapping experiment operating at 400-800 MHz that will measure the evolution of dark energy over the redshift range z=0.8-2.5 by using the characteristic baryonic acoustic oscillation scale as a standard ruler. The HIRAX radio telescope array will be sited in the radio-quiet Karoo astronomy reserve in South Africa and will ultimately comprise 1024 dishes, each six metres in diameter, placed in a compact configuration. The construction of the first eight-element HIRAX prototype is currently near completion. I will discuss the design and project status of HIRAX and its scientific prospects. This includes dark energy forecasts as well as prospects for interesting cosmological constraints from cross-correlations of HIRAX data with other large-area cosmological surveys in the southern sky.

E1.1-0018-18 DARK ENERGY WITH THE SQUARE KILOMETRE ARRAY

Laura Wolz, lwolz@unimelb.edu.au University of Melbourne, Parkville, Australia

The Square Kilometre Array (SKA) is an international radio observatory administered by ten member countries, guided by scientific contributions of thousands of scientists and engineers around the globe. The SKA instrument design is composed of two radio interferometric arrays covering the low and high radio frequencies to be placed in South Africa and Australia over two stages within the next decades. The wide frequency coverage and versatility of the array composition drive a multitude of science cases in cosmology, galaxy evolution, and the transient universe. The SKA will enable novel cosmological observations in the radio wavelengths such as galaxy surveys using the neutral hydrogen (HI) spectral line emission at 21cm, radio weak lensing, radio continuum galaxy surveys, and HI intensity mapping. The HI intensity maps trace the large-scale structure via the integrated HI line emission, a new technique avoiding selection biases while testing the continuous gas field over all redshifts up to six. Additionally, the full sky coverage of the intensity mapping observations gives access to ultra-large scales with potential to constrain non-gaussianity effects. HI galaxy surveys target the detection of a million to a billion objects over 5,000 and 25,000 sqdeg during SKA stage 1 and 2, respectively. The SKA HI galaxy surveys and SKA HI intensity mapping experiments are forecasted to detect the Baryon Acoustic Scale, acting as a standard ruler for distance measurements, for redshifts up to 2, resulting in Figures of Merit for the Dark Energy equation of state parameters highly competitive with the next generation of optical experiments. The combination of radio and optical data products is predicted to increase Dark Energy constraints through reducing cosmic variance with multi-tracer techniques, as well as mitigating instrumental systematics.

This abstract will be presented on behalf of the SKA Cosmology Science Working Group.

E1.1-0019-18 THE SUBARU PRIME FOCUS SPECTROGRAPH

Hitoshi Murayama, hitoshi.murayama@ipmu.jp

Kavli Institute for the Physics and Mathematics of the Universe, Kashiwa, Japan

Prime Focus Spectrograph (PFS) is a highly multiplexed fiber spectrograph for the Subaru telescope. Thanks to the large aperture and large field of view, it will allow for a very efficient survey for cosmology, galaxy evolution, and galactic archeology science. I will describe the state of the development of the instrument, and present major science objectives of the 300-night survey proposal with emphasis on dark energy science.

E1.1-0020-18 LEARNING THE SHAPE OF AND WHAT SHAPES DARK STRUCTURE

Julian Merten, giuliano.merten@gmail.com

Osservatorio Astronomico di Bologna, Oxford, United Kingdom

LCDM shows some tension with observations in the non-linear regime of structure formation. This includes abundance, density profiles and substructure amount for dark matter haloes at a range of masses and redshifts. Several recipes have been suggested to remedy such tensions including more detailed modelling of baryonic physics, modifications to gravity or variations to the collisionless, cold dark matter paradigm. However, current observational signatures to distinguish such models are elusive due to the vast information compression in the characterisation of observed dark matter structure via e.g. two-point correlation functions or 1D functional forms of density profiles. I will present a full morphological analysis of dark matter structure in the sky based on optimal mass mapping, computer vision and machine learning that alleviates this shortcoming. More specifically, I will focus on two characterisation schemes. The first one derives from classical computer vision and machine learning and extracts up to 3500 characterising elements directly from dark matter mass or shear maps, several of their transformations (Fourier, Chebyshev, Edge, Wavelet, .) and transformation of transformations. The second approach is based on deep learning and applies a multi-layered convolutional neural network, including state-of-the-art methods such as inception layers and region detection, to learn the main characterising features in the dark matter mass and shear maps. We apply these techniques to several sets of numerical simulations, all of which explore different aspects of the underlying model of structure formation. This includes several models of modified gravity, the degeneracy between modified gravity and the presence of massive neutrino, baryonic feedback and models of self-interacting dark matter. I will close with the application of this technique to classify the underlying structure formation model of real data coming from the KiDS and CLASH surveys and will give an outlook on the potential of future space and ground-based experiments such as Euclid, WFIRST and LSST.

E1.1-0021-18 QUASARS FROM LSST AS DARK ENERGY TRACERS

Bozena Czerny, bcz@camk.edu.pl

Center for Theoretical Physics of the Polish Academy of Sciences, Warsaw, Poland

With the prospect of new data, new cosmological tools are being devised to supplement the well established methods (Czerny et al. 2018) since the systematic errors will dominate the statistical errors. Quasars are not standard nandles but there are methods to determine absolute luminosity of each quasar at the basis of quasar variability. The most direct method relies on the delay of emission lines with respect to the continuum. Having 6 photometric channels and knowing their profiles we can disentangle strong lines from the continuum. With 10 millions of quasars measured with LSST, and out of that 100 000 quasars with high quality 10 year lightcurves in six band we will be able to measure all wOwaCDM model parameters with statistical accuracy of 0.2%.

E1.1-0022-18 DARK ENERGY INFLUENCING POLYTROPIC SPHERES MODELLING DARK MATTER HALOS

Zdenek Stuchlik, zdenek.stuchlik@fpf.slu.cz

Silesian University at Opava, OPAVA, Czech Republic Jan Novotný, jan.novotny@fpf.slu.cz

Silesian University in Opava, Opava, Czech Republic Jan Hladík, jan.hladik@fpf.slu.cz

Silesian University in Opava, Opava, Czech Republic

We discuss in the framework of general relativity the role of the dark energy represented by the cosmological constant, restricted due to cosmological tests, in the polytropic mod- els of dark matter halos. The internal spacetime of the polytropic spheres governs circular geodesic orbits that can be compared with the velocity curves observed in large galaxies, indicating the possibility to use for the halo model both non-relativistic very extended and diluted polytropes, or relativistic polytropes with nearly critical value of the relativistic parameter sigma = pmathrmc/varrhomathrmc enabling extremely large polytrope extension, limited efficiently by the influence of the dark energy to agree with extension of dark matter halos of large galaxies. We also show that the so-called trapping relativistic polytropes with extremely large extension allow for gravitational instability of their central parts leading to the creation of a supermassive black hole inside of such an extremely extended polytrope representing galactic halo.

E1.1-0023-18 IN SEARCH OF DIVINE COSMOS UNDER SHADE

Vidyardhi Nanduri, nanduri_dr_vidyardhi@hotmail.com India

From atomic scale to cosmic scale -Anoraneeyan Mahato Maheeyan-the science in philosophy comes in to prominence through Cosmic consciousness. Science frontiers cannot afford to move away from Nature, philosophy, Cosmology leading to Origins. Obviously, this search needs navigation like Dva-suparnatwin cosmic birds,one under a shade and the other searching beyond trying to catch-up prime functional Cosmic flows that spread around through visible-invisible matrix modes in nature. The Plasma Regulated Electro-Magnetic phenomena [PREM] in Magnetic field environment enshrines through 12 Jyothir-lingam concept with spread-functional routes at the base level to interlink vedas through 12 Adityas as groups of sun-shine in 3- tier Cosmic-pot Energy structures. This Divine scientific essence of Cosmic flow-field aligned knowledge becomes an attraction to all Astronomers, Cosmologists, philosophers alike looking for paradigm shift. Search from Van-Allen belts creates the necessty-demand-curiosity-Sustain management structure as a base ground mat for Spirit of Scientific research with a Noble cause beyond Heart of the Universe around 100,000 LY .Search from such a Knowledge base of Universe looks forward for cause-effect and stability index from and above Milky-way Galactic Frame as a Reflector beyond dark shades and dogmas. This prevents a state of anarchy prevailing through chaotic states adding confusion. Research reports by author over past 20 years reveal the creative function as inputs to bridge Core, Subtle and Wide observational frames under 3-tier cosmological structures to transcend super-imposition matrix towards prime Source, prime fields, Prime Reflectors with protective index in search of prime flows. Divine cosmos with float-mode structures may reveal through dimensional knowledge and the Space-Cosmological data-sets provide the trend to the next millenium with up-end universe. This mode of cosmolgy digest inter-twines consonance and resonance through nature and scienific edge in Philosophy.

E1.1-0024-18 DARK SHADOWS AROUND SUPERMASSIVE BLACK HOLES AS A TOOL TO EVALUATE DARK ENERGY AND DISCOVER EXTRA DIMENSION

Alexander Zakharov, zakharov@itep.ru

Institute of Theoretical and Experimental Physics, Moscow, Russia

There are many different suggestions to evaluate dark energy for different astronomical objects, such as Solar System, galaxies, galactic clusters and cosmology. If dark energy is indeed not the cosmological constant it would very important to investigate its possible variation. We obtain relations of black hole shadow sizes from local dark energy parameter and tidal charge which characterizes extra dimension. Evaluations of shadow size could be done for the Galactic Center and the shadow in center of galaxy M81 with the Event Horizon Telescope and projected space ground interferometer Millimetron.

E1.2-0001-18 INTRODUCTION TO THE PLANCK DAY AT COSPAR

Graca Rocha, grocha@jpl.nasa.gov

Jet Propulsion Laboratory, Pasadena, California, United States

I will introduce the Planck day at COSPAR. I will start by an overview of the main scientific achievements of Planck and implications for our understanding of the Cosmos today.

Planck results will be viewed in the context of the CMB session at COSPAR with special attention to current and future CMB experiments and the ongoing search for a stochastic background of gravitational waves that should leave a faint polarized signal in the CMB, the so-called B-modes.

E1.2-0002-18 THE PLANCK MISSION

Jan Tauber, jtauber@rssd.esa.int ESA, Noordwijk, Netherlands Planck Collaboration

Please see https://www.cosmos.esa.int/web/planck/planck-collaboration for a full list of members.

I will provide introductory context for this full day of presentations on Planck at COSPAR, which follows and summarizes the recent "Legacy" release of Planck data. I will describe the history of the development of Planck reminding the main milestones of the project. I will present an overview of all the data products which have been released to the public by ESA and the Planck Collaboration since 2011, and will introduce the Planck Legacy Archive. Finally, I will highlight some of the main scientific achievements of Planck, relative to the initial objectives of the mission.

E1.2-0003-18 LFI MAPS

Davide Maino, davide.maino@mi.infn.it Università degli Studi di Milano, Milano, Italy Planck Collaboration

Please see https://www.cosmos.esa.int/web/planck/planck-collaboration for a full list of members.

We present the description of the data processing pipeline for the Planck Low Frequency Instrument (LFI) implemented for the final 2018 data release. Several improvements have been made especially in the calibration procedure and in the correction of instrumental effects. We tested our results with a battery of null-tests and systematic effects simulations, dedicated to assess their impact on the calibration process, that demonstrate clearly the improvements with respect to previous release in particular at 30 and 44 GHz.

E1.2-0004-18 THE HIGH FREQUENCY MAPS

Jean-Loup Puget, jean-loup.puget@ias.u-psud.fr Institut d'astrophysique spatiale, Orsay, France

A new map making software has allowed a much better correction of a number of systematic effects which were affecting the Planck HFI maps. These were affecting mostly polarization at large scales but their correction improved significantly also the high spatial frequencies. The maps and their testing through very complete end to end simulations will be presented. The determination of the low value of the reionization parameter through the use of the large scale EE polarized modes is confirmed. The determination of the kinetic dipole boost due to the motion of the solar system with respect to the CMB has been measured with unprecedented accuracy and provides one of the lasting legacies of the new release. The new map making paves the way to a new type of analysis of CMB data by integrating map making and component separation, which will become critical for the very weak primordial B modes search.

E1.2-0005-18 THE PLANCK LIKELIHOOD ANALYSIS

Karim Benabed, benabed@iap.fr

Institut d'Astrophysique de Paris - CNRS/Sorbonne Université, Paris, France

The Planck Likelihood is one of the main cosmological products of the Planck mission. It compresses the Planck data into a set of statistical descriptions of our best full sky determination of the CMB temperature and polarization, and constitutes an important element of the Planck Legacy. Until a new satellite mission, with both improved resolution and sensitivity, can provide us with a new full sky determination of the CMB, some of the scales probed by the Planck data will remain a reference for all CMB observations. Thanks to numerous improvement at all steps of the Planck data processing, the legacy likelihood represents a solid improvement over the 2015 Planck Likelihood, both at large scales (with a greatly improved constraint on the large scale polarization) and at small scales (with a solid leakage model, allowing to recommend the use of the polarized data for cosmology). I will review the determination and validation of the Planck Likelihood. I will describe the different choices made to build at each of the scales probed by Planck a good approximation of the likelihood. I will explain how we modelled and mitigated the different non-idealities of the data (e.g. astrophysical foregrounds, instrumental effects.), describe the different validation we performed, based on comparing different data cuts, or using extensive End-to-End simulations, and finally give an estimate of the level of possible residual systematics.

E1.2-0006-18 COSMOLOGICAL PARAMETERS DERIVED FROM PLANCK

Silvia Galli, gallis@iap.fr IAP, Paris, France

Planck is an ESA satellite aimed at the observation of the Cosmic Microwave Background. This year, the Planck collaboration is publishing its third and last data release. In this talk, I will present the results on cosmological parameters of this year release, showing the most important changes with respect to the 2015 release, and I will discuss the consistency of our results with respect to other cosmological probes.

E1.2-0007-18 THE PLANCK 2018 CMB MAPS

R. Belen Barreiro, barreiro@ifca.unican.es

Instituto de Fisica de Cantabria (CSIC-UC), Santander, Spain Planck Collaboration

Please see https://www.cosmos.esa.int/web/planck/planck-collaboration for a full list of members

We present the CMB temperature and polarization maps derived from the third and last Planck data release. Full-sky maps are provided, including also confidence masks that exclude the unreliable regions of the sky. Four conceptually different pipelines, already adopted in previous releases, have been applied (Commander, NILC, SEVEM and SMICA) to extract the cosmological signal, showing a good level of agreement. The new versions of the CMB temperature maps agree very well with the ones in the previous release, as one would expect due to the low level of systematics, and the high signal-to-noise ratio. For polarization, the new maps provide a substantial improvement with respect to the previous version, with significantly reduced contamination from instrumental systematic effects. However, the noise properties of the polarization signal are complicated and not completely reproduced by the current best end-to-end simulations, which should be taken into account when carrying out cosmological analyses. To mitigate these limitations, we also provide CMB estimates for different data splits, which are very useful to carry out further analyses of the data. The temperature and polarization maps derived from the Planck 2018 data provide the best CMB maps up to date, and it is foreseen that this will remain the case for many years.

E1.2-0008-18 ISOTROPY AND STATISTICS OF THE PLANCK MAPS

Krzysztof Gorski, krzysztof.m.gorski@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Precise full sky measurements of the CMB anisotropies enabled important studies of the primordial seeds of structure observed in the universe. Planck Isotropy and Statistics program pursues a phenomenological investigation of the CMB maps generated by Planck mission focused on those features, mostly at relatively large angular scales, that appear anomalous with respect to the characteristics of the CMB sky expected in the standard Lambda-CDM model (that fits the data well at intermediate to small angular scales). Previous Planck data releases were accompanied by I&S publications focused on the CMB temperature anisotropy, which confirmed that such morphological oddities of our CMB sky as first noticed in the WMAP sky maps were indeed the real features of the observed universe, rather than instrumental artifacts. While the modest statistical significance of these findings did not merit serious revisions of the standard cosmological model, it remains of utmost importance to investigate whether such effects are present in the full sky CMB polarization maps. While prior Planck data releases did not allow sufficiently precise assessment of these effects, the present, definitive Planck data release comes with improved large scale polarization anisotropy maps. This talk will present the results of Isotropy and Statistics studies conducted on the final Planck CMB polarization maps.

E1.2-0009-18 PLANCK 2018 CMB LENSING

Julien Carron, j.carron@sussex.ac.uk

University of Sussex, Brighton, United Kingdom Planck Collaboration

Please see https://www.cosmos.esa.int/web/planck/planck-collaboration for a full list of members

Gravitational lensing by large-scale structures along the line of sight slightly distorts the temperature and polarization anisotropies of the cosmic microwave background (CMB). Planck data allows lensing mass reconstruction over most of the sky, and has definitely established CMB lensing as a precision probe of matter clustering in the late-time Universe. I will present the final 2018 Planck lensing results, including improved lensing spectrum band-powers in temperature and polarization, combined lensing constraints with galaxy lensing from the Dark Energy Survey, and a high-fidelity lensing mass map constructed in combination with the Cosmic Infrared Background as seen by Planck. I will also present the delensing of the Planck maps using our lensing tracers, with re-sharpening of the acoustic peaks and reduction of the B-mode power measured at high significance.

E1.2-0010-18 COSMOLOGICAL NON-GAUSSIANITY IN THE PLANCK MAPS

Benjamin Wandelt, bwandelt@flatironinstitute.org

Flatiron Institute & Sorbonne University & Princeton University, New York, New York, United States

Planck Collaboration

Please see https://www.cosmos.esa.int/web/planck/planck-collaboration for a full list of members.

The Planck mission has left a legacy of high-precision constraints on the inflationary epoch. The most precise inflationary constraint resulting from the Planck mission is on physically motivated forms of non-Gaussianity of the primordial seed perturbations. Planck constrains large classes of models that predict non-Gaussian features in the cosmic microwave background anisotropies. These features correspond to precise terms in the Lagrangian governing the very first instances of cosmogenesis. In addition to these fingerprints of physics in the very early Universe, there is a guaranteed signal of non-Gaussianity that arises from cosmic structure in a dark energy dominated phase. This effect has been detected in Planck. In this talk I will present, on behalf of the Planck team, the latest results from high-precision studies of the Planck maps and give an outlook for constraining the primordial fluctuations in the coming decade.

E1.2-0011-18 CONSTRAINTS ON INFLATION FROM PLANCK

Fabio Finelli, finelli@iasfbo.inaf.it INAF/OAS Bologna, Bologna, Italy

We present the implications for cosmic inflation of the Planck Legacy Release in combination with other data sets. We first show the constraints on the power spectra of primordial fluctuations and on single field slow-roll inflationary models. We then present the status of inflation beyond the single field slow-roll paradigm, summarizing the constraints on features in the primordial power spectrum, on isocurvature perturbations and on statistically anisotropic inflationary models.

E1.2-0012-18 THE ASTROPHYSICS OF THE MAGNETIZED DUSTY INTERSTELLAR MEDIUM

Francois Boulanger, francois.boulanger@ens.fr Ecole Normale Superieur, Paris, France Planck Collaboration

Please see https://www.cosmos.esa.int/web/planck/planck-collaboration for a full list of members.

Observations of Galactic dust are a highlight and a lasting legacy of the Planck space mission. Spectacular images combining the intensity of dust emission with the texture derived from polarization data have received world-wide attention and become part of the general scientific knowledge. Beyond this popular success, the dust maps are an immense step forward for Galactic astrophysics, greatly superseding earlier observations. Planck has provided astrophysicists with the data they needed to statistically characterize the structure of the Galactic magnetic field and its coupling with interstellar matter and turbulence. Planck multi-frequency observations have also opened a new perspective on interstellar dust, upsetting existing models. Futrhermore, the astrophysics of dust emission has become inter-connected to a paramount objective of observational cosmology: the quest for curl-like (B-mode) polarization of the cosmic microwave background expected to arise from primordial gravitational waves produced during the inflation era in the very early Universe. The need to achieve an accurate removal of the dust foreground binds the search for primordial B-modes to the astrophysics of the dusty magnetized interstellar medium. The promise of future CMB experiments depends not only on their sensitivity, but also on our ability to master the foreground interstellar dusty screen.

E1.2-0013-18 THE PLANCK SCIENTIFIC LEGACY

François R. Bouchet, bouchet@iap.fr

Institut d'Astrophysique de Paris - CNRS/Sorbonne Université, Paris, France

The Planck collaboration has produced about 150 scientific papers, half of them on cosmology, and these results have had a transformative impact on cosmology. Planck has measured LCDM fundamental parameters with a precision at the one percent level, setting the framework used in many other areas of physics and astronomy. It did establish at more than 5 sigmas the expected deviation from scale invariance of the initial distribution of power in generic inflationary models. It has dispelled many once popular variants of that base inflationary cosmology, in particular through its very tight constraints on the presence of any Primordial Non-Gaussian features. Planck has also opened the era of CMB lensing which will be a major scientific endeavor of future experiments. This is not to say that there are no more questions to answer, if anything because of a number of CMB anomalies as well as tensions when other cosmological probes are analyzed assuming LCDM. In this talk, the main Planck results on the basic cosmological model and their implications for fundamental physics, structure formation, and astrophysical cosmology will be presented and brought into context.

E1.2-0014-18 BEYOND PLANCK

Nazzareno Mandolesi, nazzareno.mandolesi@unife.it Università di Ferrara, Ferrara, Italy

Planck Collaboration

N.Mandolesi + Please see https://www.cosmos.esa.int/web/planck/planck-collaboration for a full list of members

The Planck project spanned some 25 years from conception to delivery of the final set of papers. During this long timeframe, Science has evolved and priorities shifted. Nonetheless, the Planck team was able to cope with the changes, and the mission has been a universally recognized success. A legitimate question is whether Planck really ends with the final set of papers. I will advocate that this is not the case, and there is still considerable potential to be exploited in the Planck data for CMB polarization, in addition to better characterization and cleaning up of smaller and smaller systematics. The immediate future, after the final products delivery, will undoubtedly see many projects with this aim: those that are more respectable will build upon the lessons learnt on the instruments, calibration, and systematics. At some point, however, we will exhaust Planck's information content. I will advocate that despite the tremendous effort in ground-based and balloon-borne experiments, a future space mission is necessary to exploit CMB polarization in a way analogous to what Planck has done for temperature. International collaboration is key for the success of these projects: the JAXA-led LiteBIRD might greatly benefit from an ESA mission of opportunity, while the very ambitious (and expensive) CORE may gain new life from a very timely collaboration with India.

E1.2-0015-18 THE COSMIC INFRARED BACKGROUND AS SEEN BY PLANCK: NEW INSIGHTS INTO THE CIB-CMB LENSING CROSS CORRELATION

Daniel Lenz, daniel.lenz@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology/ NASA, Pasadena, California, United States

The cosmic infrared background (CIB) is a powerful probe of large-scale structure across a very large redshift range, consisting of unresolved FIR emission from dusty galaxies. It can be used to study the astrophysics of galaxies, the star formation history of the Universe, and the connection between dark and luminous matter. The major difficulty here lies in obtaining accurate and unbiased large-scale CIB images that are cleaned from the contamination by Galactic dust. We used data of neutral atomic hydrogen from the recently-release HI4PI Survey to create template maps of Galactic dust, allowing us to remove this component from the Planck intensity maps. I will present our final CIB maps and the various processingand validation steps that we have performed to ensure the high quality of these maps. Based on these new CIB maps, I will also present a cross correlation analysis of the CIB signal and the Planck CMB lensing map, which can be used to study the primordial non-Gaussianity through a scale-dependent bias term. Aside from this particular application, the soon-to-be public maps will enable the community to investigate a wide range of questions, related to the Universe's large-scale structure.

E1.2-0016-18 WHY B MODES?

Marc Kamionkowski, kamion@jhu.edu

Johns Hopkins University, Baltimore, Maryland, United States

In this talk I will discuss the several ways in which the measurement of B modes in the CMB polarization can advance the study of the origin and evolution of the Universe and simultaneously probe new physics. The principal motivation for many of those involved in the quest for cosmic B modes is the large-angle signal from inflation. The prevailing single-field slow-roll models of inflation predict a signal in the realm of detectability within the next decade. If no such B modes are seen, it will force us to seriously reconsider the basic inflationary paradigm. However, B modes can also be used to look for novel parity-violating new physics from the early Universe (e.g., chiral gravitational waves) or late Universe (cosmic birefringence). And measurement of B modes expected from gravitational lensing are already being used as a tool in precision-cosmology endeavor. Finally, any cosmic polarization signal must be distinguished from polarized emission from the Milky Way, and the B modes associated with these "foregrounds" will provide valuable information on the physics of the interstellar medium.

E1.2-0017-18 NATURAL INFLATION: COMPARISON TO CMB DATA AND NEW DEVELOPMENTS

Katherine Freese, ktfreese@umich.edu

University of Michigan, Ann Arbor, Michigan, United States

I will discuss the status of Natural Inflation, a model that my collaborators and I originally proposed in 1990, as well as modern variants. Natural inflation uses an "axion" as the inflaton, where the term "axion" is used generically for a field with a flat potential as a result of a shift symmetry. I will compare variants of natural inflation to current and upcoming CMB data. Further, I will discuss new theoretical developments including a model of baryogenesis requiring only particles from the Standard Model of particle physics, ordinary neutrinos, and an axion as the inflaton.

E1.2-0018-18 MEASURING THE DIFFUSE FIR POLARIZED DUST EMISSION WITH PILOT FOR THE QUEST OF CMB B-MODES

Jonathan Aumont, jonathan.aumont@irap.omp.eu

IRAP - Institute of Research in Astrophysics and Planetology, Toulouse, France

Measuring precisely the faint polarization of the far-infrared and sub-millimetre sky is one of the next observational challenges of CMB cosmology. In particular, the recent BICEP2 episode has demonstrated that dust cannot be ignored when searching for B-modes in the CMB polarized signal. Indeed, precise knowledge of the dust polarization SED, and its possible variations on the sky will be necessary in the future, and very little is understood about the physics of dust alignment and processes leading to emission of polarized light. Constraining models of dust polarized emission will require far more measurements than are currently available. I will show preliminary observational results relevant to this important topic, from the analysis of the PILOT balloon-borne experiment data obtained during its last flight from Alice Springs, Australia in April 2017, during which the BICEP2 field has been observed in polarization in the far-infrared.

E1.2-0019-18 PASIPHAE: CLEARING THE PATH TO EXPERIMENTAL TESTS OF INFLATION

Konstantinos Tassis, tassis@physics.uoc.gr University of Crete, Heraklion, Greece

An inflation-probing B-mode signal in the polarization of the cosmic microwave background (CMB) would be a discovery of utmost importance in physics. Any inflationary B-mode signal, however, is contaminated by what currently constitutes a natural noise floor, produced by 3-dimensional effects in the most important CMB polarization foreground: emission from interstellar dust. I will discuss how the upcoming Polar Areas Stellar Imaging in Polarization High Accuracy Experiment (PASIPHAE) will revolutionise our ability to remove the dust foreground and beat this apparently irreducible noise floor through the newly developed technique of optopolarimetric magnetic tomography of the interstellar medium. PASIPHAE will take place simultaneously at the Skinakas observatory in Crete and the South African Astronomical Observatory. It will measure linear optical polarization at 0.1% accuracy of over 360 stars per square degree, a 1000-fold increase over the state of the art. Such a map will not only boost CMB polarization foreground removal beyond what is currently considered feasible, but it will also have a profound impact in a wide range of astrophysical research, including interstellar medium physics, high-energy astrophysics, and galactic evolution.

E1.2-0020-18 LITEBIRD FOR B-MODE FROM SPACE

Masashi Hazumi, masashi.hazumi@kek.jp KEK, Tsukuba, Japan

LiteBIRD is a JAXA-led international satellite project with an expected launch in the middle of 2020s with a H3 rocket. Its mission is to perform stringent tests of the cosmic inflation with full-sky cosmic microwave background (CMB) polarization surveys at degree scales with unprecedented precision. The full success of LiteBIRD is to achieve $\delta r < 0.001$, where δr is the total error on the tensor-to-scalar ratio r. This allows us to test well-motivated cosmic inflation models. The required angular coverage corresponds to 2 /i 200, where /i is the multipole moment. LiteBIRD will carry out full-sky surveys for three years at a Lagrangian point L2 for 15 frequency bands between 34 and 448 GHz. LiteBIRD will employ two telescopes to achieve the total sensitivity of 2.5 μKl with a typical angular resolution of 0.5° at 150 GHz. Each telescope has a half-wave plate system for modulation of polarization signals and a focal plane filled with polarization-sensitive transition-edge sensor (TES) bolometers. A cooling system provides a 100 mK base temperature for two focal planes and 2 K and 5 K stages for optical components. Although the payload module is designed to satisfy the very focused mission mentioned above, expected science outcomes of LiteBIRD are not limited to the measurement of r. In this talk, the mission, system, project and science outcomes of LiteBIRD will be reviewed.

E1.2-0021-18 PICO – THE PROBE OF INFLATION AND COSMIC ORIGINS

Charles Lawrence, charles.lawrence@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

PICO — the Probe of Inflation and Cosmic Origins — is a concept for NASA's possible future Probe line of competed missions. Designed to explore how the Universe began and evolved, PICO will survey the sky for four years with thousands of detectors over a wide frequency range. The ambitious goal of detecting or setting an upper bound on the tensor-to-scalar ratio for fluctuations of the cosmic microwave background of $r < 10{-}4$ will require exquisite control of foregrounds and systematics.

E1.2-0022-18 THE PRIMORDIAL INFLATION EXPLORER

Alan Kogut, alan.j.kogut@nasa.gov

Goddard Space Flight Center, Greenbelt, Maryland, United States

The Primordial Inflation Explorer (PIXIE) is an Explorer-class mission to characterize the signature of primordial inflation through its distinctive imprint on the cosmic microwave background. PIXIE uses a double-nulled Fourier Transform spectrometer to measure both linear polarization and the absolute intensity spectrum of the CMB and astrophysical foregrounds to background-limited sensitivity in 400 frequency channels spanning 30 GHz to 6 THz (1 cm to 50 micron wavelength). In addition to testing inflation by mapping the power spectrum of B-mode polarization, PIXIE will search for distortions in the CMB blackbody spectrum with sensitivity three orders of magnitude beyond the COBE/FIRAS limits. Sensitivity at these levels opens a new window to the early universe, probing physical processes ranging from Big Bang cosmology to dark matter decay/annihilation to the star formation history of the universe. I describe the PIXIE instrument and mission architecture needed for these new tests of the early universe.

E1.2-0023-18 THE NEXT GENERATION GROUND-BASED COSMIC MICROWAVE BACKGROUND EXPERIMENT CMB-S4

John Carlstrom, jc@kicp.uchicago.edu

The University of Chicago, Chicago, Illinois, United States

Measurements of the CMB have driven our understanding of the universe and the physics that govern its evolution from primordial quantum fluctuations to its present state. They provide the foundation for the remarkable 6-parameter cosmological model, CDM, which fits all cosmological data, although there are some tensions that may possibly hint at new physics. Far from being the last word in cosmology, the model raises deep questions: Is Inflation correct? What is its energy scale? What is the dark matter? What is the nature of dark energy? Are there light sterile neutrinos, or other light relics? This talk will describe progress on the next generation ground-based CMB experiment, CMB-S4, that is being designed to have sufficient sensitivity and control of systematics to make breakthroughs in many of these areas, i.e., to cross critical thresholds in parameter values or show that CDM is incomplete.

E1.2-0024-18 BICEP CONSTRAINTS ON PRIMORDIAL GRAVITATIONAL WAVES, CURRENT AND FUTURE

John Kovac, jmkovac@cfa.harvard.edu

Harvard University, Cambridge, Massachusetts, United States

The BICEP/Keck Array is suite of small microwave telescopes at the South Pole working together, and in conjunction with other surveys, to measure polarization patterns in the cosmic microwave background (CMB) that would arise from gravitational waves spawned in the earliest instants of time. If inflation is the process that produced the observable universe we inhabit and seeded primordial density fluctuations through quantum fluctuations operating at around GUT energy scales, then it will have produced a gravitational-wave background that may be detectable now via a faint "B-mode" pattern imprinted in the polarization of the CMB. Testing the prediction, or ruling it out for this range of energy scales, is a major goal of current CMB observations.

Detecting this faint pattern requires making maps of unprecedented sensitivity, while separating the faint polarization signals intrinsic to the CMB from other signals including polarized emission from dust and electrons in our own galaxy and patterns caused by weak gravitational lensing of large scale structure. The small-aperture BICEP/Keck Array telescopes have produced the deepest-ever maps of CMB polarization in four frequency bands. With the new BICEP3 and upcoming BICEP Array telescopes, the BICEP telescopes are exploiting the unique South Pole atmosphere to push these maps to cover a wide frequency range (30 - 270 GHz) to separate galactic emission from CMB signals. Data from other surveys including Planck, WMAP, and dedicated low-frequency instruments further improves foreground separation, while overlapping observations with the 10m South Pole Telescope provides resolution sufficient to reconstruct the weak lensing patterns of the CMB and to separate these from primordial B-mode patterns. The BICEP/Keck program is producing the most sensitive constraints yet on primordial gravitational waves, and is likely to improve these constraints over the next five years by nearly an order of magnitude.

E1.2-0025-18 THE POLARBEAR AND SIMONS ARRAY CMB POLARIZATION EXPERIMENTS

Brian Keating, bkeating@ucsd.edu

University of California San Diego, La Jolla, California, United States

POLARBEAR is a cosmic microwave background (CMB) polarization experiment located in the Atacama desert in Chile, which has been performing a deep search for CMB B-mode polarization from gravitational lensing. POLARBEAR-1 started observations in 2012, and the POLARBEAR team has published a series of results from its first two seasons of observations. The Simons Array expands POLARBEAR to include an additional two telescopes with nextgeneration POLARBEAR-2 multi-chroic receivers, observing at 95, 150, 220, and 270 GHz. The POLARBEAR-2 focal plane has 7,588 transition-edge sensor bolometers, read out with frequency-division multiplexing. In 2018, the Simons Array: an array of three POLARBEAR2 receivers and 3.5 meter diameter telescopes was commissioned, and two more telescopes will be outfitted with multichroic detectors in the coming years. We present results from the characterization, tuning, and operation of the fully integrated focal plane and readout for the first POLARBEAR-2 receiver, POLARBEAR-2A and discuss the capability of the three telescope Simons Array in the coming years.

E1.2-0026-18 COSMOLOGY WITH THE SOUTH POLE TELESCOPE: STATUS AND FUTURE PLANS

Bradford Benson, bbenson@kicp.uchicago.edu

Fermi National Accelerator Laboratory, Chicago, Illinois, United States

I will give an overview of the South Pole Telescope (SPT), a 10-meter diameter telescope at the South Pole designed to measure the cosmic microwave background (CMB). The SPT recently completed 10 years of observations, over which time it has been equipped with three different cameras: SPT-SZ, SPTpol, and SPT-3G. I will discuss recent results from the SPT-SZ and SPTpol surveys, including: an update on the SPT Sunyaev-Zel'dovich (SZ) cluster survey and joint analyses with the optical dark energy survey (DES); a comparison of CMB measurements between SPT-SZ and the Planck satellite; and the latest CMB polarization power spectrum constraints from SPTpol. In addition, I will discuss the status of the recently deployed SPT-3G camera, which achieved first light on the SPT in January 2017. The SPT-3G camera consists of 2710 trichroic pixels, each simultaneously measuring two orthogonal linear polarizations in frequency bands centered at 95, 150, and 220 GHz, and a total of 16,200 superconducting transition edge sensor (TES) bolometers, a factor of ten increase over the previously installed SPTpol camera. I will discuss the deployment of SPT-3G, its current status, and summarize the science goals of the SPT-3G experiment.

E1.3-0001-18 GAMMA-RAY/X-RAY EMISSION FROM MILLISECOND PULSAR BINARY

Jumpei Takata, takata@hust.edu.cn

Huazhong University of Science and Technology, Wuhan, China

C.Y. Hui, cyhui@cnu.ac.kr

Chungnam National University, Daejeon, Korea Jongsu Lee, skyljs1234@naver.com

Chungnam National University, Daejeon, Korea

A.K.H. Kong, akong@gapp.nthu.edu.tw

National Tsing Hua University, Hsingchu, Taiwan, China

P. H. Thomas Tam, tanbxuan@mail.sysu.edu.cn Sun Yat-sen University, Guangzhou, China Kwong Sang Cheng, hrspksc@hkucc.hku.hk

University of Hong Kong, Hong Kong, Hong Kong, China

In this presentation, gamma-ray and X-ray emission from millisecond pulsar binary will be discussed. The GeV gamma-ray emission is probably originated from the pulsar magnetosphere. But unexpected enhancement of GeV emission during the accretion power stage of the transient millisecond pulsar binary suggests the emission from the cold-relativistic pulsar wind or intrabinary shock or the disk matter injected by the propeller effects contribute to the observations. The X-ray emission can be originated from the heated polar cap, pulsar magnetosphere and intra-binary shock. By comparing the theoretical model and observation, we will discuss the magnetospheric non-thermal emission is negligible comparing to the heated polar cap and intrabinary shock emission. For redback millisecond pulsar, the X-ray emission is dominated by the intra-binary shock. For some black widow system, on the other hand, the heated polar cap emission can dominate in the observed emission.

E1.3-0002-18 PULSAR GAMMA-RAY EMISSION: MACROSCOPIC AND KINETIC MODELS

Constantinos Kalapotharakos, ckalapotharakos@gmail.com UMCP / NASA GSFC, Greenbelt, Maryland, United States

Fermi, since its launch in 2008, has played a catalytic role in the discovery of millisecond pulsars. I will present dissipative macroscopic models and kinetic PIC models that reproduce the observed phenomenology of the gamma-ray young and millisecond pulsars. Our models indicate that the gamma-ray emission is produced in regions outside the light cylinder near the equatorial current sheet. A detailed comparison of the model spectral properties with those observed by Fermi reveals the dependence of the macroscopic parameters (e.g. conductivity) and microphysical properties (e.g. particle multiplicities, particle injection rates) on the spindown rate providing a unique insight into the understanding of the physical mechanisms behind the high-energy emission of both young and millisecond pulsars.

E1.3-0003-18 RADIATION AND POLARIZATION FROM AN OFF-CENTRED ROTATING DIPOLE

Jérôme Pétri, jerome.petri@astro.unistra.fr

Observatoire Astronomique de Strasbourg, Strasbourg, France

When a neutron star forms, a strong magnetic field survives in its interior. This magnetic topology is usually assumed to be well approximated by a dipole located at the centre of the star. However, a slight shift from the centre has strong implications for the surrounding electromagnetic field. We study the effect of an off-centred dipole anchored in the neutron star interior. Exact analytical solutions are given in vacuum to any order of accuracy. The spindown luminosity and the torque exerted on its crust are computed to the lowest leading order. Results are compared to earlier works and a discussion on repercussions on pulsar braking index and multi-wavelength light curves is proposed.

Moreover, radio polarization measurements of pulsed emission from pulsars offer a valuable insight into the basic geometry of the neutron star: inclination angle between the magnetic and rotation axis, inclination of the line of sight and magnetic topology. So far, all studies about radio polarization focused on the standard rotating vector model with the underlying assumption of a centred dipole. This model is generalized to an off-centred dipole with an exact analytic expression for the phase-resolved polarization angle. The polarization angle now also depends on the emission altitude. The time lag between radio pulse profiles and surface thermal X-ray emission is naturally explained in this model.

E1.3-0004-18 PLASMA MAGNETOSPHERE OF OSCILLATING AND ROTATING MAGNETIZED NEUTRON STARS

Bobomurat Ahmedov, bahmedov@yahoo.com

Ulugh Beg Astronomical Institute, Tashkent, Uzbekistan

We discuss a number of analytical studies, aimed at adding the influence of oscillations experienced by a pulsar/magnetar on its plasma magnetopshere. We show that particular modes of oscillations may considerably increase the pulsar/magnetar luminosity and apply the obtained theoretical results on the plasma magnetosphere of oscillating and rotating neutron stars i) to propose a qualitative model for the explanation of the phenomenology of intermittent part time pulsars, ii) to study the conditions for radio emission in rotating and oscillating magnetars by focusing on the main physical processes determining the position of their death lines, i.e. of those lines that separate the regions where the neutron star may be radio loud or radio quiet, iii) to explain the subpulse drift phenomena adopting the space-charge limited ow model and comparing the plasma drift velocity in the inner region of pulsar magnetospheres with the observed velocity of drifting subpulses.

E1.3-0005-18 THE ORIGIN OF THE POLARIZED RADIO PROFILES OF MILLISECOND PULSARS

Jaroslaw Dyks, jinx@ncac.torun.pl

Nicolaus Copernicus Astronomical Center, Torun, Poland

Observed polarisation of radio pulsar profiles either follows the rotating vector model (RVM) or exhibits peculiar phenomena which result from birefringent propagation effects. Oftentimes both cases occur in different parts of the same profile. The peculiarities involve strong distortions of polarization angle from the RVM and a high circular polarization which can be maximum (instead of zero) at orthogonal polarization jumps. I will show that the peculiar polarization features can be understood in terms of coherent addition of radiation in two orthogonal polarization modes. Even simple parametrizations of the added waves' phase lag produce effects observed in radio pulsar data. In particular, the polarization profile of the 59 ms pulsar B1913+16 can be understood within a nearly full pulse window. I will also briefly describe what the intensity profiles are telling us about the dynamics of plasma in the emission region and on the geometry of the millisecond radio pulsar beam.

E1.3-0006-18 HOW TO TRIAGE RADIO PULSAR DISCOVERIES?

Evan Keane, evan.keane@gmail.com

SKA Organisation, Macclesfield, United Kingdom

The SUrvey for Pulsars and Extragalactic Radio Bursts (SUPERB) is ongoing at Parkes since 2014. It is an example of a short-pointing multi-pass radio pulsar survey, operating at 1.4 GHz. Another example, operating at 10 times lower radio frequency, is the LOFAR Tied-Array AllSky Survey (LOTAAS), which has been running since 2013. By design, these surveys are well suited to finding nulling and intermittent radio pulsars, eclipsing systems, interesting binaries, up-scintillated and nearby sources. Processing the data from these surveys is a considerable task, but has been successful with 100 pulsar discoveries between them (1/3 SUPERB, 2/3 LOTAAS). These two projects are analogues of pulsar surveys that the Square Kilometre Array will perform with SKA1-Mid and -Low, respectively. However with the SKA the discovery rate will be two orders of magnitude higher. Classifying the SKA pulsar candidates to make discoveries is a large computational problem in and of itself, but triaging the resultant discoveries to find the most interesting sources is also very challenging. Being able to recognise that we have discovered such systems in as close to real time as possible is crucial, e.g. we want to realise when a transitional MSP is on in the radio before it turns off! In this talk I propose some initial ideas on this topic and hope to kick-start an open collaboration for new ideas in this area.

E1.3-0007-18 RADIATION FROM SHOCKS IN MILLISECOND PULSAR BINARIES

Alice Harding, alice.k.harding@nasa.gov

North-West University, Potchefstroom, Potchefstroom, South Africa

A large number of new Black Widow and Redback rotation-powered millisecond pulsars have been discovered through radio searches of unidentified Fermi sources, increasing the known number of these systems from 4 to 28. We model the high-energy emission from particles accelerated to several TeV in the intrabinary shocks in these systems, and its modulation at the binary orbital period. Constructing a geometric model of the shock, we use radio eclipse data in conjunction with optical constraints on the binary inclination angle to constrain the shock stagnation point distance from either the pulsar or companion star. We next model the X-ray synchrotron orbital light curves from accelerated particles convecting downstream of the shock. Fitting our model light curves to those observed from a number of binaries we find a correlation that constrains the bulk Lorentz factor of the wind flow as well as the orbital inclination angles.

E1.3-0008-18 COMPACT BINARY PULSAR SEARCH (COBIPULSE): FIRST RESULTS

Manuel Linares, manuel.linares@upc.edu

Universitat Politecnica de Catalunya, Barcelona, Spain COBIPULSE collaboration

P. Miles-Paez, P. Rodriguez-Gil, T. Shahbaz, J. Casares, C. Fariña, R. Karjalainen, L. Portos,

A. Valenzuela

In the past decade, the large area telescope (LAT) aboard Fermi has uncovered more than three thousand gamma-ray sources. As a consequence, compact binary millisecond pulsars (with orbital periods shorter than about a day) are becoming a sizeable and rapidly-growing pulsar population. Pulsars are the main Galactic class among the known gamma-ray sources, yet nearly a thousand LAT sources remain unidentified. We present the first results from our COBIPULSE survey: a systematic search for optical variable and X-ray counterparts to Fermi-LAT pulsar candidates. These include the discovery of a new redback candidate in a 21-hr orbit (3FGL J0212.1+5320), the brightest of its kind in the optical band.

E1.3-0009-18 THERMONUCLEAR PROBES OF MILLISECOND PULSARS

Tod Strohmayer, tod.strohmayer@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States

Every few hours some accreting neutron stars in close binary systems erupt in powerful thermonuclear conflagrations. These X-ray bursts rapidly heat the surface layers, and sometimes in a nonuniform way. Rotational modulation of the anisotropic surface emission can produce X-ray pulsations at or near the neutron star spin frequency. These "burst oscillations" were first seen with NASA's Rossi X-ray Timing Explorer (RXTE) and provide a new way to see the spin periods of accreting neutron stars. I will provide an overview of this phenomenon with a focus on what detailed spectral-timing studies of these oscillations can tell us about neutron stars, including the dense matter equation of state, and thermonuclear burning on them. I will also discuss burst oscillations and nuclear burning from accreting millisecond pulsar systems and present some new results obtained with NASA's Neutron Star Interior Composition Explorer (NICER) on the recently discovered millisecond pulsar IGR J17062-6143.

E1.3-0010-18 NEW BURNING PHYSICS AND BURST OSCILLATIONS

Frank Chambers, frnchambers@uva.nl

University of Amsterdam, Amsterdam, Netherlands

Accreting neutron stars (NS) can exhibit high-frequency modulations in their lightcurves during thermonuclear X-ray bursts, known as burst oscillations. Their frequencies can be offset from the spin frequency of the NS by several Hz (known independently), and can drift by 1-3 Hz. New X-ray missions with improved sensitivity (such as eXTP and Strobe-X) aim to use the burst oscillation phenomenon to measure NS parameters, an effort that would be helped by a thorough understanding of the underlying mechanism. One plausible explanation is that a wave is present in the bursting ocean that decreases in frequency (in the rotating frame) as the burst cools, hence explaining the drifts. The strongest candidate is the buoyant r-mode, however, models for the ocean background used in previous studies over-predict frequency drifts by several Hz. Using new background models that were developed to explain the short recurrence times of some bursts (which include shallow heating, and burning in the tail of the burst), the evolution of the buoyant r-mode was calculated. The resulting frequency drifts are smaller, in line with observations.

E1.3-0011-18 TWENTY YEARS OF ACCRETING MILLISECOND PULSARS

Tiziana Di Salvo, tiziana.disalvo@unipa.it University of Palermo, Palermo, Italy Andrea Sanna, andrea.sanna@dsf.unica.it

Universita degli Studi di Cagliari, Monserrato, Italy Alessandro Papitto, alessandro.papitto@oa-roma.inaf.it

INAF-Osservatorio Astronomico di Roma (OAR), Monte Porzio Catone, Italy Luciano Burderi, burderi@dsf.unica.it

University of Cagliari, Cagliari, Italy Alessandro Riggio, riggio@dsf.unica.it University of Cagliari, Italy

Rosario Iaria, rosario.iaria@unipa.it University of Palermo, Palermo, Italy

In the last 20 years, since the discovery in 1998 of the first Accreting Millisecond Pulsar SAX J1808.4-3658, our understanding of the millisecond pulsar population changed dramatically. Thanks to the large effective area and good time resolution of the NASA X-ray observatory Rossi X-ray Timing Explorer first and the ESA XMM-Newton after, we discovered that neutron stars in Low Mass X-ray Binaries (LMXBs) spins at frequencies between 200 and 750 Hz, indirectly confirming the recycling scenario, according to which neutron stars are spun up to millisecond periods during the LMXB-phase. In this review I describe the properties of accreting millisecond pulsars, with particular attention to the last discoveries and to the long-term orbital and spin evolution. I will highlight what we know and what we have still to learn about in order to fully understand the (sometime puzzling) behaviour of these systems and their evolutionary connection to the rotation-powered millisecond pulsars population.

E1.3-0012-18 OBSERVATIONAL UPDATES ON ACCRETING MILLISECOND X-RAY PULSARS

Andrea Sanna, andrea.sanna@dsf.unica.it Universita degli Studi di Cagliari, Monserrato, Italy Luciano Burderi, burderi@dsf.unica.it

University of Cagliari, Cagliari, Italy Tiziana Di Salvo, tiziana.disalvo@unipa.it University of Palermo, Palermo, Italy Alessandro Riggio, riggio@dsf.unica.it University of Cagliari, Italy

Alessandro Papitto, alessandro.papitto@oa-roma.inaf.it

INAF-Osservatorio Astronomico di Roma (OAR), Monte Porzio Catone, Italy Enrico Bozzo, enrico.bozzo@unige.ch

ISDC, Versoix, Switzerland

After almost two decades from the discovery of the first accreting millisecond X-ray pulsar (AMXP) SAX J1808.4-3658, the sample of accreting rapidly-rotating neutron stars harboured in low mass X-ray binary systems has increased in number up to 20. The extremely short spin periods shown by the accreting millisecond X-ray pulsars are the result of long-lasting mass transfer from low mass companion stars through an accretion disc onto a slow-rotating NS as predicted by the so-called "recycling scenario". At the end of the mass transfer phase, a millisecond pulsar shining from the radio to the gamma-ray band, and powered by the rotation of its magnetic field, is expected to turn on. The close link shared by radio millisecond pulsars and AMXPs has been observationally confirmed by the transitional binary systems IGR J18245 2452 as well as by other transitional millisecond pulsars. Here I will discuss the temporal and spectral properties of the recently discovered AXMPs MAXI J0911-655 and IGR J16597- 3704. Moreover, I will present the latest updates on the long-term orbital evolution of the intermittent AMXP SAX J1748.9-2021 obtained combining the updated set of ephemeris from its 2017 outburst with those of the previous outbursts. The orbital period derivative will be then discussed in terms of the possible evolutionary scenarios of the binary system.

E1.3-0013-18 MULTI-EPOCH MODELLING OF THE HOT SPOT OF THE ACCRETING MILLISECOND X-RAY PULSAR SAX J1808-3658

Denis Leahy, leahy@ucalgary.ca University of Calgary, Calgary, Canada

SAX J1808-3658 is an accreting millisecond X-ray pulsar. The X-ray pulse shape depends on the intrinsic properties of the emission spot (size, shape, location, and emissivity) as well as the neutron star's properties (mass, radius, and spin). This was shown by the first pulse shape analysis by Poutanen and Gierlinski (2003, MNRAS, 343, 1301). The goal of such modelling is a measurement of mass and radius, which leads to constraints on the EOS of supernuclear density material. Improved modelling and constraints for SAX J1808 were carried out by Morsink and Leahy (2011, ApJ, 726, 56) and for XTE J1807-294 by Leahy, Morsink and Chou (2011, ApJ, 742,17). The current work further improves this modelling by simultaneous fitting of multiple different pulse shapes from SAX J1808-3658.

E1.3-0014-18 SPECTRAL AND TIMING ANALYSIS OF THE ACCRETING MILLISECOND PULSAR IGR J17511-3057 WITH NUSTAR, SWIFT/XRT AND XMM-NEWTON OF THE LATEST OUTBURST

Alessandro Riggio, alessandro.riggio@unica.it

Universita degli Studi di Cagliari, Monserrato (CA), Italy Andrea Sanna, andrea.sanna@dsf.unica.it

Universita degli Studi di Cagliari, Monserrato, Italy Luciano Burderi, burderi@dsf.unica.it

University of Cagliari, Cagliari, Italy Tiziana Di Salvo, tiziana.disalvo@unipa.it University of Palermo, Palermo, Italy

Alessandro Maselli, alessandro.maselli@dsf.unica.it University of Cagliari, Monserrato, Italy

Alessandro Papitto, alessandro.papitto@oa-roma.inaf.it

INAF-Osservatorio Astronomico di Roma (OAR), Monte Porzio Catone, Italy

Accretion-powered millisecond pulsars are transient low mass X-ray binaries, which show a coherent modulation of their X-ray fluxes with periods of the order of few milliseconds. Up to now, 20 accreting millisecond pulsars are known. Of these, only a few have shown more than an outburst and thus permitting to study the evolution of such a systems. We present a detailed broad band spectral analysis of the 2015 outburst of the accreting millisecond pulsar IGR J17511-3057 as simultaneously seen by NuSTAR and Swift, and compare our results with the XMM-Newton observation of the same outburst and the first outburst. We obtained a very precise orbital solution for the 2015 outburst through timing analysis of both NuSTAR and XMM-Newton observations. Moreover, comparing the this orbital solution with the one for the 2009 outburst, we are able to pose strong constraints on the orbital period derivative and the orbital evolution of the source.

E1.3-0015-18 QPO FREQUENCY CORRELATIONS IN AMXPS

Marieke Van Doesburgh, mvdoesburgh@gmail.com University of Amsterdam, Amsterdam, Netherlands Michiel Van Der Klis, michiel@science.uva.nl University of Amsterdam, Amsterdam, Netherlands

We present the comparative analysis of the RXTE archival X-ray timing data on 13 burst oscillation sources to those on 6 AMXPs. In particular, we compare the correlations best characterised by a power law between centroid frequencies of low frequency (<100 Hz) and kHz QPOs in the two source types. We test if our results match the theoretical prediction that a combination of magnetic torques, classical and nodal precession gives rise to overall net precession of an accretion disc causing such frequency correlations.

E1.3-0016-18 TRANSITIONAL MILLISECOND PULSARS

Alessandro Papitto, alessandro.papitto@oa-roma.inaf.it

INAF-Osservatorio Astronomico di Roma (OAR), Monte Porzio Catone, Italy

Millisecond pulsars attain their very quick rotation during a Gyr-long, X-ray bright phase of accretion of matter from a low mass companion star. When the mass transfer stops, magnetospheric pulsed emission powered by the star rotation and observed preferentially in the radio and gamma-ray bands, switches on. This complex evolution has been recently demonstrated by the discovery of transitional millisecond pulsars that swing between an accretion-powered X-ray pulsar regime and a rotationally-powered radio pulsar state on a time scale of a few weeks, or even shorter. These pulsars show an incredibly rich phenomenology that reflects all the possible outcomes of the interaction between the pulsar wind of particles and radiation and matter in an accretion disk. Recently, also optical pulsations have also observed from a transitional pulsar (Ambrosino, Papitto et al., 2017, Nature Astronomy), the first ever from a millisecond spinning neutron star. The pulsations were observed by using the fast photometer SiFAP at the INAF Galileo Telescope. Optical pulses were detected when the pulsar was surrounded by an accretion disk, but they are most likely originated by a rotation-powered magnetospheric process. The profound implications for our understanding of the pulsar disk/magnetosphere interaction will be discussed.

E1.3-0017-18 MULTI-BAND ORBITAL VARIABILITY IN REDBACKS AND TRANSITIONAL MSEC PULSAR BINARIES

Domitilla De Martino, demartino@oacn.inaf.it

INAF - Osservatorio Astronomico di Capodimonte, NAPLES, Italy Alessandro Papitto, alessandro.papitto@oa-roma.inaf.it

INAF-Osservatorio Astronomico di Roma (OAR), Monte Porzio Catone, Italy Nanda Rea, rea@ieec.uab.es

Consejo Superior de Investigaciones Cientificas (CSIC), Barcelona, Spain Francesco Coti Zelati, cotizelati@ice.csic.es

Institute for Space Science (CSIC-IEEC), Barcelona, Spain Diego F. Torres, dtorres@ieec.uab.es

ICREA & Institute of Space Sciences, Barcelona, Spain

We will discuss the multi-band orbital variability and the long-term behaviour observed in the two transitional msec pulsars (tMSPs) XSSJ12270-4859 and PSRJ1023+0038 and other redbacks to understand the role of the intrabinary shock during the radio pulsar state and the effects of irradiation on the companion star to shed light into the possible mechanism driving the dramatic state changes seen in tMSPs.

E1.3-0018-18 GRO J1744-28: THE SLOWEST TRANSITIONAL PULSAR?

James Court, j.m.court@soton.ac.uk

University of Southampton, Southampton, United Kingdom

GRO J1744-28 (the Bursting Pulsar) is an Eddington-limited accreting pulsar which shows highly structured X-ray variability near the end of its outbursts. We find that this variability is analogous to that seen in Transitional Millisecond Pulsars such as PSR J1023+0038: 'missing link' systems consisting of a pulsar nearing the end of a phase of recycling spin up. As such, we show that the Bursting Pulsar may also be associated with this class of objects. We discuss the implications of this scenario; in particular, we discuss the fact that the Bursting Pulsar has a significantly higher spin period and magnetic field than any other known Transitional Pulsar. If the Bursting Pulsar is indeed transitional, then this source opens a new window of opportunity to test our understanding of these systems in an entirely unexplored physical regime.

E1.3-0019-18 ACCRETION AND PROPELLER TORQUE IN THE SPIN-DOWN PHASE OF NEUTRON STARS: THE CASE OF TRANSITIONAL MILLISECOND PULSAR PSR J1023+0038

Unal Ertan, unal@sabanciuniv.edu Sabanci University, Istanbul, Turkey

The torque acting on PSR J1023+0038, one of the three confirmed transitional millisecond pulsars, was measured in radio pulsar and X-ray pulsar states. The source spins down in both states, and the torque in the X-ray pulsar phase is only about 27 % greater than in the radio pulsar phase (Jaodand et al. 2016). Using the inner disk radius, obtained recently by Ertan (2017) for the propeller phase which is close to the co-rotation radius and insensitive to the mass inflow rate, we have modelled the torque acting on PSR J1023+0038. The model can reproduce the observed torques consistently with the X-ray luminosities. The high and low X-ray luminosities in these sates correspond to accretion with spin-down (weak propeller) and strong propeller situations respectively. Several times increase in the disk mass-flow rate takes the source from the low-Lx, strong propeller to the high-Lx, accretion with spin-down phase. The resultant decrease in the inner disk radius increases the magnetic torque slightly, explaining the observed small increase in the spin-down rate. We have found that the spinup torque exerted by accreting material is much smaller than the magnetic spin-down torque exerted by the disk in both in both Lx states.

E1.3-0020-18 SIFAP: HIGH SPEED PHOTOMETRY FOR VARIABLE SOURCES IN THE OPTICAL BAND

Filippo Ambrosino, filippo.ambrosino@iaps.inaf.it INAF - IAPS Rome, Rome, Italy

Alessandro Papitto, alessandro.papitto@oa-roma.inaf.it

INAF-Osservatorio Astronomico di Roma (OAR), Monte Porzio Catone, Italy Franco Meddi, franco.meddi@roma1.infn.it

Sapienza Univeristy of Rome, Roma, Italy Adriano Ghedina, ghedina@tng.iac.es INAF, Breña Baja, Spain

The recent advent of solid-state detectors originally developed for high energy physics is revolutionizing astrophysical measurements. An ultra-fast photometer based on the Silicon Photo Multiplier technology (SiFAP, Silicon Fast Astronomical Photometer) and capable of the single photon detection in the Optical band (320-900 nm) with a time resolution down to 25 ns was developed at the Department of Physics of Sapienza Università di Roma since 2009 to study astrophysical variable sources. I will show the working principle of SiFAP and its first results obtained from observations of the Crab Pulsar, Hz Her/Her X-1, Aql X-1, and the transitional millisecond pulsar PSR J1023+0038, performed at the 1.52 m Cassini Telescope at Loiano and the 3.58 m Telescopio Nazionale Galileo (TNG). I will discuss the properties of the optical pulsations observed from the millisecond pulsar PSR J1023+0038 (Ambrosino, Papitto et al., 2017, Nature Astronomy), as well as future prospects for fast optical photometry with SiFAP.

E1.3-0021-18 NEUTRON STAR PROPERTIES AND THE EVOLUTION OF MILLISECOND PULSARS

Deepto Chakrabarty, deepto@mit.edu

Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

I will review open questions on the spin and magnetic evolution of millisecond pulsars, as well as efforts to use millisecond pulsar observations to constrain neutron star properties.

E1.3-0022-18 TWO COEXISTING FAMILIES OF COMPACT STARS: THEORETICAL BACKGROUND AND ASTROPHYSICAL IMPLICATIONS

Ignazio Bombaci, ignazio.bombaci@unipi.it University of Pisa, Pisa, Italy

It is usually thought that a single equation of state (EoS) model "correctly" represents all compact stars. In the present talk I will emphasize that two families of compact stars, viz., "normal" neutron stars and strange quark stars, can coexist in nature, and that neutron stars can get converted to strange quark stars through the nucleation process of quark matter in the stellar center. I will first briefly discuss the theoretical framework for the quark deconfinement phase transition in dense matter and in neutron star cores. Next, I will discuss some of the astrophysical consequences of the conversion process of neutron stars to quark stars, and particularly for the concept of limiting mass of compact stars (to be compared with measured neutron star masses) and the observational implications for millisecond pulsars. Finally, I will emphasize the additional complexity for constraining EoS models, for example, by stellar radius measurements using X-ray observations, if two families of compact stars coexist.

E1.3-0023-18 CONSTRAINING THE NEUTRON STAR MASS RADIUS RELATION WITH NICER OBSERVATIONS OF MILLISECOND PULSARS

Slavko Bogdanov, slavko@astro.columbia.edu

Columbia University, New York, New York, United States

One of the primary goals of the Neutron Star Interior Composition Explorer (NICER) is to carry out sensitive X-ray observations of neutron stars in order to constrain the poorly understood equation of state of cold matter at densities exceeding the nuclear saturation density. The NICER mission is focusing on measuring the masses and radii of several relatively bright, thermally-emitting, rotation-powered millisecond pulsars, by fitting sophisticated models that incorporate all relevant relativistic effects and atmospheric radiation transfer processes to their periodic soft X-ray modulations. We will present NICER data of the targets observed for this purpose, and the technique and models that have been developed by the NICER team to estimate the masses and radii of these pulsars.

E1.3-0024-18 HOW CAN TRANSIENT ACCRETION CRUCIALLY AFFECT THE SPIN RATES OF MILLISECOND PULSARS?

Sudip Bhattacharyya, sudip@tifr.res.in

Tata Institute of Fundamental Research, Mumbai, India Deepto Chakrabarty, deepto@mit.edu

Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

A crucial but previously unrecognized factor governing the spin evolution of millisecond pulsars is transient accretion. We numerically show that X-ray transients can spin up neutron stars to rates several times higher than can persistent accretors, for the same long-term average accretion rate. We analytically show that this happens because the equilibrium spin frequency for a transient can be several times higher than that for a persistent source with the same average accretion rate. Note that, as we explicitly argue for the first time, the spin equilibrium condition for a transient source is the zero net angular momentum transfer to the neutron star in each outburst cycle. Our results imply the existence of a population of submillisecond pulsars, which is not observed. This may require an additional spin-down mechanism, such as gravitational radiation, for the fastest-spinning accreting pulsars.

E1.3-0025-18 FROM TRANSIENT LOW-MASS X-RAY BINARIES TO REDBACK MILLISECOND PULSARS

Xiangdong Li, lixd@nju.edu.cn

Department of Astronomy, Nanjing University, Nanjing, China

Redback millisecond pulsars (MSPs; hereafter redbacks) are a subpopulation of eclipsing MSPs in close binaries. The formation processes of these systems are not clear. The three pulsars showing transitions between rotationand accretion-powered states belong to both redbacks and transient low-mass X-ray binaries (LMXBs), suggesting a possible evolutionary link between them. Through binary evolution calculations, we show that the accretion disks in almost all LMXBs are subject to the thermal-viscous instability during certain evolutionary stages, and the parameter space for the disk instability covers the distribution of known redbacks in the orbital period-companion mass plane. We accordingly suggest that the abrupt reduction of the mass accretion rate during quiescence of transient LMXBs provides a plausible way to switch on the pulsar activity, leading to the formation of redbacks, if the neutron star has been spun up to be an energetic MSP. We investigate the evolution of redbacks, taking into account the evaporation feedback, and discuss its possible influence on the formation of black widow MSPs.

E1.3-0026-18 MASS MEASUREMENTS FOR MILLISECOND PULSARS AND A NEW CLASS OF ECCENTRIC BINARY MILLISECOND PULSARS

Paulo Freire, pfreire@mpifr-bonn.mpg.de

Max Planck Institute fur Radioastronomie, Bonn, Germany

In this talk, I will review recent and upcoming measurements of the masses of millisecond pulsars (MSPs) in a diverse set of binary systems. These measurements have showed conclusively that MSPs have a very wide range of masses; significantly wider than the range observed for neutron stars in double neutron star systems; these have introduced important constraints on the equation of state of dense matter, a fundamental problem of nuclear physics. Somewhat surprisingly, MSP masses show no relation to any spin characteristics of the systems or the orbital characteristics of their host systems, nor their kinematic properties. I then focus on a new class of binary MSPs with eccentric orbits. The characteristics of these systems are at odds with the predictions of standard stellar evolution theories. I then show how the recent mass measurements for MSPs in these systems have ruled out most of the hypotheses advanced to explain their formation, and confirm the lack of any correlation of the MSP mass and the host system. I finally discuss the evidence on whether MSP masses are bimodal or not.

E1.3-0027-18 INCLINED MAGNETIC DIPOLE ACCRETION ONTO ROTATING NEUTRON STARS

Enrico Bozzo, enrico.bozzo@unige.ch ISDC, Versoix, Switzerland

The estimate of the magnetospheric radius, marking the boundary between the closed magnetosphere of an accreting neutron star and the material in the surrounding Keplerian accretion disk, is a long standing problem in high energy Astrophysics. We review the magnetospheric radius calculations in the so-called magnetically threaded disk model, comparing the simplified approach originally proposed by Ghosh Lamb (1979) with the revised version proposed by Wang (1987), Wang (1995), and Wang (1997). We show that for a given set of parameters the revised magnetically threaded disk model predicts a magnetospheric radius that is significantly smaller than that derived from the Ghosh Lamb (1979) treatment, especially when large inclination angles between the neutron star rotation and magnetic field axes (60 deg) are considered. Accretion onto a fast rotating neutron star is thus allowed in the Wang (1987), Wang (1995), and Wang (1997) prescriptions at lower mass inflow rates before it gets inhibited by the onset of the propeller regime. As an example, we apply these calculations to the case of transitional pulsars, which have shown X-ray pulsations at an unprecedented low luminosity level compared to other neutron stars in X-ray binaries. Assuming that the transitional pulsars are endowed with large inclination angles between the magnetic and rotation axes, we show that accretion at luminosities of 10 33 erg s 1 (and thus X-ray pulsations) may still be expected without invoking strong propeller outflows. More generally, we propose that accretion driven X-ray pulsations from rotating neutron stars in X-ray binaries can take place at a very low luminosity level in all those sources characterized by a large inclination angle between the rotation and magnetic field axes.

E1.3-0028-18 THE COLD SURFACE OF MILLISECOND PULSARS: A GOLD MINE FOR FUNDAMENTAL PHYSICS

Sebastien Guillot, sebastien.guillot@irap.omp.eu

IRAP, University of Toulouse / CNRS, Toulouse, France

The small hot polar cap emission (106K) of millisecond pulsars generates the pulsations that are modelled to d magnetic field objects. But the cold thermal emission from the remainder of their surface (at colder temperature term evolution and the amplitudes of r–modes inside these old objects. In this talk, I will present some effortst U V and soft X – ray bands, in order to determine its properties.

E1.3-0029-18 X-RAY BOUNDS ON THE R-MODE AMPLITUDE IN MILLISECOND PULSARS

University of Arizona, Tucson, Arizona, United States Dimitrios Psaltis, dpsaltis@email.arizona.edu University of Arizona, Tucson, Arizona, United States Ersin Gogus, ersing@sabanciuniv.edu

Sabanci University, Istanbul, Turkey Ergün Ege, ergun.ege@ogr.iu.edu.tr

Istanbul University, Institute of Science, Istanbul, Turkey Beste Beğiçarslan, beste.begicarslan@gmail.com

Istanbul University, Faculty of Science, Istanbul, Turkey Tugçe Kocabıyık, tugcekocabiyik3406@gmail.com Istanbul University, Faculty of Science, Istanbul, Turkey r-modes are global unstable oscillations expected to occur in rapidly rotating neutron stars. Because these modes are unstable, if not damped they are expected to grow and emit gravitational waves, which should spin the neutron star down. On the other hand the damping of these modes inside the neutron star should dissipate a significant amount of energy that heats the star, which depends on the interior composition of the object. Observations or limits on the surface emission of millisecond pulsars may prove to be a very useful probe to put constrains on the amplitude of r-mode oscillations and hence the interior of neutron stars. In this talk we present the first results of our search for thermal surface emission from some of the fastest known millisecond pulsars analyzing X-ray data via a novel neutron star atmosphere model, which takes into account the general relativistic effects due to rapid rotation. Our initial results show that the present data imposes very strong limits on the amplitude of r-modes, which shows that there is significant damping in these objects

E1.3-0030-18 THE NORTH-AMERICAN NANOHERTZ OBSERVATORY FOR GRAVITATIONAL WAVES: STATUS, RESULTS, AND PROSPECTS

Michele Vallisneri, michele.vallisneri@jpl.nasa.gov

Jet Propulsion Laboratory, Pasadena, California, United States

The NANOGrav Physics Frontiers Center uses the Arecibo Observatory and the Green Bank Telescope (the two most sensitive radio telescopes in the world) to monitor very stable millisecond pulsars with very high precision. Our goal is to detect low-frequency gravitational waves and use them to learn about supermassive black-hole binaries and other gravitationalwave sources in the nanohertz band. Our access to these observatories has allowed us to reach unprecedented sensitivities, and we expect to make a detection soon. In this talk I discuss the status and prospects of our searches.

E1.3-0031-18 EROSITA – STATUS AND SCIENTIFIC PROSPECTS

Werner Becker, web@mpe.mpg.de

Max Planck Institute for Extraterrestrial Physics, Garching, Germany eROSITA (extended ROentgen Survey with an Imaging Telescope Array) is the core instrument on the Russian Spektrum-Roentgen-Gamma (SRG) mission which is currently scheduled for launch in fall 2018. eROSITA will perform a deep survey of the entire X-ray sky. In the soft band (0.5-2 keV), it will be about 30 times more sensitive than ROSAT, while in the hard band (2-8 keV) it will provide the first ever true imaging survey of the sky. The design driving science is the detection of large samples of galaxy clusters to redshifts $z > 1$ in order to study the large scale structure in the Universe and test cosmological models including Dark Energy. In addition, eROSITA is expected to yield a sample of a few million AGN, including obscured objects, revolutionizing our view of the evolution of supermassive black holes. The survey will also provide new insights into a wide range of astrophysical phenomena, including neutron stars and pulsars, X-ray binaries, active stars and diffuse emission from supernova remnants. The talk reports on the status of eROSITA and its scientific prospects with the main focus on pulsars.

E1.3-0032-18 ORBITAL DYNAMICS OF CANDIDATE TRANSITIONAL MILLISECOND PULSAR 3FGL J1544.6-1125: AN UNUSUALLY FACE-ON SYSTEM

Christopher Britt, britt@pa.msu.edu

Michigan State University, East Lansing, Michigan, United States Jay Strader, strader@pa.msu.edu

Michigan State University, East Lansing, Michigan, United States Laura Chomiuk, chomiuk@pa.msu.edu

Michigan State University, East Lansing, Michigan, United States Jules Halpern, jules@astro.columbia.edu

Columbia University, New York, United States Ricardo Salinas, rsalinas@gemini.edu

Gemini Telescope, La Serena, Chile

We present the orbital solution for the donor star of the candidate transitional millisecond pulsar 3FGL J1544.6-1125, currently observed as an accreting low-mass X-ray binary. The orbital period is 0.2415361(36) days, entirely consistent with the spectral classification of the donor star as a mid to late K dwarf. The semi-amplitude of the radial velocity curve is exceptionally low at K2 = 39.3 ± 1.5 km s−1, implying a remarkably face-on inclination in the range 5- 8°, depending on the neutron star and donor masses. After determining the veiling of the secondary, we derive a distance to the binary of 3.8 ± 0.7 kpc, yielding a 0.3-10 keV Xray luminosity of 6.1±1.9×1033 erg s−1, similar to confirmed transitional millisecond pulsars. As face-on binaries rarely occur by chance, we discuss the possibility that Fermi-selected samples of transitional millisecond pulsars in the sub-luminous disk state are affected by beaming. By phasing emission line strength on the spectroscopic ephemeris, we find coherent variations, and argue that these variations are most consistent with emission from an asymmetric shock originating near the inner disk.

E1.3-0033-18 A HIGHLY MAGNETIC SPIDER: PSR J2129-0429 IN THE X-RAY AND OPTICAL BANDS

Hind Al Noori, haa280@nyu.edu

Redback pulsars are eclipsing millisecond pulsars (MSP) binaries that have short orbital spin periods and companion masses Mc > 0.2 M. PSR J21290429 is a 7.62 ms redback with a nondegenerate binary companion that is likely in an early stage of pulsar recycling. It has one of the largest companion masses for a redback system (0.4 M) and has an unusually high surface magnetic field for an MSP. We study X-ray and optical emission from PSR J21290429 using new NuSTAR and LCOGT data of the system as well as archival Swift and XMM-Newton data. The system is peculiar in several ways. It's light-curve exhibits a persistent double-peaked feature centered of inferior conjunction, and shows orbital modulation 5 times greater than is typical for similar systems. Its X-ray spectrum has a very hard power-law component (= 1.1 1.2) which, extends to 40 keV and exhibits an efficiency of up to a few percent in the X-ray band. The spectrum's hardness is suggestive of driven magnetic reconnection occurring at the shock. In addition, our optical observations suggest that the companion is expanding and may overflow its Roche lobe and begin accreting.

E1.3-0034-18 AN UPDATED RELATIONSHIP BETWEEN THERMAL X-RAY LUMINOSITY AND SPIN-DOWN POWER FOR MILLISECOND PULSARS.

Mallory Roberts, malloryr@gmail.com

Eureka Scientific, New York, New York, United States

Thermal emission from millisecond pulsars (MSPs) is thought to be primarily a result of heating by particles accelerated in the magnetosphere which in turn should relate to the spin-down power. Previous studies of the relationship between the spin-down power and the thermal X-ray luminosity of MSPs have been hindered by distance uncertainties and inconsistent analysis techniques.There is also the issue of untangling intrinsic spin-down from apparent due to the Schklovskii effect which requres a determination of proper motion. In recent years, both VLBI studies and pulsar timing arrays have resulted in many new, robust determinations of parallax distances to MSPs as well as proper motions. We will present an updated relationship derived only from MSPs with well determined distances using consistent analysis techniques. In principle, this could be the basis of X-ray derived estimates of distances as well as an aid to discriminating thermal emission from magnetospheric emission in more distant MSPs.

E1.3-0036-18 UNCERTAINTIES IN MASS AND RADIUS MEASUREMENTS FOR HERCULES X-1 AND SELECT MILLISECOND X-RAY PULSARS

Denis Leahy, leahy@ucalgary.ca University of Calgary, Calgary, Canada

X-ray pulse shapes depend on the properties of the emission spot or emission column on the surface of the neutron star (size, shape, location, and emissivity) and on the neutron star's properties (mass, radius, and spin). The goal of modelling X-ray pulse shapes is to measure or constrain mass and radius values for neutron stars. These can then be compared to predictions from calculations from various equations of state (EOS) in order to test the EOS of supernuclear density material. Here, recent modelling work on Hercules X-1 and millisecond X-ray pulsars (SAX J1808-3654, XTE J1807-294 and XTE J1814-338) is studied, with emphasis on determining uncertainties in mass and radius values, and their comparison with theoretical mass-radius calculations.

E1.3-0037-18 COORDINATED MULTI-WAVELENGTH STUDIES OF TRANSITIONAL MSPS

Slavko Bogdanov, slavko@astro.columbia.edu

Alessandro Patruno, patruno@strw.leidenuniv.nl Leiden Observatory, Leiden, Netherlands

Within the past few years, three neutron star binaries have been observed to switch between accreting and rotation-powered pulsar states, cementing the standard model for the formation of rotation-powered millisecond pulsars via spin-up by accretion in a low-mass X-ray binary. These so-called transitional millisecond (tMSPs) pulsars exhibit intriguing behavior spanning from radio frequencies to the GeV gamma-ray range. Multi-wavelength observations of tMSPs hold the promise of providing fresh insight into the physics of accretion and shocks, as well as compact binary evolution. I will present an overview of our extensive coordinated multiwavelength observing campaigns of confirmed and candidate tMSPs, as well as on-going surveys to uncover new systems.

RESEARCH IN ASTROPHYSICS FROM SPACE (E)

BLACK HOLE ASTROPHYSICS: OBSERVATIONAL EVIDENCE OF THEORETICAL MODELS (E1.4)

E1.4-0001-18 WHAT DO THE SPECTRAL AND TIMING PROPERTIES OF BLACK HOLES TELL US ABOUT THE ACCRETION FLOW?

Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

It is well understood that viscosity maintains the total angular momentum distribution in an accretion flow but it is difficult to maintain viscosity itself by any known self-regulating process. or a given injected flow at the outer edge, it is the viscous mechanism which eventually decides how the matter is distributed in the flow. Thus, fixing the flow rate or specific angular momentum distribution ab initio could be. From the first principles, I show beyond reasonable doubt that the disk must have, in general, at least two independent components, Keplerian and sub-Keplerian, which have higher and lower viscosity parameters respectively. Their relative importance primarily dictates the spectral and timing properties of the black holes. We show that the entire accretion-ejection jigsaw puzzle is also neatly resolved with Two Component Advective flow (TCAF) model. Fits by TCAF enables one to have physical parameters such as the two accretion rates and the size and optical depths of the Compton cloud, assumed to be the post-shock region of the disk in TCAF paradigm. We also get QPO frequencies using resonance condition between the infall and the cooling time scales. We require only four parameters to fit the spectra and extract mass of black holes. The Normalization is also constant for a given object across the spectral states. Jets are produced from the Compton cloud region. They are acceleterated by collapse of magnetized Compton clouds and collimated by toroidal flux tubes.

E1.4-0002-18 BLACK HOLE MHD

Roger Blandford, rdb3@stanford.edu

Stanford University, Stanford, California, United States

It is now widely accepted that much of the activity observed around black holes is mediated by relatively strong electromagnetic field. This can be responsible for transporting angular momentum in a disk, energizing a corona and a "lamppost", driving a centrifugal wind and extracting power from a spinning black hole. Some progress, problems and prospects on each of these topics will be discussed.

E1.4-0003-18 GEODESIC MESH MHD, A NEW PARADIGM FOR COMPUTATIONAL ASTROPHYSICS APPLIED TO SPHERICAL SYSTEMS

Dinshaw Balsara, dinshaw.s.balsara.1@nd.edu

University of Notre Dame, NOTRE DAME, Indiana, United States Sudip Kumar Garain, sgarain@nd.edu

University of Notre Dame, Notre Dame, Indiana, United States Vladimir Florinski, vaf0001@uah.edu

University of Alabama in Huntsville, Huntsville, Alabama, United States Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

Most astrophysical systems are spherical; even so, they are simulated with codes that are either Cartesian or logically rectangular. This fundamental dichotomy introduces substantial difficulties in the simulation of several astrophysical systems. In addition, most astrophysics problems involve MHD turbulence which requires at least fourth order accurate codes for their faithful simulation. However, most MHD codes tend to be second order accurate. It is, therefore, important to fundamentally rethink what simulation capabilities are desired and how one can deliver on the goals of such a simulational capability. In this paper we present a constraint-preserving MHD scheme on geodesic meshes which fundamentally bypass the coordinate singularities that occur on logically rectangular meshes. Furthermore, the scheme is up to fourth order accurate. The talk will focus on presenting the novel method and also describing frontline astrophysical applications where such a pathbreaking capability is needed.

E1.4-0004-18 UNDERSTANDING THE INNER ACCRETION FLOW AROUND GALACTIC X-RAY BINARIES WITH NUSTAR

Fiona Harrison, fionah@caltech.edu

California Institute of Technology, Pasadena, California, United States

Over the last six years, NuSTAR has performed broad band X-ray spectral and timing studies of Galactic black holes. These have constrained black hole spins, and probed the geometry and physics of the accretion flow near the central compact object. I will present an observational review, highlighting progress made using NuSTAR together with Swift and XMM. I will also point out outstanding questions that can be addressed through a combination of observations and improved modeling techniques.

E1.4-0005-18 MHD WINDS AS X-RAY ACSORBERS IN AGN ACROSS THE BLACK HOLE MASS SCALES

Demosthenes Kazanas, demos.kazanas@nasa.gov NASA/GSFC, Greenbelt, Maryland, United States Keigo Fukumura, fukumukx@jmu.edu

James Madison University, Harrisonburg, Virginia, United States

We present detailed photoionization calculations of MHD winds off accretion disks associated with AGN and/or LMXRBs, by following the transfer of radiation along the observer's Line of Sight (LoS), to model the properties of the ubiquitous X-ray absorbers in the spectra of accreting black holes. We argue that the self-similarity of these winds implies that their photoionization properties are independent of the mass of the accreting object, if the luminosity and wind mass loss are scaled to their Eddington values. Our models reproduce the Absorption Measure Distribution (AMD), introduced to account for the observed Hydrogen-equivalent column, NH, of a large number of ionic species as a function of their ionization parameter ξ. Furthermore, since our wind models determine also the winds' local velocities, we also compute and present the profiles of the absorption lines of the corresponding transitions. These compare favorably to those observed in both AGN (NGC 3783) and LMXRB (GRO 1655-40). Successful fits to the data provide both the wind mass flux as function of radius and the observer inclination angle .

Most importantly, the mass flux in the winds is found to increase with distance, with m˙ ∝ rs with s 0.3 0.5, indicating that most of the available mass is lost at the largest accretion disk radii. We present simulations of the line profiles for the AGN and LMXRB which yield well constrained values for m˙ (r) and ϑ.

E1.4-0006-18 MAGNETIZED ADVECTIVE ACCRETION FLOWS AROUND BLACK HOLES

Banibrata Mukhopadhyay, bm@iisc.ac.in Indian Institute of Science, Bangalore, India

Advective, sub-Keplerian accretion flows appear to be indispensable to explain observed data, particularly to explain hard spectral states in black hole sources. Such flows are hot enough, of two temperature in nature: e.g. two component advective flow (TCAF), to name as one of the successful models. This talk will explore the magnetized version of this model and its several natural implications. I will attempt to demonstrate that along with gravitational force and centrifugal barrier, strong magnetic fields and related barrier(s), if present, may play interesting (additional) roles to reveal astrophysical features like, multiple QPOs from the same source, outflows/jets etc. In addition, large scale strong fields can help transporting angular momentum even without any α-viscosity, when indeed strong fields suppress MRI and related transport.

E1.4-0007-18 ON RELATIVISTIC FLOWS AROUND BLACK HOLES

Indranil Chattopadhyay, indra@aries.res.in

Aryabhatta Research Institute of Observational Sciences, Nainital, India

We study accreting matter described by relativistic equation state onto a general black hole. The infalling matter is subjected to viscous dissipation and general radiative cooling processes. We present all possible transonic accretion solutions. We show how the solutions change with the change in flow composition, accretion rate and viscosity parameter. The effect of black hole spin is also discussed. We also discuss observational consequences of such solutions.

E1.4-0008-18 THE FORMATION OF STELLAR BLACK HOLES: OBSERVATIONS VERSUS THEORETICAL MODELS

Igor Felix Mirabel, mirabel@iafe.uba.ar IAFE, Buenos Aires, Argentina

I will review the observational insights on Black Holes (BHs) formed by implosion without large natal kicks from: (1) the kinematics in three dimensions of space of five Galactic BH X-ray binaries (BH-XRBs), (2) the diversity of optical and infrared observations of massive stars that collapse in the dark, with no luminous SN explosions, possibly leading to the formation of BHs, and (3) the sources of gravitational waves produced by mergers of stellar BHs detected with LIGO-Virgo. Multiple indications of BH formation without ejection of a significant amount of matter and with no natal kicks obtained from these different areas of observational astrophysics, and the recent observational confirmation of the expected dependence of BH formation on metallicity and redshift, are qualitatively consistent with the high merger rates of binary black holes inferred from the first detections with LIGO-Virgo.

E1.4-0009-18 MASS ACCRETION RATE FLUCTUATIONS IN BLACK HOLE X-RAY BINARIES

Stefano Rapisarda, s.rapisarda86@gmail.com University of Amsterdam, Amsterdam, Netherlands

Over the past 20 years, a consistent phenomenology has been established to describe the variability properties of Black Hole X-ray Binaries (BHBs). However, the physics behind the observational data is still poorly understood. The recently proposed model PROPFLUC assumes a truncated disc/hot inner flow geometry, with mass accretion rate fluctuations propagating through a precessing inner flow. These two processes give rise respectively to broad band variability and a quasi-periodic oscillation (QPO). In this scenario, because of propagation, the emission from different regions of the disc/hot flow geometry is correlated. In our study we applied the model PROPFLUC on different BHBs (including XTE J1550-564 and Cygnus X-1) in different spectral states, fitting jointly the power spectra in two energy bands and the crossspectrum between these two bands. This represents the first study to utilize quantitive fitting of a physical model simultaneously to observed power and cross-spectra. In some case (XTE J1550-564), we found quantitative and qualitative discrepancies between model predictions and data. We concluded that those discrepancies are generic to the propagating fluctuations paradigm and may be related to the mechanism originating the QPO.

E1.4-0010-18 GENERAL RELATIVISTIC NUMERICAL SIMULATION OF SUB-KEPLERIAN TRANSONIC ACCRETION FLOWS ONTO BLACK HOLES

Sudip Kumar Garain, sgarain@nd.edu

University of Notre Dame, Notre Dame, Indiana, United States Jinho Kim, jkim@kasi.re.kr

University of Notre Dame, Notre Dame, Indiana, United States Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

We study time evolution of sub-Keplerian transonic accretion flows onto black holes using a general relativistic numerical simulation code. We perform simulations around the black holes having zero as well as non-zero rotation. We first compare one-dimensional simulation results with theoretical results and validate the performance of our code. Next, we present results of axisymmetric, two-dimensional simulation of advective flows. We find that even in this case, for which no complete theoretical analysis is present in the literature, steady state shock formation is possible.

Friedrich-Alexander University Erlangen-Nuermberg, Bamberg, Germany

Accretion of matter onto compact objects such as black holes (BHs) displays a common phenomenology based on the fact that the physical processes acting on these systems are the same and appear to scale with the mass of the BH, covering a wide range of values from stellar-mass (e.g. black hole binaries; BHBs) to supermassive (e.g., active galactic nuclei; AGN). Most of this phenomenology is observed in the X-ray band, including relativistic and ionized reflection, reverberation time lags, and quasi period oscillations (QPOs). Here we discuss several controversial results derived from our analysis of the observational data for several accreting BHs. In particular, the physical origin of the hard X-ray continuum in accreting black holes is still unknown, as it can be explained by either a Comptonizing gas of hot electrons (the "corona") or the base of a relativistic jet. The geometry and properties of this central source of X-rays are still a mystery. In BHBs, the truncation of the accretion disk is also a controversial subject, with predictions that differ by orders of magnitude when reflection spectroscopy and/or timing techniques are implemented. Another unexpected result is the questionably large abundance of iron required by

most reflection models to explain the observable data from both BHB and AGN alike. The strong correlations among these and other important parameters pose serious limitations on the understanding of accreting sources. We present concrete efforts in answering these questions for several emblematic BHBs and AGNs, with particular emphasis on the advances and limitations of current models for ionized X-ray reflection in strong gravitational fields.

E1.4-0012-18 A NEW LAMPPOST REFLECTION MODEL AND ITS APPLICATION TO NGC 4151 AND CYG X-1

Andrzej Niedzwiecki, niedzwiecki@uni.lodz.pl University of Lodz, Lodz, Poland

Andrzej Zdziarski, aaz@camk.edu.pl

Copernicus Center, Warsaw, Poland, Warsaw, Poland Michal Szanecki, mtszanecki@gmail.com

Copernicus Center, Warsaw, Poland, Warsaw, Poland

We study the X-ray emission in the lamppost geometry, which has become a popular model for both X-ray binaries and AGNs. We point out the importance of the reduction of the observed luminosity due to photon trapping, time dilation and gravitational redshift, which effects have been neglected in most of lamppost studies. We also point out a major effect overlooked so far, namely that of the emission of the bottom lamp being gravitationally focused toward an observer on the top side of the accretion disc. These effects, with several other improvements in modeling the observed spectra of thermal Comptonization and its reflection, are implemented in our new xspec model for the lamppost geometry. We apply the model to the Suzaku/NuSTAR observations of NGC 4151 and Cyg X-1 in its hard state and we find that in both cases it favors truncation of an optically thick disc above 10 gravitational radii.

E1.4-0013-18 FORMATION OF TWO-COMPONENT ADVECTIVE FLOWS AROUND NEUTRON STARS

Ayan Bhattacharjee, ayan12@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

We use the Smoothed Particle Hydrodynamics (SPH) method to simulate the behavior of viscous matter accreting on a neutron star. The fundamental difference between accretion onto black holes and neutron stars is the presence of a hard surface for the latter, which forces matter to stop moving in the radial direction at the surface of the star, making the flow subsonic. On the contrary, for black holes, matter is advected into the horizon supersonically. Thus, apart from the immediate vicinity of the compact object, the flow should be similar for both the objects. We show that for an advective flow with nominal viscosity and angular momentum, the solution allows two shocks in the flow. The outer one, forms due to strong centrifugal barrier and is called CENtrifugal pressure dominated Boundary Layer or CENBOL, which is a common feature for both neutron stars and black holes. The inner shock forms very close to the surface of a neutron star, due to the presence of the physical boundary. We use different viscosity prescriptions to study the behavior of the shock wave. The cases we study show a significant deviation from the ones studied in the context of black holes. We show how the angular momentum distribution deviates from a Keplerian distribution when 1) the spin of the neutron star is varied, 2) the radiative pressure effect from NBOL is added. The behavior of shock wave with the variation of viscosity parameter is also studied to determine the critical value of the viscosity parameter, up to which shocks are allowed in the flow. We study 1) the time evolution of such a viscous flow, 2) the oscillation of the post-shock region with viscous time-scale for intermediate viscosity. When cooling effects are added, the CENBOL cools down and the outer shock moves in towards the star and is seen to be oscillating steadily. If the viscous stress is above its critical value in the equatorial plane, angular momentum is redistributed faster and a Keplerian-like disk is produced. In presence of strong cooling (blackbody emission from the optically thick region), a disk is formed along the equatorial plane. The two-components, disk, and halo are disaggregated out of the halo component and remains steadily oscillating through hundreds of dynamical timescales. This indicates that the TCAF is the most general flow configuration for a neutron star when the magnetic field is weak.

E1.4-0014-18 HYPERMAGNETIZED ACCRETION DISKS: A GLOBAL STABILITY ANALYSIS

Upasana Das, upasana.das@gmail.com

University of Colorado, Boulder, Boulder, Colorado, United States Mitch Begelman, mitch@jila.colorado.edu

University of Colorado, Boulder, Boulder, Colorado, United States Geoffroy Lesur, geoffroy.lesur@univ-grenoble-alpes.fr

Institut de Planétologie et Astrophysique de Grenoble, Saint Martin D'Hères, France

We examine the stability properties of hypermagnetized accretion disks in a global framework, with a particular focus on the evolution of the weak-field magnetorotational instability (MRI), which is believed to trigger angular momentum transport in accretion flows. Local magnetohydrodynamic (MHD) simulations have shown that in the presence of a sufficiently strong but subthermal (plasma-β 1) vertical magnetic flux, a large-scale, suprathermal (plasma-β

< 1) toroidal field is generated, which becomes the dominant source of pressure support in the accretion disk. We term such magnetically dominated disks as hypermagnetized accretion disks, which have the potential to resolve several observational shortcomings of the standard, geometrically thin, accretion disk model. The suprathermal toroidal field makes the curvature effects due to the cylindrical geometry of the disk non-negligible, which are otherwise ignored in weak-field studies. Furthermore, these intrinsically global effects may not be accurately captured in a local model. Hence, in order to self-consistently account for the curvature effects, we perform a global eigenvalue analysis of the linearized MHD equations for a compressible, differentially rotating flow in cylindrical geometry. We find that MRI gets highly suppressed at a critical suprathermal toroidal field and two new instabilities appear beyond this limit. These results are additionally verified using numerical simulations. Our analysis partly confirms the predictions of a local model but reveals important differences, which highlight the necessity of a global treatment to accurately model hypermagnetized accretion disks.

E1.4-0015-18 RADIATION SPECTRA OF TWO TEMPERATURE ACCRETION DISCS AROUND ROTATING BLACK HOLES

Samir Mandal, samir@iist.ac.in

Indian Institute of Space Science & Technology, Thiruvananthapuram, India Indu Kalpa Dihingia, i.dihingia@iitg.ernet.in

IIT Guwahati, Guwahati, India Santabrata Das, sbdas@iitg.ernet.in IIT Guwahati, Guwahati, India

The self-consistent two temperature transonic accretion solutions around rotating black holes are important to understand the observed spectro-temporal features. We study the twotemperature accretion solutions in presence of radiative dissipations and use these solutions to compute the emitted radiation spectrum from the accretion disc. We have taken into account several general relativistic effects on the emitted radiation. We aim to compare our model calculations with the observed spectra of few black hole candidates and estimate the flow parameters.

E1.4-0016-18 A NON-KERR EXTENSION OF THE RELXILL X-RAY REFLECTION MODEL

Dimitry Ayzenberg, dimitry@fudan.edu.cn Fudan University, Shanghai, China Cosimo Bambi, bambi@fudan.edu.cn Fudan University, Shanghai, China

Sourabh Nampalliwar, sourabh@fudan.edu.cn Fudan University, Shanghai, China

The X-Ray reflection spectrum produced by accretion disks around black holes is one of a few electromagnetic observations of black holes that can be used to test the Kerr hypothesis and General Relativity in the strong gravity regime. RELXILL is currently the most advanced model for the X-Ray reflection spectrum, but it cannot model the spectrum for non-Kerr spacetimes. In this talk I will present a recent extension of RELXILL to a generic stationary, axisymmetric, and asymptotically flat black hole metric (Astrophys.J. 842: 76, 2017). I will show that this extension retains the accuracy for the Kerr spacetime that is expected of the RELXILL model, but can also be used to test the Kerr hypothesis. I will also present the results from recent work in placing constraints on deviations from the Kerr metric using observational data (Phys. Rev.Lett. 120, 051101, 2018).

E1.4-0017-18 VERTICAL OSCILLATION IN THICK ACCRETION FLOW AND ITS EFFECT ON OUTFLOWS

Arnab Deb, arnabdeb1988@gmail.com

S. N. Bose National Centre for Basic Sciences, Kolkata, India Kinsuk Giri, kinsuk@nitttrkol.ac.in

National Institute of Technical Teachers' Training & Research (NITTTR), Kolkata, Kolkata, India

Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

We study the time evolution of two-dimensional inviscid accretion flows around black without reflection symmetry on the equatorial plane in order to inspect if the disk along with the centrifugal barrier oscillated vertically. In the inviscid limit, we find that the CENtrifugal pressure supported BOundary Layer (CENBOL) is oscillating vertically, more so, when the specific angular momentum is higher. As a result, the rate of outflow produced from the CENBOL also oscillates and also, outflow rates in the upper half and the lower half are found to be anti-correlated. The cause of oscillation appears to be due to the interaction among the backflow from the centrifugal barrier, the outflowing winds and the inflow. We carry out the exercise for a series of specific angular momentum (Λ) of the flow in order to demonstrate effects of the centrifugal force on this interesting behavior. We find that, as predicted in theoretical models of disks in vertical equilibrium, the CENBOL is produced only when the centrifugal force is significant and more specifically when $\Lambda > 1.5$. Outflow rate itself is found to increase with Λ as well and so is the oscillation amplitude. For low angular momentum, the backflow as well as the oscillation are missing.

E1.4-0018-18 PHOTON MOTION IN THE FRAMEWORK OF GENERAL RELATIVITY COUPLED TO NON-LINEAR ELECTRODYNAMICS

Zdenek Stuchlik, zdenek.stuchlik@fpf.slu.cz

Silesian University at Opava, OPAVA, Czech Republic

We discuss the photon motion in the framework of general relativity coupled to non-linear electrodynamics. Photons no longer follow the null-geodesics of the spacetime but rather nullgeodesics of associated effective metric. Here we compare structure of circular geodesics and time-delays of neutrinos in Bardeen spacetimes with those of photons in effective geometry. We also discuss construction the Keplerian disks images in the Bardeen spacetimes and compare them with the images of Keplerian disks in RN spacetime.

E1.4-0019-18 TCAF SOLUTION AS AN ADDITIVE TABLE MODEL IN XSPEC: AN EFFICIENT TOOL TO UNDERSTAND ACCRETION FLOW PROPERTIES OF BLACK HOLES

Dipak Debnath, dipakcsp@gmail.com

Indian Centre for Space Physics, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India Santanu Mondal, astrophy.sm@gmail.com

Universidad de Valparaiso, Valparaiso, Chile

It has been more than two decades since Chakrabarti and his collaborators for introduced the two component advective flow (TCAF) model as a global solution to accretion flow processes around black holes. In 2014, we successfully been able to implement this solution into HEASARC's spectral analysis software package XSPEC as an additive table model to fit energy spectra from black hole candidates (BHCs) and obtain physical informations about accretion flow processes such as, two component (Keplerian disk and sub-Keplerian halo) accretion rates, shock (location, i.e., the size of the Compton cloud, and the compression ratio) parameters, mass of the black hole. Evolutions of spectral and timing properties during active phases of black hole X-ray binaries are now more transparent from the nature of the variations of the TCAF model fitted/derived physical parameters. Reasons of different spectral states and their transitions (if any) of BHCs are also clear. One can predict frequencies of the dominating type-C quasi-periodic oscillations (QPOs) from TCAF model fitted shock parameters and even estimate most accurate mass range of an unknown BHC from TCAF fits. One can estimate Xray flux contributions from jets/outflows (if present) from TCAF model fitted spectral analysis as well. To our knowledge this gives us the most physical tool to investigate the accretion flow dynamics of BHCs during their active phases.

E1.4-0020-18 SPECTRAL AND TEMPORAL PROPERTIES OF THE X-RAY QPO IN ACCRETING BLACK HOLE SYSTEMS.

Piotr Zycki, ptz@camk.edu.pl

N. Copernicus Astronomical Center, Warsaw, Poland

X-ray quasi-periodic oscillations are an interesting phenomenon, as they show the existence of a (quasi-) clock in otherwise broad band timescale systems. I am going to review the observed spectral and temporal properties of both the lowand high-frequency QPO across the range of black hole masses. Then I will consider those models of the QPO which can make predictions of their spectral and timing properties, i.e. models that consider the spectral formation of the X-ray emission, including the specific process of QPO. Finally I will compare the model predictions with the observations.

E1.4-0021-18 THE REFLECTION SPECTRUM OF CYGNUS X-1 AS MEASURED BY NUSTAR

John Tomsick, jtomsick@ssl.berkeley.edu

Space Sciences Laboratory, University of California, Berkeley, United States

Cygnus X-1 is an accreting black hole binary that has been persistently bright throughout the history of X-ray astronomy. Over the years, observations of Cyg X-1 across the electromagnetic spectrum have led to breakthrough results, including dynamical evidence that its compact object is a black hole, measurements indicating that the black hole is rapidly rotating, resolving its compact jet in the radio band, obtaining parallax distance and proper motion measurements, and the discovery of soft and hard spectral states. The NuSTAR satellite has obtained 3-79 keV observations of Cyg X-1, sampling soft, hard, and intermediate states over the past several years. The NuSTAR bandpass, energy resolution, and throughput provide measurements of the Compton reflection component with unprecedented quality, and results have been reported for the soft state (e.g., Tomsick et al. 2014; Walton et al. 2016), the hard state (e.g., Parker et al. 2015; Basak et al. 2017), and the intermediate state (Tomsick et al. 2018). The relativistic distortion of the reflection component depends on the location of the inner radius of the disk and the geometry of the source, and spectral modeling can lead to constraints. However, in some cases, the models also lead to unphysically high iron abundances, and this may be a source of systematic uncertainty for the other model parameters. Here, we investigate possible reasons for the high iron abundances, focusing on detailed modeling of one of the intermediate state Cyg X-1 spectra.

E1.4-0022-18 SIGNATURES OF BLACK HOLES – STAR MOTION, ACCRETION DISKS, AND SHADOWS

Claus Laemmerzahl, claus.laemmerzahl@zarm.uni-bremen.de ZARM, University of Bremen, Bremen, Germany

Eva Hackmann, eva.hackmann@zarm.uni-bremen.de ZARM, University of Bremen, Bremen, Germany Volker Perlick, volker.perlick@zarm.uni-bremen.de ZARM, University of Bremen, Bremen, Germany

We consider the effects of Black Holes on nearby objects, like stars, light, and accretion disks. All the effects related to the various objects can be used to identify the properties of the Black Hole, that is, mass, spin, and perhaps additional parameters. For the description of the effects we work within a wide class of analytically given Black Hole space-times, namely the PlebanskiDemianski electrovac solutions of the Einstein field equations. We introduce the basic notions of Black Holes like the horizon, the singularities, the ergoregion, causality violation regions, and the region of outer communication.

At first we describe the motion of stars around Black Holes by analytically solving the geodesic equation. From these solution we can analytically calculate the perihelion shift, the LenseThirring effect and the conicity as major observables. From corresponding observations the Black Hole parameters can be deduced. We also discuss the motion of spinning stars.

Next we introduce the notion of the shadow of a Black Hole. We analytically calculate the shadow for all Plebanski-Demianski Black Holes. We also calculate the shadow for moving observers. Based on these analytical results we, among others, determine the exact shape and the size of the shadow of the Black Holes SgrA* and of M87 which will be observed with the EHT.

At last we discuss accretion disks. We analytically determine the shape of thick disks and show how their shape depends on the Black Hole's space-time geometry.

E1.4-0023-18 TIME LAG PROPERTIES OF THE BLACK HOLE X-RAY TRANSIENTS: A COMPARISON OF HIGH AND LOW INCLINATION SOURCES

Broja Gopal Dutta, brojadutta@gmail.com

Department of Physics, RBC College & Indian Centre for Space Physics, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

We study the variability properties of black hole X-ray transients during outbursts for the low (GX339-4, XTE J1650-500, XTE J1752-223, XTE J1817-330 etc.) and high inclination (H1743-322, XTE J1859+226, XTE J1748-288, XTE J1550-564, GRO J1655-40, GRS 1915+105

etc.) sources. We closely compare the evolution of the sources in terms of Quasi Periodic Oscillation (QPO) frequency and time lag. We study the energy dependence of time lag and QPO amplitude. We find that time lag is always positive (i.e., hard lag) for lower inclination objects and time lag switches from hard to soft for the higher inclination sources. We concluded that the evolution of QPO frequency is independent of the inclination of the source whereas time lag depends on the inclination. These behaviors indicate the implication of specified accretion geometry during the evolution of the source.

E1.4-0024-18 SPECTRAL STUDY OF DIFFERENT BLACK HOLE CANDIDATES AND MEASUREMENT OF SPIN PARAMETER

We study different black hole candidates using different satellites (RXTE, Swift and NuSTAR) data. We show how the spectral shape changes with the change in geometry of the disk and accretion rates. Our analysis attempts to explain these using TCAF model fitted physical parameters. We also explain different spectral states of a complete outburst from the accretion rate behavior. It is evident that the evolution of flow parameters in the decline phase may not retrace path of the rising phase. We shed light on that from our model fitting. The presence of Fe Kα line is well detected in accretion disk for Galactic X-ray sources and active galactic nuclei due to the rotating matter around the central object. We study the presence of Fe Kα line emission from the NuSTAR observation of transient source GX 339-4 during its 2013 outburst. Throughout the outburst, to fit the spectra with TCAF model, we require LAOR model. Our estimated value of spin parameter is 0.99 for this candidate.

S.N. Bose National Centre for Basic Sciences, Kolkata, India

Detailed spectral and temporal study of Galactic halo black hole candidate XTE J1118+480 has been done using the archival data of RXTE PCA and HEXTE instruments to study nature of the source in a broad energy range. During 2000 outburst of the source, very low frequency quasi-periodic oscillations (QPOs) are observed. The spectral analysis of the source has been done with two types of models: the phenomenological power-law (PL) and the physical two component advective flow (TCAF) fits file in XSPEC. From the nature of the evolution of the spectral fitted parameters, it is evident that the 2000 outburst or active phase is not similar to a 'conventional' type outbursts. During the entire phase of the so-called outburst, source remained in hard/low hard spectral state with low photon index values and high dominance of PL flux or sub-Keplerian halo matters. The source was highly dominated by jets/outflow, which was evident from high radio fluxes during most period of the outburst. More interestingly, during the late declining phase of the outburst, PL indices increased slowly, i.e., spectra become slightly softer (within the hard spectral band) with a slow rise in Keplerian disk rate. This feature is also quite uncommon. So, we feel that this 2000 active phase of the source could not be termed as 'outburst'. We also estimate the mass of the BHC and contribution of the jet X-rays from our TCAF model fitted spectral analysis.

S.N. Bose National Centre for Basic Sciences, Kolkata, India

The galactic black hole candidate Cygnus X-1, one of the brightest sources in the sky, is the first ever black hole candidate to be discovered. Despite being a very well-studied source due to its persistent brightness in X-rays, there has been a lot of difficulty in determining its mass since its discovery. While Bolton (1972) and Paczynski (1974) estimated the lower limit of the mass of the black hole to be ~ 4M0, Gies and Bolton (1986) reported that the mass of the compact object should lie in the range 7 M0 to 16 M0. Ninkov et al. (1987) further estimated the mass of the compact object to be 10 ± 1M0 while according to Herrero et al. (1995) the estimated mass is between 5M0 15M0. All these mass measurements are subject to several uncertainties because of the high degree of errors associated with the measurement of the distance. Once Reid et al. (2011) constrained the distance to be ~ 1.86 kpc, Orosz et al. (2011) provided a stronger constraint on the mass of the BHC in Cygnus X-1 to be M = 14.8 1.0M0. In this work, we estimate the mass of Cygnus X-1 by analyzing its spectral properties. We use RXTE/PCA archival data and implement the Two Component Advective Flow Solution for spectral analysis. Since mass of the black hole is also an input parameter of the TCAF model, we obtain a constraint on the mass of the black hole from each of the spectral fits. The object exhibits both persistent and flaring behavior and we analyze data during both these phases for constraining the mass of the source. For Cygnus X-1, our estimated mass appears to be

Mavg = 14.57 ± 0.68M0 which is consistent with previous estimates reported in the literature.

E1.4-0027-18 DOES CYG X-1 HAVE A TINY ACCRETION DISK?

Arindam Ghosh, arindam.ghosh@bose.res.in

Results of analysis of several outbursts in a few transient sources are studied using the RXTE/PCA (2.5-25 keV) data as well as RXTE/ASM (1.5-12 keV) data spanning over a long time. A typical time lag is found between the arrival times of the Keplerian disk component and the halo component of the Two-Component Advective Flow (TCAF) when the spectral data is fitted with TCAF solution. This is due to the fact that Keplerian disks have higher viscosity and matter takes a longer time to fall, while the halo has a lower viscosity and falls almost in the free-fall time scale. The wind-fed high-mass X-ray binaries have low angular momentum dominated flow and the lag is expected to be smaller due to the difficulty in making a large Keplerian disk and the arrival time would not differ significantly in the two components of TCAF. On the contrary, a bigger Keplerian disk is likely to form when the accretion is through the Roche-lobe overflow in LMXBs and thus the lag is expected to be very large. Using earlier results in several outburst LMXBs and fitting with TCAF during state transitions of a well known HMXB Cyg X-1, we find that this is indeed the case. Several days of time lags were found in LMXBs while for Cyg X-1 the lag is negligible. We also computed the cross-correlation between the disk and the halo accretion rates and found that the lag is roughly what is observed directly from TCAF extracted parameters. This confirms that the size of the Keplerian disk in Cyg X-1 must be relatively smaller than that in LMXBs studied here.

E1.4-0028-18 A WINGED MICROQUASAR NEAR THE GALACTIC CENTRE

Josep Marti, jmarti@ujaen.es Universidad de Jaén, Jaén, Spain Pedro Luque-Escamilla, peter@ujaen.es Universidad de Jaén, Jaén, Spain

Valenti Bosch-Ramon, valenti@cp.dias.ie

Dublin Institute for Advanced Studies, Dublin, Ireland Josep M. Paredes, jmparedes@ub.edu

Universitat de Barcelona, Barcelona, Spain

GRS 1758-258 is one of the two Galactic Center microquasars together with its twin 1E 1740.7- 2942. Here we report a deep radio observation of GRS 1758-258 that combines both archival and present-day observing runs obtained with the Jansky Very Large Array. As a result, we find that the system of radio jets and its terminal lobes strongly resemble the Z-shaped morphology typical of some winged radio galaxies. This opens a new perspective for a comparative understanding of relativistic outflows in stellar and super massive black holes. In particular, the winged appearance of this microquasar is better understood in terms of simple hydrodynamic backflow when the relativistic ejecta collides with the dense interstellar medium surroundings. By extrapolating our findings to the extragalactic case, we suggest that that spin-flip models involving the merger of super-massive black holes are not necessarily the preferred scenario in all cases.

E1.4-0029-18 FAST VARIABILITY IN BLACK-HOLE BINARIES: ACCRETION AND GENERAL RELATIVITY

Tomaso Belloni, tomaso.belloni@brera.inaf.it INAF, Merate, Italy

I will review the current standpoint of fast variability from black-hole binary systems. The large amount of data obtained in the past two decades has led to a significant advancement in our knowledge, although it still needs to be consolidated through new observations. I will present the more recent evidences of General Relativistic effects obtained from RossiXTE data and will present new data from the Astrosat mission.

E1.4-0030-18 SPECTRAL EVOLUTION OF IGR J17091–3642 DURING ITS 2016 OUTBURST AND THE HEARTBEATS

Yanan Wang, yanan@astro.rug.nl

Kapteyn Astronomical Institute, University of Groningen, Groningen, Netherlands Mariano Mendez, mariano@astro.rug.nl

University of Southampton, Southampton, United Kingdom Aru Beri, a.beri@soton.ac.uk

University of Southampton, Southampton, United Kingdom Zheng Cheng, zheng@astro.rug.nl

University of Groningen, Groningen, Netherlands

We present simultaneous NuSTAR and SWIFT observations of the black hole transient IGR J17091– 3642 during its 2016 outburst. By jointly fitting six NuSTAR and four SWIFT average spectra,

we found that during this outburst the source evolves from the hard to the hard/soft intermediate and back to the hard state, similar to the 2011 outburst. One difference with respect to the previous outburst is that in this case we observed both a broad emission and a narrow absorption line in those observations. Our fits favour an accretion disc with relatively low inclination angle of 45o with respect to the line of sight and a high iron abundance of 3.5 in units of the solar abundance. This high iron abundance, however, is likely model-dependent. We also observed heartbeat variability in one NuSTAR observation. We fitted the phase-resolved spectra of this observation and found that the direct emission varies independently from the reflection component, which suggests that during the heartbeat state the corona is very far away from the disc in IGR J17091–3642. Assuming that in IGR J17091–3642 the inner radius of the disc both in the average and the phase-resolved spectra is located at the radius of the innermost stable circular orbit, with 90% confidence the spin parameter of the black hole in this system is $-0.13 \le a* \le 0.27$.

E1.4-0031-18 X-RAY REFLECTION SPECTROSCOPY OF BLACK HOLE BINARY XTE J1550- 564: EXPLORING ACCRETION EVOLUTION WITH IMPROVED SENSITIVITY

Black hole binaries exhibit a wealth of astrophysical phenomena as they go into outburst, evolving through two principal spectral states: hard and soft. Since BHB accretion flows evolve on such short timescales (typical duty cycles are on the order of years to decades) we can track the structural changes to their accretion flows in realtime with a multitude of ground and space based observatories across the electromagnetic spectrum. One useful technique for probing the accretion flows of BHBs is to model the X-ray reflection spectrum, a signature of the reflection of the primary continuum off the accretion disc. The characteristic relativistically broadened Iron K-alpha line and Compton reflection hump allow us to constrain the black hole spin, inner disc radius, and other key properties of the accretion disc such as the abundance of iron and the inclination of the disc with respect to the line of sight. Such modeling depends on high sensitivity spectral observations in order to distinguish these reflection features and therefore constrain key physical parameters. I present ongoing reflection modeling of newly calibrated RXTE PCA-and-HEXTE X-ray spectra of the BHB XTE J1550-564, covering multiple outburst cycles across all spectral states, using the most-up-date X-ray reflection spectroscopic code, relxill. The archival dataset includes 517 spectra with a total exposure of 971 ks, making use of 876 million PCA (3-45 keV) counts and 114 million HEXTE (20-200) counts. We utilize the drastically improved calibration of RXTE's PCA and HEXTE (cluster B) instruments-using the publicly available recalibration tools pcacorr and hexBcorr-which allows us to increase the data precision by up to an order of magnitude over previous studies, and reduces instrumental features typically present in the residuals. The goal is to track key physical parameters of XTE J1550-564 (black hole spin, inner disc radius, iron abundance) as it evolves through its spectral states. We optimize the prominence of reflection features in the spectrum (such as the iron line and Compton reflection hump) by combining multiple spectra in groups according to spectral hardness and intensity, and employ Markov Chain Monte Carlo techniques to explore the statistical landscape and constrain key model parameters. This work is part of a broader campaign to systematically analyze several bright black holes. With the increased instrument sensitivity we will be able to better constrain the evolution of the inner disc radii of a number of BHBs during multiple outbursts, as well as their black hole spins, building a more complete picture of the physics of black hole accretion.

E1.4-0032-18 X-RAY MONITORING OF THE GALACTIC MICROQUASAR V4641 SGR

Kazutaka Yamaoka, yamaoka@stelab.nagoya-u.ac.jp Nagoya University, Nagoya, Japan

John Tomsick, jtomsick@ssl.berkeley.edu

Space Sciences Laboratory, University of California, Berkeley, United States Satoshi Nakahira, nakahira@phys.aoyama.ac.jp

Aoyama Gakuin University, Sagamihara-city, Japan

V4641 Sgr is the black hole (BH) candidate which exhibits a giant outburst with an X-ray intensity up to 12 Crab on September 1999. Since then, several small outbursts with 1-100 mCrab level have been observed almost every year. However, it remains unclear whether this source has typical spectral states such low/hard and high/soft states seen in BH candidates and what X-ray emission mechanisms are. Large-scale radio jets have also benn observed from this source, hence it is very important source to study the relation between jets and accretion flows. Since 2008, we have monitored this source in an outburst with MAXI/GSC and Swift/XRT, and carried out detailed observations with Suzaku and NuSTAR in 2014. The observed X-ray flux ranges up to 40 mCrab. The spectra of this source look like high/soft state, and can be well explained by multi-color disk model with an innermost temperature of 1.0–1.5 keV, but the innermost radii, 8-21% of Schwarzchild radii, are too small to explain its emission region and does not keep constant. We also detected iron emission lines at 6.8 keV due to highly ionized irons from Swift/XRT, NuSTAR, and Suzaku spectra, and first revealed the presence of photoionized plasma in this source. In this paper, we will discuss the origin of X-ray continuum and iron emission lines, and similarity to the peculiar microquasr V404 Cyg.

E1.4-0033-18 THE BRIGHT AND HOT DISK OF THE LMXB 4U 1957+11

Victoria Grinberg, vgrinberg@cosmos.esa.int ESA-ESTEC, Noordwijk, Netherlands Michael A. Nowak, mnowak@space.mit.edu

MIT, Cambridge, Massachusetts, United States 4U 1957+11 is a low mass X-ray binary (LMXB) but, opposed to most other LMXBs, it is in a persistently bright accreting state. It shows one of the cleanest examples of a disk spectrum in the X-ray band, with an extremely small inner disk radius and a disk temperature in the 1.3-1.8 keV range and therefore among the highest detected. The low absorption towards 4U 1957+11 makes disk studies especially rewarding. The spectral shape, together with the low short-term variability, hints towards it being the most rapidly spinning galactic LMXB as long as its mass is over 3 solar masses at a distance greater than 10 kpc. Optical modulation has, however, been used to argue that the mass cannot be greater than 3 solar masses, favoring a neutron star interpretation.

We reassess the historical RXTE data, using recent revisions of the RXTE calibration. We use these observations, along with an assessment of all sky monitor lightcurves, to place more recent pointed observations in their proper context of the overall behavior of the source. These pointed observations include a coordinated XMM + NuSTAR + HST/COS campaign that allows us to probe disk models over a wider bandpass than previously possibly. In particular we can asses the underlying spectral correction factor (the ratio of color to thermal temperature) and test whether the spin results and thus the black hole interpretation of the source can be upheld when taking the UV signature of the disk into account.

Disc instability models predict that in quiescence, there should be a slow but prominent brightening of the optical flux between outbursts of black hole X-ray binaries (BHXBs). There is also expected to be an optical precursor to outbursts – a brightening at optical wavelengths of the accretion disc, prior to the X-ray outburst. Tracking the X-ray variations of BHXBs in quiescence is generally not possible, so optical monitoring provides the best means to measure the mass accretion rate variability between outbursts. With our regular Faulkes Telescope / Las Cumbres Observatory (LCO) monitoring we are routinely detecting the optical rise of new X-ray binary outbursts before they are detected by X-ray all-sky monitors.

We present long term optical monitoring of several black hole X-ray binaries, with the Faulkes Telescopes and LCO. We have detected the slow rise between outbursts in the BHXBs GS 1354-64, H1705-250 and Swift J1357.2-0933, and the optical precursor to the bright 2015 outburst of V404 Cyg.

In Swift J1357.2-0933, the quiescent light curve is dominated by high amplitude, short-term (seconds - days) variability spanning 2 mag, with an increasing trend of the mean flux over five years that is steeper than in any other X-ray binary found to date (0.17 mag/yr). Such a steep optical flux rise preceding an outburst is expected according to disk instability models, but the high amplitude variability in quiescence is not. We find that a variable optical/infrared jet spectrum is responsible for the brightening in this source.

We show that it may be possible to predict when new outbursts are likely to occur, by estimating the accumulation of matter in the disc in quiescence from optical monitoring.

Finally, we introduce our new real-time data analysis pipeline, the "X-ray Binary New Early Warning System (XB-NEWS)" which aims to detect and announce new X-ray binary outbursts within a day of first optical detection. This allows us to trigger X-ray and multi-wavelength campaigns during the very early stages of outbursts, to constrain the outburst triggering mechanism.

The idea that the hot, moderately bright, advection-dominated accretion flow during a flat, powerlaw dominated spectral state in black hole X-ray binaries can give rise to the low energy infrared/ optical photons has been discussed on several occasions but not convincingly demonstrated using spectral and timing information from multi-wavelength observations with high time resolution. To test this hypothesis, we perform optical (SALT)/X-ray (Swift and INTEGRAL) simultaneous monitoring of the hard X-ray outburst from the black hole X-ray transient BW Circini (= GS 1354-64). During the rising phase of the X-ray outburst, when the source Xray intensity is moderately high, optical/X-ray light curve shows a strong anti-correlation with X-ray photons lagging optical. Optical and X-ray power spectra show quasi-periodic oscillations (QPOs) at a frequency of 18 mHz. Both optical and X-ray auto-correlation width are found similar. Simultaneous fitting of Swift/XRT and INTEGRAL spectra in the range 0.5-1000.0 keV shows non-thermal, power-law-dominated (>90 percent) spectra with a hard power-law index of 1.48 0.03, inner disc temperature of 0.12 0.01 keV and an inner disc radius of 3000 km. All evidence is consistent with the prediction of the cyclo-synchrotron radiation in a non-thermal, hot electron cloud extending to 100 Schwarzschild radii being a major physical process for the origin of optical photons. We also compute the Cyclo-synchrotron luminosity based on observed parameters and found that the observed optical luminosity is 0.21 percent of the X-ray luminosity which is well within the predicted limit of <1-3 percents.

E1.4-0036-18 A MASS ESTIMATIVE FOR THE BLACK HOLE CANDIDATE 1E 1740.7-2942 USING BROAD BAND X-RAY SPECTRUM

Paulo Eduardo Stecchini, paulo.stecchini@inpe.br

Instituto Nacional de Pesquisas Espaciais (INPE), São José Dos Campos, Brazil Manuel Castro Avila, manuel.castro@inpe.br

National Institute for Space Research (INPE), São José Dos Campos, Brazil Flavio D'Amico, damico@das.inpe.br

Instituto Nacional de Pesquisas Espaciais - INPE, Sao Jose Dos Campos, Brazil Joao Braga, joao.braga@inpe.br

INPE, Sao Jose Dos Campos, Brazil

The object 1E 1740.7-2942 is one of the strongest hard X-ray emitters around the Galactic Center region. It was classified as a black hole candidate due to its spectral similarities with Cyg X-1. The lack of information about its counterpart prevents the mass function f(M) of the system from being determined, since it depends on parameters usually better estimated through optical/infrared observations of the companion. In the context of alternative methods, broad band spectrum and the presence of a broadened iron line have opened the possibility of weighting black holes with only X-ray data. In this study, we gather public available data of 1E 1740.7-2942 from 3 different missions to produce a broad band spectrum. NuSTAR data suggest the presence of an iron line and a reflection component. Broad band coverage and thus better fit modeling was achieved including data from XMM and INTEGRAL. Although the observations were not taken simultaneously, their individual fits indicate that the source was in the same spectral state. Preliminarly results point to a black hole mass around 4 solar masses for 1E 1740.7-2942.

E1.4-0037-18 THE EVOLUTION OF GX 339-4 IN THE LOW-HARD STATE AS SEEN BY NUSTAR AND SWIFT

Institut de Planétologie et d'Astrophysique de Grenoble, Grenoble, France

We analyze eleven NuSTAR and Swift observations of the black hole X-ray binary GX 339–4 in the hard state, six of which were taken during the end of the 2015 outburst, five during a failed outburst in 2013. These observations cover luminosities from 0.5%–5% of the Eddington luminosity. Implementing the most recent version of the reflection model relxillCp, we perform simultaneous spectral fits on both datasets to track the evolution of the properties in the accretion disk including the inner edge radius, the ionization, and temperature of the thermal emission. We also constrain the photon index and electron temperature of the primary source (the "corona"). We observe a maximum truncation radius of 37 Rg in the preferred fit for the 2013 dataset, and a marginal correlation between the level of truncation and luminosity. We also explore a self-consistent model under the framework of coronal Comptonization, and find consistent results regarding the disk truncation in the 2015 data, providing a more physical preferred fit for the 2013 observations.

E1.4-0038-18 A RELATIVISTIC OUTFLOW DETECTED IN THE HARD STATE FROM THE MICROQUASAR GRS 1758-258.

Mark Reynolds, markrey@umich.edu

University of Michigan, Ann Arbor, Michigan, United States Jon Miller, jonmm@umich.edu

Wayne State University, Detroit, Michigan, United States Ashley King, ashking@stanford.edu

Stanford University, Stanford, California, United States

Outflows are observed from accreting systems on all mass scales in the form of collimated jets and wider angle accretion disk winds. Previous observations have suggested a paradigm wherein the accretion disk wind is strongly suppressed in the hard spectral state and present in the soft spectral state, whereas the jet is observed to behave in the opposite sense. We will present the results of a Suzaku observation of the persistently accreting Galactic microquasar GRS 1758-258 while the source was in the low-hard state (Lx 0.01 LEdd). Analysis of the Suzaku observation reveals the presence of a highly ionized relativistic wind (v 0.1c) originating in the inner regions of the accretion flow. The broad nature of the observed absorption line suggests that it is the signature of a stratified relativistic outflow. This is the highest velocity wind detected from a stellar mass X-ray binary to date, demonstrating the viability of the wind launching mechanism down to luminosities of at least 1% LEdd.

E1.4-0039-18 HIGH ENERGY EMISSION IN BLACK HOLE BINARIES

Melania Del Santo, melania@ifc.inaf.it INAF - IASF Palermo, Palermo, Italy

In the X/-ray domain, black hole binaries (BHBs) show several and complex spectral behaviors and transitions. Based on INTEGRAL observations, we have now a new view on the high energy emission of black-hole binary. An additional component above 200 keV has been observed in a number of systems, during either hard/intermediate or hard states. The nature of this hardtail is still debated, as also the one observed in the soft state. However, among a number of models, it is usually attributed to the presence of a small fraction of non-thermal electrons in a hot-Comptonising plasma, eventhough the jet nature of this component has not been ruled out. I review on the high energy emission observed by the INTEGRAL telescopes in a few systems and models applied to explain their X/-ray spectra.

E1.4-0040-18 A HIGH-RESOLUTION VIEW OF THE 2015 OUTBURST OF THE BLACK HOLE X-RAY BINARY V404 CYGNI

James Miller-Jones, james.miller-jones@curtin.edu.au ICRAR - Curtin University, Perth, Australia Alexandra Tetarenko, tetarenk@ualberta.ca University of Alberta, Edmonton, Canada

Matt Middleton, m.j.middleton@soton.ac.uk

University of Southampton, Southampton, United Kingdom Gregory Sivakoff, sivakoff@ualberta.ca

University of Alberta, Edmonton, Canada

The 2015 outburst of the black hole X-ray binary V404 Cygni was the brightest such outburst in over a decade, providing an unparalleled opportunity to study the accretion and ejection processes around an accreting stellar-mass black hole. The exceptionally bright fluxes across the electromagnetic spectrum stimulated intensive observing campaigns at all wavelengths, from the radio to the gamma-ray regime. In this talk I will present the results of our highcadence radio monitoring with the Very Long Baseline Array, detailing the real-time evolution of the jets on timescales as short as minutes. These observations show that the jet is precessing on a timescale no longer than several tens of minutes, most likely due to a precessing inner accretion flow. I will also show how the jet behaviour evolves through the different phases of the outburst, from the initial rapid flaring to the bright ejection event at the peak of the outburst and the re-establishment and fading of the compact jet. Since V404 Cygni is one of the few Xray binaries with a known distance from geometric parallax, we can directly convert measured proper motions into accurate physical parameters, such as jet speeds and Lorentz factors, to determine the energetics of the ejection events. Finally, with such intensive coverage at multiple wavelengths, we can seek to compare the ejection times derived from high-resolution imaging with the contemporaneous behaviour of the accretion flow to determine the events leading to jet ejection.

E1.4-0041-18 SPECTRAL AND TIMING PROPERTIES OF MAXI J1535-571 DURING ITS 2017 OUTBURST

S.N. Bose National Centre for Basic Sciences, Kolkata, India

We present spectral and timing analysis results of the newly-discovered X-ray transient source MAXI J1535-571, which is likely a Galactic black hole binary. It was discovered on 2017 Sep.

02. During the soft/high state, the maximum X-ray flux in 0.3-10 keV band increased by 25 times than that in the quiescent state, which is about 4 Crab. Using the Swift XRT BAT observations, we study accretion flow processes around the black hole from spectral fits with the Two-Component Advective Flow (TCAF) model in XSPEC. Significant emission lines from neutral Fe K and Fe XXV K are observed. Type-C QPOs are also significantly detected in the raising and the declining phases of the outburst. Propagating Oscillatory Shock (POS) model is used to study monotonic evolution of the QPO frequencies during the declining phase of the outburst. This allowed us to have a rough estimation of the evolution of the central Compton cloud region (known as CENtrifugal pressure supported BOundary Layer; CENBOL) by measuring instantaneous locations, strength, velocity etc. of the propagating shock wave. The shock parameters obtained from POS model fit is also found to be consistent with the TCAF model fitted shock parameters. It has been observed that the CENBOL shrinks in the rising phase and expands in the declining phase of the outburst. We also estimate mass of the black hole candidate to be 10 solar masses from our TCAF model fitted spectral fits, suggesting that it is a stellar mass black hole system.

E1.4-0042-18 NEAR INFRARED OBSERVATION OF MAXI J1535-571

Nobuyuki Kawai, nkawai@phys.titech.ac.jp Tokyo Institute of Technology, Tokyo, Japan Kotaro Morita, morita@hp.phys.titech.ac.jp Tokyo Institute of Technology, Tokyo, Japan Katsuhiro Murata, murata@hp.phys.titech.ac.jp Tokyo Institute of Technology, Tokyo, Japan Ryosuke Itoh, itoh@hp.phys.titech.ac.jp

Tokyo Institute of Technology, Tokyo, Japan Yutaro Tachibana, tachibana@hp.phys.titech.ac.jp Tokyo Tech, Tokyo, Japan

MAXI J1535-571 is a black hole binary candidate discovered by MAXI and Swift at the outburst in September 2017. We performed a series of near infrared observations with IRSF in J, H, and K bands, in which we found significant flux variations on short time scales. We discuss the origin of the infrared emission based on its timing properties, colors, and broad-band SED.

E1.4-0043-18 TIMING BEHAVIORS OF THE BRIGHT NEW BH CANDIDATE MAXI J1535- 571

Yue Huang, huangyue@ihep.ac.cn

Institute of High Energy Physics, Chinese Academy of Sciences, Beijing, China Jinlu Qu, qujl@ihep.ac.cn

Institute of High Energy Physics, BEIJING, China

We present the X-ray timing results of the new black hole candidate (BHC) MAXI J1535- 571 during its 2017 outburst from Insight-HXMT observations taken from 2017 September 6 until September 23. We find the source exhibits state transition of Low/Hard state (LHS) → Hard Intermediate state (HIMS) → Soft Intermediate state (SIMS). Quasi-periodic oscillations (QPOs) were found in the intermediate states, which seem to be of different types. We present the energy dependence of the QPO amplitude up to 100 keV which was totally unexplored area in timing domain. We find that the phase lag at the type-C QPOs frequency is negative (soft lags) and strongly correlated with the centroid frequency of the QPOs. By assuming a geometrical origin of type-C QPOs, the source is consistent with a high inclination.

E1.4-0044-18 EXPLAINING THE OUTBURSTS OF THE INTERMEDIATE-MASS BH HLX-1 AS A WIND-DRIVEN INSTABILITY

Roberto Soria, roberto.soria@curtin.edu.au

University of the Chinese Academy of Sciences, Beijing, China

We model the optical/UV emission of the intermediate-mass black hole HLX-1, using three sets of HST observations (from 2010, 2012, 2013), together with XMM-Newton and Swift data. We quantify the relative contributions of a bluer component, function of X-ray irradiation, and a redder component, constant and likely coming from an old stellar population. By combining optical and X-ray data, in particular around its state transitions, we estimate a BH mass 2 x 104M sun, aspinparametera/M 0.9f or a moderately face–on view, and a peak outburst luminosity 0.3timest

We discuss the discrepancy between the characteristic size inferred from the short X-ray timescale

(R a few 1011 cm) and the characteristic size of their radiated optical emitter (Rsqrt[costheta] 2x1013cm).One ray outburst cycle. We propose that the recurrent outbursts are caused by an accretion rate oscillation driven by term average accretion rate of a few percent of Eddington, just below the upper limit of the low/hard state; aw driven oscillation can trigger transitions to the high/s of tstate, with a recurrence period 1 year (much longer 1 and in the Galactic BHV 404Cyg.

E1.4-0045-18 POSSIBLE IMAGES OF SGR A* IN TWO COMPONENT ADVECTIVE FLOW PARADIGM

Kinsuk Giri, kinsuk@nitttrkol.ac.in

National Institute of Technical Teachers' Training & Research (NITTTR), Kolkata, Kolkata, India

Arka Chatterjee, arka019icsp@gmail.com Indian Centre for Space Physics, Kolkata, India

Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

The existence of Two Component Advective Flow around a black hole was proposed earlier and very recently it is proved through time dependent numerical simulation. However, the images, spectra and degree of polarization corresponding to the variation of physical parameters like accretion rate, viscosity and mass are studied in the current context. Self-consistent formation of Keplerian disk around Low Luminosity AGNs like Sgr A* are presented.

E1.4-0046-18 CORONAL PROPERTIES FROM NUSTAR OBSERVATIONS OF AGN AND THEIR IMPLICATIONS

Douglas Buisson, djkb2@cam.ac.uk

University of Cambridge, Cambridge, United Kingdom Andy Fabian, acf@ast.cam.ac.uk

University of Cambridge, Cambridge, United Kingdom Anne Lohfink, alohfink@astro.umd.edu

University of Maryland, College Park, College Park, Maryland, United States

A significant fraction of the power produced by accretion onto the central black hole of AGN is released in the X-ray band. It is widely accepted that this emission is produced by inverse Compton scattering of UV disc photons by a region of electron plasma known as the corona. However, the detailed conditions in the corona are still poorly constrained.

The recent NuSTAR mission, with significantly greater sensitivity in the hard X-ray band than previous missions, has allowed a step-change in the quality of our observations of the corona. In particular, the Comptonised continuum can now be measured for many sources up to around its high energy cut-off, allowing precise measurements of the coronal temperature and other related parameters.

These measurements suggest that pair production may play an important role in the regulation of coronal temperatures. The increasing sample of sources with high-quality NuSTAR observations allows us to improve the detail and precision of our inferences, such as by considering the prevalence of non-thermal electrons in the plasma.

We will present the latest results from our ongoing campaigns to measure coronal properties with NuSTAR and the significance of these results for the wider accretion process.

E1.4-0047-18 THE ROBOPOL OPTOPOLARIMETRIC BLAZAR MONITORNG PROGRAM

Vasiliki Pavlidou, pavlidou@physics.uoc.gr University of Crete, Heraklion, Greece

Optical Synchrotron emission from blazars is significantly polarized and the polarization probes the magnetic field structure in the jet. Rotations of the polarization angle in blazars reveal important information about the evolution of disturbances responsible for blazar flares. The RoboPol program for the polarimetric monitoring of statistically complete samples of blazars was developed in 2013 to systematically study this class of events. RoboPol is a collaboration between the University of Crete, the Max-Planck Institute for Radio Astronomy, Caltech, the Inter-University Centre for Astronomy and Astrophysics in India, and the Nicolaus Copernicus University in Poland. Using a novel polarimeter operating at the 1.3m telescope of the Skinakas Observatory in Crete, it has succeeded in its 4 years of operation in taking optopolarimetric rotations of blazars from novelty status to a well-studied phenomenon that can be used to answer long-standing questions in our theoretical understanding of jets. I will review the RoboPol program and its most important results in the classification of the optopolarimetric properties of blazars, the statistical properties of polarization rotations, and their relation to gamma-ray activity in blazar jets.

E1.4-0048-18 TIME VARIABILITY OF THE CORE-SHIFT EFFECT IN THE BLAZAR 3C454.3

Wara Chamani, wara.chamani@aalto.fi

Aalto University Metsähovi Radio Observatory, Espoo, Finland Tuomas Savolainen, tuomas.k.savolainen@aalto.fi

Aalto University, Espoo, Finland

The so-called core-shift effect in relativistic jets observed at radio wave bands has been widely studied and used for estimating physical parameters such as the magnetic field strength and the particle number density. In this work, we have investigated the time variability of the coreshift effect in the very luminous blazar 3C454.3 (z=0.859). We have analysed multi-frequency (5,8,15,22,43 GHz) Very Long Baseline Array data of 19 epochs from 2005 to 2010. Core-shift measurements have been performed using image plane cross-correlation and visibility plane model-fitting. These measurements allow us to study the time variability of the core-shift in the blazar as well as the time evolution of the spectra. We compare our results with long-term 37 GHz total flux density monitoring observations made at the Metsähovi Radio Observatory searching for correlations. Our preliminary results show that the index kr of the core-shift effect

(rcore ν−1/kr) varies in the range of 0.50 < kr < 1.63 during the observed time period. We suggest that this variability is mainly linked to the occurrence of outbursts. We will discuss the reliability of the core-shift measurements as a proxy for the jet magnetic field strength.

E1.4-0049-18 RECONCILING OBSERVATIONS AND THEORY OF THE OUTBURST OF 3C 279

Eugenio Bottacini, eugenio.bottacini@unipd.it University of Padova, Padova, Italy

Blazars become extremely bright at all frequencies during outburst phases. Multifrequency data of such phases can be modeled through radiation transfer models which in turn allows for testing reconciliation of data and theory of the emission mechanism that is powered by the central supermassive black hole. We have caught the prominent blazar 3C 279 with INTEGRAL in its brightest outburst at high energies. The multifrequency campaign around this detection ranges from IR frequencies to gamma-ray energies (GeV), covering the outburst with public available data from the Small and Moderate Aperture Research Telescope System (SMARTS), the Swift/UVOT, the Swift/XRT, the INTEGRAL/IBIS, and the Fermi-LAT. Eventually also proprietary TeV data of the same outburst by the H.E.S.S. Cherenkov Telescopes were released. We model the outburst with a leptonic and lepto-hadronic model. In this talk I will show the results and how theory and observations can be reconciled. Yet, the modeling predicts extreme conditions in the jet that fail to lead to an exhaustive physical explanation.

E1.4-0050-18 VARIABLE NATURE OF MAGNETICALLY-DRIVEN ULTRA-FAST OUTFLOWS (UFOS) FROM AGN ACCRETION DISKS

Keigo Fukumura, fukumukx@jmu.edu

James Madison University, Harrisonburg, Virginia, United States Demosthenes Kazanas, demos.kazanas@nasa.gov

NASA/GSFC, Greenbelt, Maryland, United States Chris Shrader, chris.r.shrader@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States Ehud Behar, ebehar@technion.ac.il

Technion, Haifa, Israel

Ioannis Contopoulos, icontop@academyofathens.gr Greece

Francesco Tombesi, francesco.tombesi@roma2.infn.it University of Rome "Tor Vergata", Rome, Italy Francesco Tombesi, ftombesi@astro.umd.edu University of Rome "Tor Vergata", Rome, Italy

With an increasing number of high-S/N spectroscopic observations of nearby radio-quiet Seyfert galaxies in the past decade, it is becoming more obvious that a sub-class of X-ray winds, known as ultra-fast outflows (UFOs) could be more ubiquitous than ever thought while quite variable in nature. It is suggested that the observed UFOs, especially those detected in Fe K band, may exhibit some likely correlations. For example, in the case of a luminous nearby quasar, PDS 456, and a narrow-line Seyfert 1, IRAS 13224-3809, the observed velocity of the Fe K UFOs (i.e. Fe xxv/xxvi) and its equivalent width (EW) are found to be (both) correlated with the ionizing X-ray flux/luminosity across different epochs. Attributed to their extreme brightness particularly in O/UV band most likely powered by accretion process, it is speculated that strong UV radiation field responsible for producing sufficiently high line-opacity due to bound-bound transition may effectively drive the observed UFOs in these systems. However, a certain optimal ionization condition is necessary in such a scenario to acquire high velocity by avoiding overionization, while the observed UFOs are typically characterized by high ionization parameter.

In this work, it is shown that the action of global magnetic fields, another equally promising launching mechanism, can naturally explain the observed UFO conditions in PDS456 as a case study. By detailed photoionization calculations with xstar code, the MHD-driven disk-wind model predicts that H/He-like Fe are formed at smaller radius where the velocity is higher with higher X-ray luminosity, while the net ionic columns drop due to its higher ionization parameter thus reducing the EW. We successfully fit the 2013-2014 XMM-Newton/NuSTAR campaign spectrum with this model and also show a simulated XARM/micro-calorimeter spectrum. We further demonstrate that the observed multi-epoch correlations of UFOs are well explained within the framework of MHD-driven disk-winds.

The anticipated scientific advances made possible by XARM and Athena in the forthcoming decades will allow us to answer these fundamental questions by exploring AGN winds more throughly.

E1.4-0051-18 THE ORIGIN OF THE BROAD LINE REGION IN ACTIVE GALACTIC NUCLEI

Bozena Czerny, bcz@camk.edu.pl

Center for Theoretical Physics of the Polish Academy of Sciences, Warsaw, Poland

Broad emission lines are the most characteristic features of AGN but the origin of the material responsible for the observed emission is still hotly debated. Reverberation studies show the predominantly Keplerian motion of the BLR clouds but mixed with the inflow or outflow. I will review various options, paying attention to the division of the lines into Low Ionization Lines and High Ionization Lines. In the case of LIL, I will discuss in detail FRADO (Failed Radiatively Accelerated Dusty Outflow) model which successfully describes the BLR radius - luminosity relation from the first principles. I will briefly mention the issue of the outliers from this relation in the case of highly Eddington sources and at low Eddington ratio tail.

E1.4-0052-18 THE ORIGIN OF THE BROAD LINE REGION IN AGN

Ari Laor, laor@physics.technion.ac.il Technion, Haifa, Israel

Broad emission lines are the defining property of type 1 AGN. What is the origin of the gas which produces these lines? I will describe our recent study of the vertical structure of a dusty accretion disk atmosphere. The dust opacity leads to an inflated inner disk profile. The illuminated surface of this inflated structure provides a natural source for the broad line emission. I will described various future observations which can be used to test this mechanism.

E1.4-0053-18 HOW UNIVERSAL IS THE BIG BLUE BUMP IN ACTIVE GALACTIC NUCLEI? HOW IMPORTANT IS REPROCESSED LIGHT IN THE OPTICAL?

Matthew Malkan, malkan@astro.ucla.edu UCLA, Los Angeles, California, United States

Aside from some known minor contributions arising from recombination emission in the Broad Line Region, the optical continuum from quasars and Seyfert 1 galaxies appears to be thermal emission from an optically thick 'surface'. One very successful model for this is an accretion disk. But an additional possible component that has also been considered, is re-processed emission. This is energy which was ultimately produced by accretion, as high energy photons, which were then absorbed and re-emitted further out. Thus this re-processed continuum comes from regions of larger radii and lower temperatures than a plain (self-heated by viscosity) accretion disk.

Reprocessing is already known to produce most of the near-IR continuum observed in most Seyfert 1's and quasars. I will consider several possible observational indicators that reprocessing becomes important, and even dominant, in producing the optical continuum from many AGN. I will discuss the relative strengths of broad emission lines, the near-infrared/optical/UV/Xray continuum spectra, constraints on emission region sizes from microlensing, and also from time delays measured in reverberation experiments. If a substantial fraction of radiation from the inner disk is re-captured by optically thick gas at large radii, the effective temperature should fall off not as r**-3/4 but more gradually, as r**-1/2. A simple calculation of accretion disk-plus-reprocessing which can fit the observations will be presented.

E1.4-0054-18 CONSTRAINT ON AGN CORONA SIZE WITH FULLY RELATIVISTIC MODELING OF 3D CORONA

Wenda Zhang, zhang@asu.cas.cz

Astronomical Institute, Academy of Sciences of the Czech Republic, Prague, Czech Republic

The “lamp-post” scenario was usually used to describe AGN corona, in which the corona is assumed to be an infinitesimal point source on the symmetry axis. In some AGNs, especially NLS1s, the broad iron line profile requires extremely compact corona. On the other hand, the corona must be large enough to intercept enough seed photons to be able to produce the observed X-ray continuum and reflection spectrum. One attempt to constrain AGN corona size was made by Dovciak Done 2016, in which the corona size was estimated by conservation of photons during Comptonization process. They found out that for one NLS1 1H 0707-495, the size of the corona must be substantially larger than 1 GM/c2. In that work, the Comptonized spectrum was evaluated assuming lamp-post geometry and the corona size was estimated under the assumption that the emission of the corona is homogeneous. To calculate the spectrum of 3D corona (i.e., the corona is extended and with finite height) self-consistently, we perform a fully relativistic Monte Carlo calculation of energy and polarization spectrum of AGNs of disk-corona geometry, taking into account propagation of null geodesic in Kerr space-time and Compton scattering process. With the calculated spectra, we are able to put constraint on AGN corona size for an AGN sample with simultaneous XMM-Newton X-ray/UV observations.

E1.4-0055-18 THE JET-DISK MODEL FOR SGR A*

Heino Falcke, h.falcke@astro.ru.nl

Radboud Universiteit Nijmegen, Nijmegen, Netherlands

Where does the persistent and flaring emission of the Galactic Center black hole, Sgr A*, originate from? Does it come from an accretion flow or is it produced in a relativistic jet- like outflow? Answering this question is not only important for understanding the plethora of multi-wavelength data available for Sgr A*, it is also crucial for interpreting upcoming VLBI images of the shadow of the event horizon. Using advanced three-dimensional general relativistic magnetohydrodynamics simulations coupled to general relativistic ray tracing simulations, we can now model the dynamics and emission of the plasma around starving black holes in great detail out to several thousand Schwarzschild radii. A crucial parameter is the heating of radiating electrons and we argue that electron-proton coupling is low in the accretion flow and high in the magnetized region of the jets. This makes the jet an important ingredient for the overall appearance of the source. This comprehensive model is able to predict the radio size and appearance, the spectral energy distribution from radio to X-rays, the polarization properties, the variability, and the time lags of Sgr A* surprisingly well.

E1.4-0056-18 THE EVOLVING JET IN THE NEW BLACK HOLE X-RAY BINARY MAXI J1535-571

Thomas Russell, t.d.russell@uva.nl

University of Amsterdam, Amsterdam, Netherlands Alexandra Tetarenko, tetarenk@ualberta.ca University of Alberta, Edmonton, Canada

James Miller-Jones, james.miller-jones@curtin.edu.au ICRAR - Curtin University, Perth, Australia Gregory Sivakoff, sivakoff@ualberta.ca

University of Alberta, Edmonton, Canada David Russell, dave.russell@nyu.edu

New York University Abu Dhabi, Abu Dhabi, United Arab Emirates Diego Altamirano, d.altamirano@soton.ac.uk

University of Southampton, Southampton, United Kingdom

MAXI J1535-571 is a recently discovered and very bright Galactic black hole X-ray binary. Here, I will present results from our comprehensive ATCA radio and ALMA millimetre monitoring of this source throughout its outburst. Our multi-frequency coverage show the observed jet spectrum changing rapidly as the source transitioned from the hard state towards the soft state, indicating dramatic changes in the jet over relatively short timescales. Surprisingly, we detect core radio emission throughout the soft state, placing limits on the level of jet quenching in this source. I will also discuss the monitoring of two downstream radio knots/shocks, allowing us to place constraints on their speed and time of their ejection, which can then be linked back to changes in X-ray properties. These radio and millimeter observations provide an unprecedented insight into the changing jet structure, and how the accretion flow may be driving those changes.

E1.4-0057-18 ACCRETION - EJECTION MECHANISM OF MAXI J1836-194 WITH THE TCAF SOLUTION

MAXI J1836-194 showed its first activity in Aug 2011. It was active for 3 months before it went to quiescent state for 4 months. It renewed its activity again in March 2012 for 2 months. We have analyzed spectral data of 3-25 keV RXTE/PCA for the 2011 outburst and 0.5-10.0 keV Swift/XRT for 2012 outburst with the current fits file of the two component advective flow (TCAF) model in XSPEC. The detailed accretion flow properties of the source during its 2011 outburst has been done from spectral and temporal analysis under TCAF paradigm. Based on the variation of the TCAF model fitted physical flow parameters and nature of observed quasi-periodic oscillations (QPOs), we classified entire outburst into two harder spectral states: hard (HS) and hard-intermediate (HIMS), which are observed in the sequence of HS(Ris.)-> HIMS(Ris.)-> HIMS(Dec.)-> HS(Dec.). We estimated mass of the source from our TCAF model fitted spectral analysis. We also have estimated contribution of jet X-ray fluxes with a newly developed method based on TCAF model. We find that the jet contributes in the X-ray as high as 86% of total intensity during its 2011 outburst. We find jet X-ray (Fouf) correlates with radio flux (FR) as FR F 0.61, which is similar to standard correlation. However, when the correlation is done with total X-ray, we find unusual steep index sim 1.82. This could be due to the surrounding clouds from the excretion disk of the companion Be star. In the correlation plots, we find LR Lx points lie on the jet line for the 2012 outburst and quiescent state indicating observed radio flux is from earlier epoch. Another reason could be that the quiescent and the 2012 outburst is dominated by radiatively inefficient sub-Keplerian flow, the phases are highly jet dominated.

An important problem of astrophysics is whether a jet from an accreting black hole is aligned with the black hole spin axis or the accretion disk angular momentum vector. An answer to this question can provide important information about the jet triggering mechanism, disk-jet coupling, and the high energy radiation mechanisms in a black hole system. Tidal Disruption Event (TDE) of a star by a supermassive spinning black hole provides a unique astrophyical laboratory to study the jet alignment through the possibility of Lense-Thirring precession of the jet. In this work, we investigate the Swift XRT light curve of the most well sampled jetted TDE, Swift J1644+57. In the thick disk regime of the light curve, we estimate, using a known optimistic method and a new conservative method developed by us, the tilt angle of the jet with respect to the black hole spin axis as a function of the black hole spin parameter. We find that the jet in Swift J1644+57 is more likely to be aligned with the black hole spin axis.

E1.4-0059-18 GLOBAL RADIO VERSUS BOLOMETRIC X-RAY FLUX CORRELATION IN THE BLACK HOLE X-RAY BINARY GX 339-4

Nazma Islam, nislam@camk.edu.pl

Nicolaus Copernicus Astronomical Center, Warsaw, Poland Andrzej Zdziarski, aaz@camk.edu.pl

Copernicus Center, Warsaw, Poland, Warsaw, Poland

Compact radio jets are ubiquitous in stellar mass black hole binaries in their spectrally hard state. The correlation between the radio emission from the compact jets and X-ray emission from the accretion disk around the black hole, is of major importance in understanding the nature of accretion diskjet coupling in black hole X-ray binaries. Previous works investigating the radio versus X-ray emission correlation properties, used the narrow 3-9 keV or 1-10 keV Xray energy band luminosity as proxy for accretion rate. However, the bulk of X-ray emission in the hard spectral state of black hole X-ray binaries, is emitted around 100 keV. We investigated the global radio versus bolometric X-ray luminosity correlation for the black hole X-ray binary GX 339-4 using RXTE observations. We have found that these correlations show an effect of hysteresis, previously found in the relationship between the X-ray hardness and flux, but not in the radio band. These correlations will provide new insights into the various accretion disk and jet ejection models.

E1.4-0060-18 CORRELATED X-RAY AND OPTICAL VARIABILITY DURING THE 2015 SUPER-EDDINGTON OUTBURST OF V404 CYG

Philip Charles, p.a.charles@soton.ac.uk

University of Southampton, Southampton, United Kingdom Julia Alfonso-Garzon, julia@cab.inta-csic.es

Centro de Astrobiología, Villanueva De La Cañada, Spain Poshak Gandhi, p.gandhi@soton.ac.uk

University of Southampton, Southampton, United Kingdom

The 2015 June/July outburst of V404 Cyg was the brightest X-ray transient event ever recorded, but only lasted for barely 2 weeks. During that time V404 Cyg was extensively monitored by INTEGRAL, providing unprecedented soft and hard X-ray (with JEM-X and ISGRI) and optical (with OMC) coverage of this event. A number of dedicated simultaneous observations were also undertaken by NuSTAR and ULTRACAM at high time resolution. Here we give an overview of the remarkable variations that are displayed during the outburst, identifying a number of episodes of correlated X-ray and optical variations which we associate with the inflow of the inner accretion disc, and subsequent ejections of a relativistic jet.

E1.4-0061-18 THE MULTI-WAVELENGTH EMISSION OF X-RAY BINARY JETS POWERED BY INTERNAL SHOCK

Julien Malzac, julien.malzac@irap.omp.eu

IRAP, University of Toulouse / CNRS, Toulouse, France

The emission of steady compact jets observed in the hard spectral state of X-ray binaries and in AGN is likely to be powered by internal shocks caused by fluctuations of the outflow velocity. Those fluctuations are likely to originate in the accretion flow. Using the internal shock model ishem, I explore this possible connection between accretion and ejection. The fluctuations of the accretion flow can in principle be traced by the X-ray light curves, while the response of the synchrotron jet can be observed with radio and IR measurements. Under the assumption that the power spectrum of the jet fluctuations is identical to that of the observed X-ray light curve, we calculate the predictions of the model and make comparisons to spectral and timing data from several X-ray binaries. The we find that in GX 339-4 and MAXI J1836- 194 the model provides a good description of the observed radio optical SEDs. In the case of MAXI J1836-192 we model the evolution of the SED in the hard state during an outburst. Our results indicate that in this source, not only the jet power but also the jet time averaged Lorentz factor increases with luminosity. We also find that the quenching of the jet in the soft state might be related to the drop in X-ray variability: the jet could be present in the soft state but undetected due to a very low radiative efficiency associated to very weak velocity fluctuations. The model also predicts a strong, wavelength dependent jet variability that resembles the observed one. In particular, strong sub-second variability is predicted in the infrared and optical bands. In the cas of GX 339-4 complex timing correlations are observed between the IR/optical light curves and the X-rays that we use to probe the fast dynamics of the accretion/ejection connection. In this source also low frequency QPOs have been detected simultaneously in X-ray and IR. The appearance of the IR QPO could be caused by jet precession driven by Lense-Thirring precession of the X-ray accretion flow.

E1.4-0062-18 MAPPING SUPERMASSIVE BLACK HOLE WINDS, FROM THE EVENT HORIZON UP TO GALAXY SCALES

Powerful winds driven by active galactic nuclei (AGN) are often invoked to play a fundamental role in the evolution of both supermassive black holes (SMBHs) and their host galaxies, possibly quenching star formation and explaining the tight SMBH-galaxy relations. Additional support for this “quasar-mode” feedback came from new X-ray observations of mildly relativistic disk winds, a.k.a. ultrafast outflows, in some ultra-luminous infrared galaxies and their connection with galactic molecular outflows observed in mm and IR wavebands. In particular, the combination of X-ray (Suzaku, NuSTAR), IR (Herschel), and mm (ALMA) observations of IRAS F11119+3257 allowed us to link the SMBH activity to molecular outflows that may quench star formation. Therefore, synergistic observations in X-ray and other wavebands have the power to map AGN winds from the event horizon up to galaxy scales, providing a promising avenue to study the multi-phase SMBH feeding and feedback. Spectroscopic observations suggest that such SMBH winds may be common in local AGN and quasars. However, their origin and characteristics are still not fully understood. Theoretical models and simulations focused on radiation, magnetohydrodynamic (MHD) or a combination of these two processes to investigate the acceleration mechanisms and dynamics of these winds. Revolutionary improvements are expected from upcoming X-ray space observatories, such as Athena and XARM, in synergy with other major spaceand ground-based facilities.

E1.4-0063-18 CAN THE RELATIVISTIC LIGHT BENDING MODEL EXPLAIN X-RAY SPECTRAL VARIATIONS OF SEYFERT GALAXIES?

Masahiro Tsujimoto, tsujimot@astro.isas.jaxa.jp ISAS/JAXA, Kanagawa, Japan

Many Seyfert galaxies are known to exhibit Fe-K broad emission line features in their X-ray energy spectra. The observed lines have three distinct features; (1) the line profiles are skewed and show significant low-energy tails, (2) the Fe-K band have low variability, which produces a broad and deep dip in the root-mean-square (rms) spectra, and (3) photons in this band have time lags behind those in the adjacent energy bands with amplitudes of several Rg/c, where Rg is the gravitational radius. The “relativistic light bending model” is proposed to explain these observed features, where a compact X-ray source (lamp post) above an extreme Kerr black hole illuminates the innermost area of the accretion disc. We critically examine the relativistic light bending model by computing the rms spectra and the lag features using a ray-tracing technique, when a lamp post moves vertically on the black hole spin axis. As a result, we found that the observed deep rms dip requires that the iron is extremely overabundant (> 10 solar), whereas the observed lag amplitude is consistent with the normal iron abundance. Furthermore, disappearance of the lag in the high-flux state requires a source height as high as 40Rg, which contradicts the relativistically broad emission line feature. Therefore, we conclude that the relativistic light bending model may not explain the characteristic Fe-K spectral variations in Seyfert galaxies.

E1.4-0064-18 STRONG DISC WINDS TRACED THROUGHOUT OUTBURSTS IN BLACKHOLE X-RAY BINARIES

University of Alberta, Edmonton, Canada

Recurring outbursts associated with matter flowing onto compact stellar remnants (such as black holes, neutron stars and white dwarfs) in close binary systems provide constraints on the poorly understood accretion process. Taken as a whole, the light-curves of these outbursts are shaped by the efficiency of angular-momentum (and thus mass) transport in the accretion discs in these systems, which has traditionally been encoded in the α-viscosity parameter. Numerical simulations of the magneto-rotational instability that is believed to be the physical mechanism behind this transport yield values of α of roughly 0.1–0.2, consistent with values inferred from observations of accreting white dwarfs. However, equivalent viscosity parameters have never been estimated for discs around neutron stars or black-holes (i.e., low-mass X-ray binaries) before. We have combined theory, advanced Bayesian statistical techniques, and the observed X-ray light-curves to build an innovative methodology, which for the first time, measures the α-viscosity parameter in low-mass X-ray binary discs. Here we report the results of applying this methodology to the Galactic black-hole low-mass X-ray binary population. We discuss how these results suggest that strong accretion disc winds, with the ability to remove a substantial fraction of the disc mass, must exist in all accretion states throughout outbursts of accreting stellar-mass black-holes.

E1.4-0065-18 MAGNETIC RECONNECTION, PARTICLE ACCELERATION AND VERY HIGH ENERGY EMISSION AROUND BLACK HOLES AND JETS

Particle acceleration induced by fast magnetic reconnection in the surrounds of black holes and their relativistic jets may help to solve current puzzles specially related to the interpretation of the very high energy (VHE) emission produced in BHBs, AGNs and GRBs. In this talk, we will discuss this process in the framework of these sources, showing our recent results of analytical and three-dimensional numerical MHD simulations with test particles. Our numerical simulations of accretion disk-corona systems reveal the growth of turbulence driven by MHD instabilities that lead to the development of both large scale magnetic loops and magnetic reconnection with fast reconnection rates around 0.13-0.17 VA (where VA is the local Alfven speed). These results are crucial for testing recent theories of particle acceleration and VHE driven by turbulence-induced fast magnetic reconnection around magnetized compact objects (e.g., de Gouveia Dal Pino et al. 2016 and references therein). Furthermore, our numerical simulations of relativistic MHD jets subject to current-driven-kink instability reveal the formation of several compact sites of fast reconnection induced by the kink turbulence (with reconnection rates around 0.15 VA). The injection of thousands of test particles in these reconnection regions of the jet resulted in their acceleration up to energies of 1017 eV, thus demonstrating the ability of this process to accelerate particles and produce the observed VHE in these sources.

E1.4-0066-18 IMAGES OF TWO COMPONENT ADVECTIVE FLOW AROUND BLACK HOLES IN PRESENCE OF OUTFLOWS AND COOLING

Arka Chatterjee, arka019icsp@gmail.com Indian Centre for Space Physics, Kolkata, India

Heritage Institute of technology, Kolkata, India

In the literature, several authors have presented images of black holes surrounded by Keplerian disks or simple one component disks. However, successful fitting of the spectral and timing properties suggest that the disks around black hole are of two components, one Keplerian and the other sub-Keplerian. We present images, spectra and energy dependent time lags of Two Component Advective Flow. Hydrodynamical configuration of low angular momentum, sub-keplerian component is generated by the Total Variation Diminishing (TVD) method. To produce the spectra, we incorporate Comptonization via Monte-Carlo technique. The spectral energy distribution, images over various inclination angles on observer plane are obtained by Ray-Tracing process. Variations caused by the self consistent outflows are reported.

The X-ray/Ultraviolet/Optical emission from accretion-powered sources shows phenomenological similarities, characterized by a lognormal flux distribution, a linear relation between intrinsic variability and flux (rms-flux), and a (broken) power-law power spectral densities (PSDs). These features have normally been argued to be a result of the multiplicative combination of fluctuations in the accretion disk. Here, we present results from exploration of these properties in gamma-ray emission of four radio-loud Active Galactic Nuclei (AGNs): radio-galaxy NGC 1275 and three blazars - Mrk 421, PKS 1510-089, and B2 1520+31, using continuously sampled light curves between 2008 - 2015 from Fermi-LAT. All the sources, except Mrk 421, display flux spanning 2 orders of magnitude between the extremes with a lognormal profile describing the blazars flux histogram better compared to a Gaussian while none favored for the non-blazar source NGC 1275. The rms-flux relation, however, is linear for all, irrespective of histogram profile while the PSDs are typical of the accretion-powered source, exhibiting a red noise power-law spectrum of slope 1, though there is hint of breaks. The inferred results are consistent with the statistics of magnetic-reconnection powered minijets-in-a-jet model as well as with the statistics of X-ray emission from the whole Solar disk. The results thus suggest magnetic reconnection as the potential process powering the emission, consistent with the non-thermal spectrum observed from these sources. The broad similarity of properties with other accretion-powered sources also suggest that the magnetic reconnection may likely be an imprint of fluctuation in the accretion disk to the jet.

E1.4-0068-18 USING ASTROCHEMISTRY TO PROBE JET PROPERTIES AND ENERGETICS IN GALACTIC BLACK HOLE X-RAY BINARIES

Alexandra Tetarenko, tetarenk@ualberta.ca University of Alberta, Edmonton, Canada Erik Rosolowsky, rosolowsky@ualberta.ca University of Alberta, Edmonton, Canada

James Miller-Jones, james.miller-jones@curtin.edu.au ICRAR - Curtin University, Perth, Australia Gregory Sivakoff, sivakoff@ualberta.ca

University of Alberta, Edmonton, Canada

Relativistic jets launched from accreting black holes in our Galaxy can carry large amounts of energy and matter into their surrounding environment. Identifying where these jets interact with the ISM, and probing the physical conditions at these interaction sites, can provide crucial insight into highly sought-after jet properties, such as the jet power, composition, duty cycles, and the efficiency of jet feedback. Molecular lines observable in the sub-mm frequency bands are excellent diagnostics of shock energetics and ISM excitation in these jet-ISM interaction zones. In this talk, I will present new results from our ALMA observations of a candidate jet-ISM interaction zone near the black hole X-ray binary (BHXB), GRS 1915+105. Through examining the morphological, spectral, and kinematic properties of the molecular emission, we find several lines of evidence that support the presence of a jet-ISM interaction at this site, including a jet-blown cavity in the molecular gas. We also estimate the likelihood of finding such jet-molecular cloud interactions elsewhere in our Galaxy, with the interaction probability per BHXB system being 3%. Our work here demonstrates that astrochemistry can be used as a powerful new tool to identify and probe these jet-ISM interaction zones near accreting black holes in our Galaxy.

E1.4-0069-18 WOBBLING JETS IN ACTIVE SUPER-MASSIVE BLACK HOLES

Bindu Rani, bindu.rani@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States

Powered by accretion onto super-massive black holes (masses up to 10 billion Solar mass), active galactic nuclei (AGN) are strong emitters of electromagnetic radiation over a range spanning more than 20 decades in energy. About 1 in 10 AGN convert a substantial fraction of accretion energy into highly collimated and relativistic outflows of energetic plasma called "JETS". Many AGN jets do wobble, i.e., show temporal variations in their direction on parsec scales. While the causes of "jet wobbling" are not agreed upon, it is a powerful probe of energy extraction from super-massive black holes. I will present a comparison of jet wobbling with first-principles general relativistic magnetohydrodynamic (GRMHD) simulations.

E1.4-0070-18 SPIN DEPENDENT SPECTRA AND IMAGES OF TWO COMPONENT ADVECTIVE FLOW IN VARIOUS SPECTRAL STATES

Arka Chatterjee, arka019icsp@gmail.com Indian Centre for Space Physics, Kolkata, India

Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

We employ generalized Ray-tracing formulation to compute the spectra and images Two Component Advective Flow. Coupled second order Four dimensional geodesic equations are solved to obtain the images on the plane of the observer. Monte-Carlo technique has been used to generate seed photons. Comptonization has been added to produce the spectrum. Spin dependent image and spectral variations are reported. Time lag maps of accretion disk are presented.

E1.4-0071-18 OBSERVATIONS OF THE SEYFERT 1 AGNS ZW 229.015 AND MRK 493 VISA-VIS THEORETICAL PREDICTIONS

Oluwashina Adegoke, adegoke.olushina@gmail.com Indian Institute of Science, Bangalore, India Banibrata Mukhopadhyay, bm@iisc.ac.in

Indian Institute of Science, Bangalore, India Gulab Chand Dewangan, gulabd@iucaa.in IUCAA, Pune, India

By using the archival XMM-Newton and Swift data of the nearby Seyfert 1 AGNs Zw 229.015 and Mrk 493, we study both the spectral and temporal properties of the central blackholes in remarkable detail. The energy spectra show soft excess emission (much stronger for Mrk 493) which is consistent with both inverse comptonisation from a cold corona and relativistically blurred reflection close to a black hole. From the time lag estimate between the soft and the hard X-rays, we compute the size of the corona system to be about 20Rg for Zw 229.015. On the other hand, on longer time-scale using the Swift archival data for Zw 229.015, a time delay between the UVW2 and X-ray emissions could not be established with certainty although apparently the source appears to be brighter in UV when softer in X-rays. The UV/X-ray emissions from Mrk 493 show strong correlation that is consistent with the prediction of Comptonisation of seed UV photons in the hot corona.

E1.4-0072-18 ELECTROMAGNETIC FIELDS AND ENERGY EXTRACTION FROM BOOSTED ROTATING BLACK HOLE IMMERSED IN MAGNETIC FIELD

Bobomurat Ahmedov, bahmedov@yahoo.com

Ulugh Beg Astronomical Institute, Tashkent, Uzbekistan

We have studied electromagnetic fields and processes in the vicinity of the boosted rotating black hole immersed in external magnetic field. The exact solution of the Maxwell equations for the electromagnetic field has been found for the exterior of the boosted rotating black hole. Charged particle motion around the boosted rotating black hole in the presence of external magnetic field have been studied. The presence of the boost velocity will increase the innermost stable circular orbits around rotating black hole. Energetic processes of the energy extraction from the boosted rotating black hole have been also discussed. The exact analytic expression for the efficiency of magnetic Penrose process in the presence of boost velocity has been obtained. It was shown that boost velocity sufficiently increases the efficiency of the magnetic Penrose process.

E1.4-0073-18 LORENTZ FACTORS OF COMPACT JETS IN BLACK HOLE X-RAY BINARIES

David Russell, dave.russell@nyu.edu

New York University Abu Dhabi, Abu Dhabi, United Arab Emirates
Payaswini Saikia, ps164@nyu.edu

New York University Abu Dhabi, Abu Dhabi, United Arab Emirates

Compact, continuously launched jets in black hole X-ray binaries (BHXBs) produce radio to optical–infrared (OIR) synchrotron emission. These jets are launched in the hard X-ray state, and are quenched in the soft state. They are not spatially resolved except in a few cases using VLBI radio observations. One of the basic properties of these jets is the bulk Lorentz factor, which is notoriously difficult to measure, with to date only weak constraints for a few BHXBs. Here, we adopt simple models to constrain the Lorentz factor of the compact jets in several BHXBs using the amplitude of the jet fade and recovery at infrared wavelengths over state transitions.

The accretion disc tends to dominate the OIR emission throughout BHXB outbursts, but in some sources such as GX 339–4, there is an infrared excess due to synchrotron emission. In other BHXBs this IR excess is very faint or absent. Here, we investigate why some BHXBs have prominent IR excesses and some do not, quantified by the amplitude of the IR quenching or recovery over the transition from/to the hard state. Theoretically, the jet luminosity should correlate with the inclination angle if the emission is strongly beamed. Indeed, we find that some of the sources with the brightest IR excesses compared to their discs are systems with low inclination angle (e.g. 4U 1543–47 and MAXI J1836–194).

In addition, systems with longer orbital periods will produce more OIR disc emission, diluting the jet contribution. We find that the amplitude of the IR fade or recovery over state transitions is expected to be the highest for very low, or very high, inclination BHXBs. For high inclination systems the disc is almost edge-on, which reduces the disc emission but not the jet emission if the jet is not highly beamed, which can lead to relatively bright IR excesses. For intermediate inclination angles (30 – 60 deg), no bright IR excess is expected for any Lorentz factor, and indeed all of the BHXBs with inclination angles within this range do not have prominent IR excesses. Using the amplitude of the IR fade/recovery and the known orbital parameters, we constrain for the first time the Lorentz factor of compact jets in several BHXBs. We find that the very high amplitude IR fade/recovery seen repeatedly in GX 339–4 requires a Lorentz factor greater than 3 and a low inclination angle. These results are strongly supportive of the

IR excess being produced by synchrotron emission in a relativistic outflow, and demonstrate how useful OIR monitoring over state transitions is for studying jet properties.

E1.4-0074-18 THE LONG GAMMA-RAY BURSTS: STANDARD CANDLES OR SOURCES POPULATION INHOMOGENEITY.

Irene Arkhangelskaja, irene.belousova@usa.net

National Research Nuclear University "MEPhI", Moscow, Russia

Typically GRBs are subdivided by two classes: long and short separated by t90 = 2 s. Unfortunately, burst duration strongly depends on detector energy band and method used for temporal profile analysis: the same events could had different duration on data of various detectors. For example, 170405A (18:39:48 UT) had t90 = 165 32 s in energy range 15-350 keV on Swift/BAT data but t90 = 81.601 0.923 s in energy band 50-300 keV on Fermi/GBM data. There are several peaks at this burst light curve and last peak was located at more than 50 s from main three-peaks episode and appears only at low energies. This peak is sufficiently slight than first episode: ten times smaller than first peak on Swift/BAT data in energy range 15-100 keV and is absent in energy band 100-350 keV. On Fermi/GBM data in energy band 10- 44 keV its intensity is about only 50 counts/s over background count rate 1200 counts/sec against 2000 counts/s over background count rate 1300 counts/s during first peak. And this peak separation cause difficulties just because of geomagnetic modulation of Fermi/GBM background. Thus Fermi/GBM burst table doesn't contain information about this episode of GRB170405A.

In addition, sufficient amount of GRBs located at high redshift and cosmological correction should be taken into account in event classes' separation due to duration analysis. Thus, GRB110731A (11:09:30 UT) had t90 = 38.8 32.0 s in energy range 15-350 keV on Swift/BAT data but t90 = 7.485 0.923 s in energy band 50-300 keV on Fermi/GBM data. Its z= 2.83 and after cosmological correction t90 1.95 s on Fermi data (short burst) and t90 10.1 s on Swift/BAT data (long event).

Moreover, separation point between short and long GRBs shifted to 1 s on preliminary results of analysis of Swift/BAT events with known z and duration (351 GRBs) and intermediate group of events occurs in range 1 < t90 < 10 s. Last facts can indicate inhomogeneity of long GRBs population. Unfortunately analogous Fermi/GBM subset is insufficient for statistical analysis. It contains only 50 events because of more than 55% of Fermi/GBM bursts has 1-sigma statistical uncertainty in the t90 duration bigger than 10%.

Redshift distribution analysis results should represent GRBs population homogeneity if it's shape similar to one of objects with real uniform distribution in our Metagalaxy. Usually SN1a used as standard candles (for example, for definition of Ω and Λ for our Metagalaxy). But GRBs redshift distribution for subset of events with known z and duration registered by Swift/BAT sufficiently differ: there is deficit of bursts at z 2. It can be caused by long GRBs population inhomogeneity too.

So, results of preliminary analysis of bursts distribution on redshift and duration allows to make conclusion about possibility of use only certain GRBs subsets as "standard candles" ones after completion of advanced events classification. However, the large majority of long GRBs are related to SNe and collapse of massive stars. Thus inhomogeneities of long GRBs population require new theoretical implications to collapse models.

E1.4-0075-18 FREQUENCY DEPENDENT CORE SHIFT EFFECT IN BLAZARS

Aditi Agarwal, aditi.agarwal@iiap.res.in

Indian Institute of Astrophysics, Bangalore, India

Blazars constitute an ambiguous subset of radio-loud Active Galactic Nuclei consisting both BL Lacertae objects with largely featureless optical spectra and flat spectrum radio quasars which have prominent emission lines. Blazars are characterized with luminous core, rapid variability over entire electro-magnetic spectra, high radio to optical polarization, superluminal motion, non thermal emission and a Doppler boosted relativistic jet pointing < 10 deg with the line of sight. We study the core shift effect in the parsec scale jet of blazars which were monitored at five different frequencies ranging from 4.8 GHz - 36.8 GHz using the University of Michigan Radio Astronomical Observatory, the Crimean Astrophysical Observatory, and Metsahovi Radio Observatory for over 40 years. We have developed piecewise Gaussian fit analysis technique to fit each flare, which is used to determine peak amplitude, and their half width. We also calculate time lags between the observation frequencies. We then determine the spectral indices based on peak amplitudes which range from 16.67 to 2.41. From the fitting of time-lag Vs frequency plots, we find equipartition between the magnetic field energy density and the particle energy density. Other jet parameters including core position offset, core radius, mean magnetic field strength at 1 pc and at the core are also estimated following various proposed theoretical models. Based on the statistical trend shown by the estimated core position offset and the core radius, we infer that synchrotron opacity model may not be valid in all cases. The mean magnetic field strength at 1 pc and at the core, are in agreement with previous estimates. We apply the magnetically arrested disk model to estimate black hole spins for these blazars, indicating that the model is consistent with expected accretion mode in such sources. The power law shaped power spectral density is interpreted in terms of multiple shocks or magnetic instabilities. Important objectives met in this study include: the demonstration of the computational efficiency and statistical basis of the piecewise Gaussian fit; consistency with previously reported results; evidence for the core shift dependence on observation frequency and its utility in jet diagnostics in the region close to the resolving limit of very long baseline interferometry observations.

E1.4-0076-18 OFF-EQUATORIAL ACCRETION DISCS - IMITATION BY CIRCLING CHARGED FLUIDS

Jiri Kovar, jiri.kovar@fpf.slu.cz

Astronomical Institute, Academy of Sciences of the Czech Republic, Prague, Czech Republic

Charged fluids circling in strong central gravitational and ambinet magnetic fields, characteristic for compact objects backgrounds, can embody interesting configurations. In contrast to the widely considered neutral fluid structures imitating thick equatorial accretion discs with negligible loss of mass, when the fluid is properly charged, we can find it forming unique toroidal structures 'levitating' above the equatorial plane and also those hovering near the symmetry axis. Along with analytical topological studies of these structures, we can also present an survey of their basic physical characteristics, such as pressure, density and temperature profiles.

E1.4-0077-18 ON THE PROPERTIES OF STANDING AND DISSIPATIVE SHOCKS IN ACCRETION AND WIND FLOWS.

Soumen Mondal, soumenjuphysics@gmail.com Jadavpur University, Kolkata, India

In the present work, we study the properties of standing and dissipative accretion shocks around a Kerr black hole. We consider accretion flows around a stellar-mass black holes which emit hard X-rays from the post-shock region, also known as Compton cloud and located close to the inner edge of the disc. The radiative loss primarily comes from the thermal and kinetic energy of the flow during its pre-shock to post-apocalyptic transition phase and takes place via Comptonization process. To explain the temporal variation of this radiative loss, we study the dynamical properties of the dissipative shocks as well as the standing shocks in a self-confident way and compare the results. We quantitatively show how the energy loss at the shock affects the location of the shock itself around a rotating black hole. We find that for a suitable range of input parameters, the upper limit of the maximum release of energy at shock could be as high as 90 percent of the total available energy of the inflow matter without violating the Rankine-Hugoniot shock conditions. However, as the energy remove is sIn the present work, we study the properties of standing and dissipative accretion shocks around a Kerr black hole. E1.4-0079-18 INTERMEDIATE-MASS BLACK HOLES IN DWARF GALAXIES

Paramita Barai, paramita.barai@iag.usp.br

Instituto de Astronomia, Geofísica e Ciências Atmosféricas - Universidade de São Paulo (IAGUSP), São Paulo, Brazil

Elisabete De Gouveia Dal Pino, dalpino@astro.iag.usp.br

Instituto de Astronomia, Geofísica e Ciências Atmosféricas, Universidade de São Paulo, São Paulo, Brazil

Black holes are usually observed to be of stellar-mass or supermassive. By natural extension, there should be a population of Intermediate-Mass Black Holes (IMBHs: with mass between 100 to 106M0) in the Universe; which has started to been observed. An exciting claim has been made recently by Silk, J.(2017, ApJ, 839, L13): that there are IMBHs in essentially all old Dwarf

Galaxies. Early feedback by IMBHs in gas-rich dwarf galaxies at z = 5 8, can potentially solve multiple dwarf galaxy problems (e.g. core-cusp, number) within the Λ-cold-dark-matter cosmology.

I am performing Cosmological Hydrodynamical Simulations to test the case for IMBHs in Dwarf Galaxies. Our simulations employ the 3D TreePM SPH code GADGET3, and include metal cooling, star formation, chemical enrichment, supernova feedback, AGN accretion and feedback (Barai, P.etal.2016, M N RAS, 461, 1548). We are simulating small (2M pc)3 cosmological volumes with periodic boundary conditions, starting from z = 100. Black

Holes of mass 1000M0 are seeded inside halos when they reach a mass of 107M0. The black holes grow by accretion of gas from their surroundings and by merger with other black holes, and consequently eject feedback energy. Currently, I am analyzing the simulation output in post-processing to study the growth of the first IMBHs. We quantify the impact of IMBHs on their host Dwarf Galaxies; especially the effects on star formation in terms of negative or positive feedback.

Our conclusions, based on numerical simulation results, support the phenomenological ideas made by *Silk* (2017). IMBHs at the centers of dwarf galaxies can be a strong source of feedback to quench star-formation and generate outflows. At the same time, these IMBHs form the missing link between stellar-mass and supermassive BHs.

E1.4-0080-18 IS MATTER IN H1743-322 SUPPLIED AT A CONSTANT RATE?

Shreeram Nagarkoti, srnagarkoti@gmail.com Indian Centre for Space Physics, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India Dipak Debnath, dipakcsp@gmail.com

Indian Centre for Space Physics, Kolkata, India

We study all the RXTE/ASM and MAXI/GSC data received from the transient H 1743-322 till date. The total energy radiated during each outburst shown by the source since 2003 was obtained. The comparison of energy radiated per day of outburst and per day of quiescence during each outburst is carried out. The total energy radiated per day of quiescence during all outbursts are nearly uniform (except in 2004). We speculate why this happens. We conclude that after each outburst, the matter pile-up radius (where matter piles up before being fed in towards the compact object, triggering the outburst) has been getting closer and closer in this particular transient. We also suspect this phenomenon to be a supercycle which started from 2003 and is about to reach its end, leading to a long quiescence before another supercycle begins.

E1.4-0081-18 SYNCHROTRON RADIATION REACTION OF CHARGED PARTICLES AROUND ASTROPHYSICAL BLACK HOLES

Arman Tursunov, arman.tursunov@fpf.slu.cz

Silesian University in Opava, Opava, Czech Republic

There are convincing evidences that magnetic fields are indeed present in the vicinity of black holes, which imply that in many astrophysically relevant situations, the synchrotron radiation reaction force acting upon charged particles can not be neglected. Depending on the magnitude of the external magnetic field, the radiation-reaction force can considerably shift the stable orbits of particles, which can sufficiently influence the predictions of black hole parameters as well as due to the shifts of observational spectral frequencies. Moreover, the radiation reaction can support the accretion of charged particles from accretion disk towards the black hole. However, it is worth noting that the problem of the radiation reaction in curved spacetime still remains the source of discussion. Generically, the equations of motion are plagued by runaway solutions, so I will present the computational ways to avoid this problem in constructing numerical solutions. I will show, that depending on the orientation of the Lorentz force, the oscillating charged particle either spirals down to the black hole, or stabilizes the circular orbit by decaying its oscillations. The later case leads to an interesting effect of shifting of the particle orbit outwards from the black hole. I will also discuss the astrophysical relevance of the presented approach and provide estimations of the main parameters of the model applied to some particular black hole candidates.

E1.4-0083-18 VERY HIGH ENERGY HADRONIC AND LEPTONIC EMISSION FROM MAGNETIC RECONNECTION EVENTS AROUND BLACK HOLE ACCRETION DISKS: NUMERICAL GRMHD RADIATIVE TRANSFER-PARTICLE SIMULATIONS

Juan Carlos Rodríguez-Ramírez, juan.rodriguez@iag.usp.br IAG - Universidade de São Paulo, Sao Paulo, Brazil Elisabete De Gouveia Dal Pino, dalpino@astro.iag.usp.br

Instituto de Astronomia, Geofísica e Ciências Atmosféricas, Universidade de São Paulo, São Paulo, Brazil

Rafael Alves Batista, 8rafael@gmail.com

IAG - Universidade de São Paulo, 05508-090, Brazil Pankaj Kushwaha, pankaj.tifr@gmail.com

IAG - Universidade de São Paulo, Sao Paulo, Brazil

The origin of the very high energy (VHE) emission around black hole sources is still not understood. We here present numerical simulations of the very high energy emission produced in the core region of black hole (BH) accretion disk systems. We first perform general relativistic magnetohydrodynamical (GRMHD) simulations of these systems and then we carry out radiative transfer calculations in order to obtain the density, magnetic, and photon fields of the environment. The obtained photon field is due to electron synchrotron and inverse Compton (IC) radiation, with the synchrotron component being the appropriate target for photo-hadronic interactions. Then, assuming that high energy protons are accelerated by magnetic reconnection in the background magnetic field, we compute photon fluxes stemming from proton interactions with the local photon and magnetic fields (using the CRPropa3 code). From the resulting gamma rays, we obtain the spectral energy distributions, and the IC emission. Finally, we discuss the possible constraints on BH accretion disk system processes based on their emission profiles.

E1.4-0084-18 INTEGRATED MECHANISM THAT BOTH REMOVES ACCRETION DISK ANGULAR MOMENTUM AND DRIVES ASTROPHYSICAL JETS

Paul Bellan, pbellan@caltech.edu

California Institute of Technology, Pasadena, California, United States

A mechanism [1,2] that simultaneously removes accretion disk angular momentum and drives astrophysical jets is proposed.

The mechanism depends on the extreme difference between the governing physics in a weaklyionized, highly collisional accretion disk and the governing physics in the completely-ionized, nearly collisionless region outside the disk. In the completely-ionized exterior region, axisymmetric Hamiltonian mechanics constrain charged particles to move on nested poloidal magnetic flux surfaces. In contrast, fluid elements in the weakly-ionized, highly-collisional accretion disk behave as collisionless meta-particles having an effective charge to mass ratio reduced from than that of an ion by the extremely small disk fractional ionization α. This extremely small charge to mass ratio allows meta-particles to have an effective cyclotron frequency ωc = αqB/m comparable to the Kepler frequency ωK = M G/r3 in which case there is a direct competition between gravitational and magnetic forces.

For meta-particles in a stratum having a critical ionization fraction α, the charge to mass ratio αq/m is such that the meta-particles have zero canonical angular momentum; i.e., the mechanical and magnetic parts of the canonical angular momentum Pϕ = mrvϕ + qrAϕ are equal and opposite. Hamiltonian mechanics shows that these Pϕ = 0 meta-particles experience no centrifugal force and so spiral in towards the central body while conserving canonical angular momentum at Pϕ = 0. Because these inward spiraling meta-particles contain positive charge, their accumulation near the central body produces a radially outward electric field.

This electric field drives an out-of-plane poloidal electric current in the completely-ionized region exterior to the disk. This current and its associated toroidal magnetic field produce J B magnetic forces that drive bi-directional astrophysical jets flowing normal to and away from the disk. The increase in linked toroidal magnetic flux as the jet lengthens is associated with the radial voltage drop at the disk in accordance with Faraday's law.

E1.4-0086-18 X-RAY SPECTRAL STUDIES OF THE ULTRA-LUMINOUS X-RAY SOURCE M81 X-6

V Jithesh, vjithesh@iucaa.in IUCAA, Pune, India

Ranjeev Misra, rmisra@iucaa.in IUCAA, Pune, India

We present the X-ray spectral studies of the ultra-luminous X-ray source (ULX) M81 X-6 using the Suzaku and XMM-Newton observations performed during 2001 - 2015. We systematically analysed the observed spectra with different physical models including a multi-temperature blackbody model for a thin, steady state, general relativistic accretion disc around a Kerr black hole. Spectral modelling results suggest that the source exhibits three distinct spectral shapes with different luminosity in these observations. Using the relativistic accretion disc model, we attempt to constrain the mass of the black hole, mass accretion rate and spin of the system. Our analysis suggests a maximally rotating black hole for M81 X-6 with a black hole mass of

< 100 solar mass, which is broadly consistent with the scenario that this ULX is a stellar-mass black hole emitting at Eddington or super-Eddington luminosity.

E1.4-0087-18 STUDY OF SUPERMASSIVE BLACK HOLE BINARY EVOLUTION IN EQUILIBRIUM TRIAXIAL GALAXIES USING DIRECT NBODY SIMULATIONS

Abdul Salam, kumbhersalam@yahoo.com

Pakistan Space & Upper Atmosphere Research Commision (SUPARCO), Karachi, Pakistan Fazeel Mahmood Khan, khan@ari.uni-heidelberg.de

Institute of Space Technology, Islamabad, Islamabad, Pakistan

Nearly every galaxy in the universe harbor Supermassive Black Hole (SMBH) in its center. During galaxy mergers, dynamical friction drives supermassive black holes to the center of the merger remnant subsequently form a binary. The inspiral of two SMBHs produce gravitational waves (GWs) which can be detected by Laser Interferometer Space Antenna (LISA). In spherical galaxies, binary stalls at the separation of one parsec ejects all of their stars in the loss cone region leading to Final Parsec Problem (FPP). However, triaxial galaxies may avoid FPP during merger providing more loss cone refilling of stars in centrophilic orbit, thus producing coalescence. In this study, initial conditions are generated by using adiabatic squeezing technique for triaxial galaxy model with axis ratio 1:0.85:0.92 using 1000K and 500K number of particles. Starting with spherical Hernquist model with inner density slope γ=1, we then applied the artificial drag to particles velocities along each axis of the model to attain triax- ial shape. Once the initial conditions are generated then their stability were checked for the model by comparing with dehnan density profile with inner density slope γ=1, and scale radius ro=0.5. Direct N-body simulations were then performed on high performance graphic processing unit (GPU) cluster Advanced Computing Center for Research and Education (ACCRE) at Vanderbilt University using the phi-GPU code with 4th order Hermite integration scheme. The SMBH were placed in the xy, yz and xz plane. It was observed that in xy plane the binary separation and semi major axis are decreases more rapidly due to loss of angular momentum. It was also found that the density in the center decreases rapidly due to gravitational slingshot and stars interacting with central SMBH entering into zone of chaos destroying the triaxility in the central region. It is concluded that at axis ratio 1:0.85:0.92 system does not retain its triaxility. Hence, binary coalescence proceeds slowly and FPP persists.

E1.4-0088-18 EFFECTS OF LARGE SCALE STRONG MAGNETIC FIELD IN ADVECTIVE ACCRETION FLOWS AROUND BLACK HOLES: DISC-OUTFLOW COUPLING.

Tushar Mondal, mtushar@iisc.ac.in

Indian Institute of Science, Bangalore, India Banibrata Mukhopadhyay, bm@iisc.ac.in Indian Institute of Science, Bangalore, India

The outward transfer of the angular momentum of accreting matter leads to the accretion flow and formation of disk around the compact objects. Here, we discuss the importance of large scale strong magnetic field in the removal of angular momentum outward, as well as the possible origin of different kinds of magnetic barrier in advective, geometrically thick, subKeplerian accretion flows around black holes. The origin of this large scale strong magnetic field near the event horizon is due to the advection of the magnetic flux by the accreting gas from the environment, say, the interstellar medium or a companion star, because of flux freezing. In this simplest vertically averaged, 1.5-dimensional disc model, we choose the maximum upper limit of the magnetic field, which the disc around a black hole can sustain. In this circumstances, the accreting gas either decelerates or faces the magnetic barrier near the event horizon by the accumulated magnetic field depending on the geometry. We suggest that these types of flow are the building block to produce jets and outflows in the accreting system. We also find that in some cases, when matter is trying to go back to infinity after knocking the barrier, matter is prevented being escaped by the cumulative action of strong gravity and the magnetic tension, hence by another barrier. In this way, magnetic field can lock the matter in between these two barriers and it might be a possible explanation for the formation of episodic jet.

The most self-consistent approach, in order to understand vertical transport of matter through the magnetic effects, which in turn leads to the radial in-fall of the rest of the matter, is considering the flow to be moving in the vertical direction from the disk plane as well. Such an attempt, in the absence of magnetic effects, was made earlier by Bhattacharya, Ghosh Mukhopadhyay (2010) in the model framework of coupled disk-outflow systems. In such a framework, we can see the energetics of the disk outflow strongly depend on the mass, accretion rate, and spin of the black holes.

Here, we also try to explore the coupled 2.5-dimensional disk-outflow systems in the presence of large-scale magnetic field enabling angular momentum transport, when the magnetic field plays an indispensable role in order to generate vertical flux in the three-dimensional flows.

E1.4-0089-18 OBSERVABLES FOR MASSLESS TEST PARTICLES AROUND KERR-SEN BLACK HOLE SPACETIME IN STRING THEORY

Rashmi Uniyal, rashmiuniyal001@gmail.com

Government Degree College Narendranagar Tehri Garhwal Uttarakhand India, Narendranagar, India

We study the geodesic motion in the background of the Kerr-Sen black hole which arises in low energy limit of string theory. The nature of the effective potential is discussed in both the radial and latitudinal, directions with a special class of spherical photon orbits along with an expression for the turning point for the radial photons. Few observables for test particles on the angular plane such as the bending of light, perihelion precession for massive test particles and red/blue shift of photons emitted by massive test particles are calculated for a distant observer. The spin and mass parameters for the Kerr-Sen black hole are then estimated theoretically by using the red/blue shift.

E1.4-0090-18 TWO-TEMPERATURE FLOWS AROUND COMPACT OBJECTS

Shilpa Sarkar, shilpa@aries.res.in

Aryabhatta Research Institute of Observational Sciences, Nainital, India Indranil Chattopadhyay, indra@aries.res.in

Aryabhatta Research Institute of Observational Sciences, Nainital, India

Two-temperature solutions of rotating flows around black holes is one of the topics in astrophysics which is least understood and worked upon. We address this problem in greater details in the general relativistic regime. The thermodynamics of each constituent species of the relativistic fluid is governed by relativistic equation of state. Cooling has pronounced effect on electrons but negligible effect on protons. On the other hand, various dissipative processes like viscosity affects protons more than the electrons. So, electrons and protons are likely to settle down at two separate temperatures for realistic Coulomb interaction term which controls the energy exchange between these two constituent species of the gas. For inviscid accretion flow, at any given distance from the black hole, we have three unknowns velocity v, electron temperature (Te), proton temperature (Tp) and two constants of motion: generalized Bernoulli parameter and accretion rate. So, for different combinations of v, Te and Tp, we get distinctly different solutions for the same value of Bernoulli parameter and accretion rate. In other words, the solutions are not unique. We found a smart way of fixing this problem by using the principles of second law of thermodynamics. We are able to define the expression of entropy close to the horizon. Since the law of nature is to always prefer a solution of higher entropy, we identify the solution with highest entropy to be the physical one. According to our knowledge no general way of finding the solutions taking into account the degeneracy problem have not been reported so far. This is the first time we have attempted towards obtaining the general picture of the physical solutions in the two-temperature regime.

E1.4-0091-18 THE ORIGIN AND EVOLUTION OF THE MULTI-BAND VARIABILITY IN THE RADIO SOURCE 4C 38.41

Juan Carlos Algaba, algaba@astro.snu.ac.kr Seoul National University, Seoul, Korea Bindu Rani, bindu.rani@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States

The flat spectrum radio quasar 4C 38.41 showed a significant increase of its radio flux density during the period 2012 March - 2015 August which correlates with gamma-ray flaring activity. Multi-frequency simultaneous VLBI observations were conducted as part of the interferometric monitoring of gamma-ray bright active galactic nuclei (iMOGABA) program and supplemented with additional monitoring observations at various bands across the electromagnetic spectrum. The epochs of the maxima for the two largest gamma-ray flares coincide with the ejection of two respective new VLBI components and the evolution of the physical properties seem to be in agreement with the shock-in-jet model. Derived synchrotron self absorption magnetic fields, of the order of 0.1 mG, do not seem to dramatically change during the flares, and are much smaller, by a factor 10,000, than the estimated equipartition magnetic fields, indicating that the source of the flare may be associated with a particle dominated emitting region. Analysis on the physical properties of the ejected components indicate a semi-parabolic geometry, and magnetic and electron densities seem to fall along the jet in agreement with theoretical predictions.

E1.4-0092-18 LABORATORY EXPERIMENT OF SIMULATED ASTROPHYSICAL JET COLLIDING WITH A GAS CLOUD

Byonghoon Seo, bhseo@caltech.edu

California Institute of Technology, Pasadena, California, United States Magnus Haw, mhaw@caltech.edu

California Institute of Technology, Pasadena, California, United States Paul Bellan, pbellan@caltech.edu

California Institute of Technology, Pasadena, California, United States

High-speed, highly collimated plasma jets are observed in astrophysical systems having a wide range of length scales; examples are active galactic nuclei (AGNs), young stellar objects (YSOs), and planetary nebulae [1,2]. These jets sometimes have strong interactions with the surrounding gas medium as, for example, the interstellar cloud of the radio galaxy IC 5063 [3]. We present a laboratory experimental study of a simulated astrophysical jet colliding with a gas cloud. The laboratory astrophysical jet is launched from two concentric coplanar electrodes and accelerated by MHD forces to attain a velocity that is a fraction of the Alfvén velocity. A neutral gas cloud is puffed from a side gas tube and is arranged to be in the path of the jet so the jet impacts the target cloud. The changing magnetic field, electron temperature and electron density were measured during the interaction. Adiabatic compression of the density, an increase in the magnetic field and electron heating were observed using comprehensive diagnostics including Thomson scattering, laser interferometry, emission spectroscopy, and a magnetic probe array. Continuum radiation and line emission associated with plasma energy dissipation and cooling indicated that there was a significant radiative energy loss. In addition, the magnetic probes have measured a radially propagating disturbance, tentatively identified as an Alfvén wave, associated with the collision of the jet with the target cloud. This study is also relevant to magnetized target fusion where plasma is adiabatically compressed to achieve fusion-grade density and temperature.

Chengkui Li, lick@ihep.ac.cn

Institute of High Energy Physics, Chinese Academy of Sciences, Beijing, China Ju Guan, jguan@ihep.ac.cn

Institute of High Energy Physics, Chinese Academy of Sciences, Beijing, China

The Insight-HXMT telescope launched on June 15 2017 is China's first X-ray astronomy satellite. One of the main scientific goal is to scan the Galactic Plane to find new transient sources and to monitor the known variable sources, and to observe X-ray binaries to study the dynamics and emission mechanism in strong gravitational or magnetic fields. We will detail the scanning strategythe data processing pipeline and some interesting results in this report.

E1.4-0094-18 RADIATIVELY DRIVEN RELATIVISTIC JETS IN CURVED SPACE-TIME

Mukesh Kumar Vyas, mukesh.vyas@aries.res.in

Aryabhatta Research Institute of Observational Sciences, Nainital, India Indranil Chattopadhyay, indra@aries.res.in

Aryabhatta Research Institute of Observational Sciences, Nainital, India

We carry out a general relativistic study of radiatively driven fluid jets around black holes and investigate the effects and significance of radiative acceleration, as well as radiation drag. We apply relativistic equations of motion in curved space-time for the jet, plying through the radiation field of the accretion disc. Radiative moments were computed using the information of curved space-time. Slopes of physical variables at the sonic points are found using L Hôpital's rule and employed Runge-Kutta's 4 th order method to solve equations of motion. The analysis is carried out, using the relativistic equation of state of the jet fluid. The terminal speed of the jet depends on how much thermal energy is converted into jet momentum and how much radiation momentum is deposited on to the jet. Many classes of jet solutions with single sonic points, as well as, radiation driven internal shocks are obtained. Variation of all flow variables along the jet-axis has been studied. Jets with terminal orentz factors up to 3 are obtained for high energy electron-proton jets under intense radiation field. Moderate terminal speed v T 0.5 is obtained for moderately luminous discs. Lepton dominated jets may achieve Lorentz factors up to 10. Variety of jet solutions are obtained, due to the interaction of accretion disc radiation with the out-flowing jet, where the possibility of moderate jets to relativistic jets is possible depending on the intensity of the radiation field and the energetics of the jet. We establish that radiation field is able to induce steady shocks in jets, one of the criteria to explain high energy power law emission observed in spectra of some of the astrophysical objects.

We present an update to an observational campaign to measure the mass of the black hole candidate in M62. The existence of stellar mass black holes in globular clusters has forced a rethinking of cluster dynamics in recent years. M62-VLA1 was identified as a black hole candidate on the basis of its luminous radio emission with a flat radio spectrum, and a position on the fundamental plane of X-ray and radio luminosity consistent with stellar mass black holes. Spectroscopy with MUSE and HST reveals an F7IV donor star, with 60% of the continuum light originating from the accretion disk. Multiple epochs of spectroscopy reveal variable, double-peaked Hα emission and allow radial velocity measurements to constrain both the orbital period and the mass of the accretor.

E1.4-0096-18 SPECTRAL ANALYSIS OF H 1743-322 IN ITS 2004 OUTBURST USING THE TCAF SOLUTION

Anuvab Banerjee, anuvab.banerjee@bose.res.in

Indian Centre for Space Physics, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

The black hole transient H 1743-322 exhibited several outbursts with different spectral variability since its discovery in 1977. The 2004 outburst was the first stereotypical one after the truly anomalous and intense outburst in 2003. This motivated us to investigate the accretion flow dynamics of this object during its 2004 outburst. We employed spectral analysis in the 2.5-25.0 keV energy range using Two Component Advective Flow (TCAF) solution. We extract spectral fitted parameters like the disk and halo accretion rate, the shock location and also mass, which is intrinsic property to the black hole. The fitting was also done by keeping the normalization constrained in a narrow range, and the new fitted parameters are consistent with the previous case. Thereby the normalization of this object is directly obtained by spectral fitting. We also constrained the mass within a narrower range compared to the previous findings.

E1.4-0097-18 EXPLORING THE EVOLUTION OF INNER DISC RADIUS AND OTHER INTRINSIC PARAMETERS ACROSS THE INTERMEDIATE STATES OF THE BLACK HOLE BINARY GX 339-4 USING X-RAY REFLECTION SPECTROSCOPY

One of the unsettled issues pertaining to Black Hole x-ray binaries is the origin of state transitions and evolution of various intrinsic physical parameters of the accretion disc during outbursts. In order to explore the same, we analyse several RXTE observations from two different outbursts of the Black Hole binary GX 339-4, and perform a consistent study of the reflected spectrum in its bright intermediate states. We employ the most recent version of the relxill family of relativistic reflection models, and perform simultaneous spectral fits on the observations from each outburst, to probe the evolution of the properties of the accretion disk including the inner disk radius (Rin), ionization parameter (ξ), and the temperature of the inner disk. In order to test the capability of RXTE/PCA in detecting narrow emission lines corresponding to a large disc truncation, several simulations are performed with gaussian and reflection (relxill) models for different cases of Black Hole spin ($a*$) and reflection fraction. Data/Model ratios reveal no evident relativistic broadening in the reflection features with decrease in hardness ratio values, qualitatively suggesting no substantial change in Rin across the bright intermediate states. Our analysis with the relativistic reflection models suggest that, the inner edge of the disk reaches $\sim$ Risco during the bright hard state, and the truncation remains at a value of $1 \sim 5 \times$ Risco throughout the bright horizontal branch across the intermediate states.

E1.4-0098-18 ATOMIC OPACITIES AND THERMAL INSTABILITY IN ACCRETION DISKS

Mikolaj Grzedzielski, mikolaj.grzedzielski@gmail.com

The radiation pressure instability in geometrically thin, optically thick, Shakura-Sunayev alpha accretion disk causes the instable beaviour of numerous sources like GRS1915 and IGR J17091 microquasars, as well as the HLX-1 intermediate-mass black hole candidate. The thermoviscous instability is determined by local thermal instability, determined by the gap between the viscous heating and radiative cooling.

As the viscous heating depends on pressure and structure of the magnetic field, in the optically thick disk the radiative cooling is inversely proportional to optical thickness, it means that the various processes of interaction between light and matter can shape the stability parameter function and stabilize (or destabilize) the disk.

In our previous models we included only the Thomson type of scattering, being constant value independent on the disk temperature.

In our current work we apply the tabelarized data containing values of atomic opacities connected with the transitions in ionized heavy atoms and investigate their influence on disk instability in both aspects - local and global.

ORIGIN OF COSMIC RAYS (E1.5)

E1.5-0001-18 LATEST RESULTS FROM THE AMS EXPERIMENT

Samuel Ting, samuel.ting@cern.ch

MIT, Cambridge, Massachusetts, United States Andrei Kounine, andrei.kounine@cern.ch

Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

The Alpha Magnetic Spectrometer, AMS, steadily collects data on the International Space Station for 7 years. The AMS data sample corresponds to over 115 billion charged cosmic rays. In this presentation I will review the latest results from the AMS experiment.

Precision measurements by the Alpha Magnetic Spectrometer on the International Space Station of the primary cosmic-ray e+, eand (e- + e+) fluxes in the energy range up to 2000 GeV are presented. The electron flux and the positron flux are significantly different in their magnitude and energy dependence, however their behavior is consistent with a contribution from a new source of high energy particle contributing equally to the fluxes of electrons an positrons.

A precision measurement by AMS of the positron fraction in primary cosmic rays in the energy range from up to 1000 GeV based on 25 million positron and electron events is presented. This measurement extends the energy range of our previous observation and increases its precision. The new results show that at 290 GeV the positron fraction reaches its maximum. This is consistent with a new source of high energy electrons an positrons.

E1.5-0004-18 ANTIPROTON FLUX AND PROPERTIES OF ELEMENTARY PARTICLE FLUXES IN PRIMARY COSMIC RAYS MEASURED WITH THE ALPHA MAGNETIC SPECTROMETER ON THE INTERNATIONAL SPACE STATION

The fluxes and flux ratios of charged elementary particles in cosmic rays are presented in the absolute rigidity range from 1 to 1000 GV. In the absolute rigidity range 60 to 500 GV, the antiproton, proton, and positron fluxes are found to have nearly identical rigidity dependence and the electron flux exhibits different rigidity dependence. Below 60 GV, the antiproton-toproton, antiproton-to-positron, and proton-to-positron flux ratios each reaches a maximum. Particular emphasis is made on new observations of the properties of elementary particles in the rigidity range above 500 GV.

E1.5-0005-18 ANTIDEUTERON IN PRIMARY COSMIC RAYS WITH THE ALPHA MAGNETIC SPECTROMETER ON THE INTERNATIONAL SPACE STATION

Sadakazu Haino, sadakazu.haino@cern.ch Academia Sinica, Taipei, Taipei, Taiwan, China

Antideuterons and deuterons in Primary Cosmic Rays will be discussed based on over the first 6.5 years of AMS data on the International Space Station

E1.5-0006-18 OBSERVATION OF THE IDENTICAL RIGIDITY DEPENDENCE OF THE PRIMARY COSMIC RAYS HELIUM, CARBON AND OXYGEN WITH THE ALPHA MAGNETIC SPECTROMETER ON THE INTERNATIONAL SPACE STATION

Precision measurement of the primary cosmic rays fluxes of helium, carbon and oxygen in the rigidity range from 2 GV to 3 TV is presented based on 90 million helium, 8 million carbon and 7 million oxygen nuclei collected by AMS during first 5 years of operation. Unexpectedly, above 60 GV, these three spectra have identical rigidity dependence.They all deviate from a single power law above 200 GV and harden in an identical way.

The average lifetime of cosmic rays in the Galaxy related with their confinement within the Galactic propagation halo, is a very important parameter to understand comic-ray propagation processes and the cosmic-ray origin. The measurement of the 10Be/9Be secondary isotopes ratio, as 10Be has half-life of 1.39 million years, can be used to constrain the propagation lifetime. The 6Li/7Li ratio, as both isotopes are secondary and stable, is expected to reflect the ratio between the production cross sections and therefore constitutes a good check of the reconstruction method. Measurement of the lithium isotopes ratio (6Li/7Li) as a function of the kinetic energy per nucleon from 0.5 GeV/nucl to 10 GeV/nucl based on data collected by AMS during the first 5 years of operation is presented. Prospects for measurement of the beryllium and boron isotopic ratios with AMS-02 will be presented.

E1.5-0008-18 PRECISION MEASUREMENTS OF 3HE-TO-4HE RATIO AND INDIVIDUAL 3HE AND 4HE FLUXES IN COSMIC RAYS WITH THE ALPHA MAGNETIC SPECTROMETER ON THE INTERNATIONAL SPACE STATION.

The spectral shape of the secondary isotopes in cosmic rays is completely determined by the source spectrum of the parent elements and by the propagation process. In particular, 3He in cosmic rays is believed to result from the interaction of primary 4He with the interstellar medium, providing a powerful tool to constrain the parameters of the galactic cosmic rays propagation models. A precise measurement of the helium isotopes ratio (3He/4He) and the individual 3He and 4He fluxes in the kinetic energy per nucleon range from 1.0 GeV/nucl to 10 GeV/nucl based on data collected by AMS during the first 5 years of operation are presented.

The nitrogen flux in cosmic rays is expected to contain both primary and secondary components, so the knowledge of their relative contributions is important in understanding the origin, acceleration, and propagation of cosmic rays. A precise measurement of the nitrogen flux with rigidity from 2 GV to 3 TV based on 2 million nuclei collected by AMS during first 5 years of operation is presented.

E1.5-0010-18 PRECISION MEASUREMENT OF SECONDARY-TO-PRIMARY COSMIC RAYS FLUX RATIOS WITH THE ALPHA MAGNETIC SPECTROMETER ON THE INTERNATIONAL SPACE STATION.

Precision measurement of Secondary-to-Primary Cosmic Rays Flux Ratios Li/He, Be/He, B/He, Li/C, Be/C, B/C, Li/O, Be/O, and B/O is presented based on 5.4 million secondary nuclei and more than 100 million primary nuclei collected by AMS during the first 5 years of operation. Remarkably, above 200 GV, the secondary cosmic rays harden more than the primary cosmic rays. This observation is important for the study of the origin of the hardening in cosmic ray fluxes and for the global understanding of the origin, acceleration and propagation of cosmic rays.

We report on the observation of new properties of secondary cosmic rays, Li, Be, and B, measured in the rigidity range 1.9 GV to 3.3 TV with a total of 5.4 million nuclei collected by AMS during the first 5 years of operation. Unexpectedly, the Li and B fluxes have an identical rigidity dependence above 7 GV and all three fluxes have an identical rigidity dependence above 30 GV with the Li/Be flux ratio of 2.0 ± 0.1. The three fluxes deviate from a single power law above 200 GV in an identical way.

E1.5-0012-18 THE LESSON OF PAMELA

Piergiorgio Picozza, piergiorgio.picozza@gmail.com INFN and University of Rome Tor Vergata, Rome, Italy

PAMELA is a medium-sized space experiment for the detection of cosmic rays that took data for 10 years from 2006 to 2016. Composed of a magnetic spectrometer and several auxiliary detectors it has been completely realized, at a very reasonable cost, by the collaboration: its different parts at Physics Departments in Italy, Russia, Sweden and Germany and finally the integration in the clean rooms of INFN at Rome Tor Vergata University. The reduced dimensions of the instrument required high performance of the individual detectors to obtain high-precision measurements over a range of energy from tens of MeV/n to 1 TeV/n. In ten years of data taking in space, the experiment PAMELA has shown very interesting features in cosmic rays, namely in the fluxes of protons, helium, electrons, that might change our basic vision of the mechanisms of production, acceleration and propagation of cosmic rays in the Galaxy. In particular, remarkable and stimulating have been the measurements of cosmic antiproton and positron fluxes that have allowed the nature of dark matter to be probed in a new way, suggesting new ideas and setting strong constraints to the models. The continuous particle detection allowed for a constant monitoring of the solar activity and detailed study of the solar modulation for a long period, giving important improvements to the comprehension of the heliosphere mechanisms. PAMELA also measured the radiation environment around the Earth, and discovered an antiproton radiation belt.

E1.5-0013-18 OBSERVATION OF COMPLEX TIME STRUCTURES IN THE COSMIC-RAY ELECTRON AND POSITRON FLUXES WITH THE ALPHA MAGNETIC SPECTROMETER ON THE INTERNATIONAL SPACE STATION

Stefan Schael, schael@physik.rwth-aachen.de RWTH Aachen University, Aachen, Germany

High-statistics, precision measurements of the time and energy dependence of the primary cosmic-ray electron flux and positron flux over 79 Bartels Rotations from May 2011 to May 2017 in the energy range from 1 to 50 GeV are presented. For the first time, the charge-sign dependent modulation during solar maximum can be investigated in detail by leptons alone. Based on 23.5 million events the observation of short-term structures on the time scale of months coincident in both the electron flux and the positron flux is reported. These structures are not visible in the positron/electron flux ratio. The precision measurements across the solar polarity reversal show that the ratio exhibits a smooth transition from one value to another. The midpoint of the transition shows an energy dependent delay relative to the reversal. Unfolding the time-dependent solar modulation will constrain the physics of cosmic rays outside the solar system.

The features observed by AMS in high energy cosmic rays e+, e-, p, He,. are new phenomena, which may be connected to the presence of new astrophysical sources. Possible anisotropies in the arrival directions of cosmic rays therefore provide crucial information to understand their origin. Based on a sample collected during the first 6 years of AMS operation on the ISS, a measurement of the anisotropy in the arrival directions of primary cosmic rays will be presented.

E1.5-0015-18 NEW RESULTS OF VERY-LOW ENERGY ANTIPROTON SPECTRUM AND ANTIDEUTERON SEARCH IN BESS-POLAR II

Kenichi Sakai, kenichi.sakai@nasa.gov NASA/GSFC, Greenbelt, Maryland, United States

High-precision measurement of the cosmic-ray antiproton spectrum and sensitive search for cosmological antihelium has been published from BESS-Polar II (Balloon-borne Experiment with a Superconducting Spectrometer) for core study of the early Universe using elementary particle measurements. With a thin plastic scintillator middle-TOF (MTOF) hodoscope that is installed on the lower surface of the magnet bore to measure low-energy particles that cannot reach the lower-TOF, new absolute spectrum of the cosmic-ray antiproton in the range 0.1 to 0.8 GeV and the antiproton/proton ratio calculated with upper-middle TOF trigger events would be reported. We also report the result of a new search for antideuterons with unprecedented sensitivity using BESS-Polar II data that is more than ten times the statistics of the most sensitive reported search from BESS97 in near solar minimum conditions. The low-energy antiproton spectrum and the search for antideuteron probe possible exotic sources, such as dark-matter candidates.

E1.5-0016-18 ON THE ACCELERATION AND TRANSPORT OF GALACTIC COSMIC RAYS

Elena Amato, amato@arcetri.astro.it

INAF-Osservatorio Astrofisico di Arcetri, Firenze, Italy

I will review recent developments on the subject of acceleration and transport of Galactic Cosmic Rays. Recent observations, and the data collected by PAMELA and AMS02 in particular, have revealed a number of unexpected features in the spectra of both primary and secondary Cosmic Rays. These findings seem to challenge the standard description of Cosmic Ray propagation through the Galaxy and also impact our theories on the origin of these particles.

I will discuss how at least some, if not all, of the presumed anomalies allow for an explanation based on non-linear effects associated with CR transport, and more generally what they suggest about the origin and propagation of Galactic Cosmic Rays.

E1.5-0017-18 DAMPE AND ITS LATEST RESULTS

Jin Chang, chang@pmo.ac.cn

Purple Mountain Observatory, Chinese Academy of Sciences, NanJing, China

Dark Matter Particle Explorer (DAMPE), the first Chinese astronomical satellite, was launched into a Sun-synchronous orbit at an altitude of about 500 km on 17 December 2015. DAMPE is a high-energy particle detector optimized for observations of cosmic ray electrons and gammarays up to about 10 TeV. In this talk I'll introduce the on-orbit performance of the detector, the calibration, and the latest results on cosmic rays and gamma-rays of DAMPE.

Since December 17th, 2015, the DAMPE (DArk Matter Particle Explorer) detector is orbiting at the altitude of 500 km and collecting data smoothly. The main goal of the mission includes the indirect search of Dark Matter, by looking for signatures in the electron and photon spectra with energies up to 10 TeV, and in general the study of cosmic charged and gamma radiation in space. The large effective area and calorimeter depth (32 radiation lengths), in particular, enable DAMPE to study the elemental composition of cosmic rays and to measure their fluxes in the energy range from 20 GeV up to hundreds of TeV, thus providing insight on their origin and propagation mechanisms. Here the analysis progress in the study of the Helium and heavier components in cosmic rays will be presented and discussed.

E1.5-0019-18 ANALYSIS OF COSMIC RAY PROTON SPECTRUM WITH THE DARK MATTER PARTICLE EXPLORER

Qiang Yuan, yuanq@pmo.ac.cn

Purple Mountain Observatory, Chinese Academy of Sciences, Nanjing, China

Precise measurements of the energy spectra of cosmic rays are very important for understanding such fundamental questions as the origin, acceleration, and propagation of cosmic rays. The Dark Matter Particle Explorer (DAMPE), a satellite-borne high-energy particle detector, is able to measure nuclear cosmic rays to kinetic energies up to hundreds of TeV and is expected to advance significantly such studies. The DAMPE mission was launched on December 17th, 2015, and all detectors operate smoothly for over two years. In this talk the preliminary analysis of the proton component of Galactic cosmic rays will be reported.

E1.5-0020-18 COSMIC RAY ENERGETICS AND MASS (CREAM) LAUNCH AND ON-ORBIT PERFORMANCE

Eun-Suk Seo, seo@umd.edu

University of Maryland, College Park, Maryland, United States ISS-CREAM Collaboration

E.S. Seo, Y. Amare, T. Anderson, D. Angelaszek, N. Anthony, K. Cheryian, G.H. Choi, M. Copley, S. Coutu, L. Derome, L. Eraud, L. Hagenau, J.H. Han, H.G. Huh, Y.S. Hwang, H.J. Hyun, S. Im, H.B. Jeon, J.A. Jeon, S. Jeong, S. C. Kang, H.J. Kim, K.C. Kim, M.H. Kim, H.Y. Lee, J. Lee, M.H. Lee, J. Liang, J.T. Link, L. Lu, L. Lutz, A. Menchaca-Rocha, T. Mernik, J.W. Mitchell, S.I. Mognet, S. Morton, M. Nester, S. Nutter, O. Ofoha, H. Park, I.H. Park, J.M. Park, N. Picot-Clemente, R. Quinn, J.R. Smith, P. Walpole, R.P. Weinmann, J. Wu, Y.S. Yoon

The CREAM experiment was launched on a SpaceX Falcon 9 rocket to the International Space Station (ISS) from NASA's Kennedy Space Center on August 14, 2017. The instrument was successfully installed and activated on the ISS Japanese Experiment Module Exposed Facility as an attached payload on August 22, 2017. The CREAM instrument was initially developed to measure cosmic ray elemental spectra using a series of ultra-long-duration balloon flights. The balloon-borne CREAM experiment was flown seven times between 2004 and 2016 over Antarctica accumulating 191 days of flight time, the longest known exposure for a single balloon project. Building on the success of the balloon flights, the payload was transformed for accommodation on the ISS. This version of CREAM, aka ISS-CREAM, is configured with redundant and complementary particle detectors capable of precise measurements of elemental spectra for $Z = 1 - 26$ nuclei, as well as electrons. The four layers of its finely segmented Silicon Charge Detector provide precise charge measurements, and its ionization calorimeter provides energy measurements. In addition, scintillator-based Top and Bottom Counting Detectors and Boronated Scintillator Detector distinguish electrons from nuclei. At least an order of magnitude increase in data collecting power is expected by utilizing the ISS to reach the highest energies practical with direct measurements. On-orbit performance of the instrument and preliminary results from the ongoing analysis will be presented.

E1.5-0021-18 SUPERNOVA REMNANTS AS ACCELERATORS OF VERY HIGH ENERGY COSMIC RAYS

Vladimir Ptuskin, vptuskin@hotmail.com

Pushkov Institute of Terrestrial Magnetism, Ionosphere and Radio wave propagation of Russian Academy of Sciences, Moscow, Russia

Vladimir Zirakashvili, zirak@izmiran.ru

Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation of the Russian Academy of Sciences (IZMIRAN), Troitsk, Moscow Region, Russia

Cosmic ray acceleration by astrophysical shocks in supernova remnants of different types is discussed. Results of numerical modeling for young and middle-age supernova remnants and acceleration in interstellar bubbles created by powerful stellar winds of supernova progenitors are presented. Non-thermal electromagnetic and neutrino emission produced by accelerated particles in supernova remnants is compared with the available data of radio, X-ray, gammaray and neutrino astronomy.

E1.5-0022-18 THE CALORIMETRIC ELECTRON TELESCOPE (CALET) ON THE INTERNATIONAL SPACE STATION

Shoji Torii, torii.shoji@waseda.jp Waseda University, Tokyo, Japan

The CALorimetric Electron Telescope (CALET) space experiment, which has been developed by Japan in collaboration with Italy and the United States, is a high-energy astroparticle physics mission installed on the International Space Station (ISS). The primary goals of the CALET mission include investigating possible nearby sources of high-energy electrons, studying the details of galactic particle propagation and searching for dark matter signatures. During a two-year mission, extendable to five years, the CALET experiment measures the flux of cosmicray electrons (including positrons) to 20 TeV, gamma-rays to 10 TeV and nuclei with Z=1 to 40 up to 1,000 TeV. The instrument consists of two layers of segmented plastic scintillators for the cosmic-ray charge identification (CHD), a 3 radiation length thick tungsten-scintillating fiber imaging calorimeter (IMC) and a 27 radiation length thick lead-tungstate calorimeter (TASC). CALET has sufficient depth, imaging capabilities and excellent energy resolution to allow for a clear separation between hadrons and electrons and between charged particles and gamma rays. The instrument was launched on August 19, 2015 to the ISS with HTV-5 (H-II Transfer Vehicle 5) and installed on the Japanese Experiment Module-Exposed Facility (JEM-EF) on August 25 .

Since the start of operation in mid-October, 2015, a continuous observation has being kept mainly by triggering high energy (>10 GeV) showers without any major interruption. The number of the triggered events over 10 GeV is nearly 20 million per month. By using the data obtained during the first two-years, we will have a summary of the CALET observations: 1) Electron+Positron energy spectrum, 2) Proton and Nuclei spectrum, 3) Gamma-ray observation, with results of the performance study on orbit. We also present the results of observations of the electromagnetic counterparts to LIGO-VIRGO gravitational wave events and high-energy counterparts to GRB events measured with the CALET Gamma-ray Burst Monitor (CGBM).

E1.5-0023-18 MEASUREMENT OF COSMIC-RAY ELECTRON AND POSITRON SPECTRUM FROM CALET ON THE ISS

The CALET (CALorimetric Electron Telescope), launched to the International Space Station (ISS) in August 2015 and accumulating scientific data since October 2015, is an all-calorimetric instrument with total vertical thickness of 30 radiation lengths and fine imaging capability, designed to achieve large proton rejection and excellent energy resolution well into the TeV energy region. CALET will allow for the detailed search for various spectral structures of highenergy electron cosmic rays, perhaps providing the first experimental evidence of the presence of a nearby astrophysical cosmic-ray source.

Electron spectrum analysis starts with detailed detector calibrations covering from detector alignment to energy determination, followed by electron event selection and flux normalization. Special care was taken to identify electrons in the presence of a large hadron background. Possible source of systematic errors are carefully surveyed, and associated uncertainties are estimated for each contribution. As a result, electron + positron spectrum is obtained including the TeV energy range.

In this contribution, we will present electron and positron spectrum measured by CALET with an emphasis on a detailed analysis of the systematic uncertainties.

E1.5-0024-18 MEASUREMENTS OF COSMIC-RAY CARBON AND OXYGEN NUCLEI SPECTRA WITH CALET

Paolo Maestro, paolo.maestro@pi.infn.it University of Siena and INFN Pisa, Siena, Italy

The Calorimetric Electron Telescope (CALET) was installed onboard the International Space Station in August 2015 and since October 2015 it is collecting data with smooth and continuous operations. The instrument consists of two layers of segmented plastic scintillators to identify the charge of individual elements from proton to iron, a thin imaging tungsten-scintillating fiber calorimeter providing accurate particle tracking and complementary charge measurement, and a thick total absorption calorimeter made of lead-tungstate crystal logs. In addition to high precision measurements of the electron spectrum up to several TeV, CALET can measure the individual spectra and elemental composition of cosmic-ray nuclei from few tens of GeV to the PeV scale, which is of fundamental importance to shed light on the mechanism of acceleration and propagation of cosmic rays in the galaxy. In this paper, preliminary measurements of the energy spectra of carbon and oxygen and their ratio will be presented.

E1.5-0025-18 PROPAGATION OF COSMIC RAYS IN COLLECTIVE AND NONDIFFUSIVE REGIMES

Mikhail Malkov, mmalkov@ucsd.edu

University of California, San Diego, La Jolla, California, United States

Advanced measurements of cosmic ray (CR) spectra have revealed vast gaps in our knowledge of how they propagate through the ISM and Heliosphere. The propagation is thought to be a diffusion controlled by particle scattering on the hydromagnetic turbulence present in the medium. Although the limitations of the diffusive approximation are apparent in many cases, ways to overcome them are not, which hinders the interpretation of observed spectra. One glaring flaw arises with increasing particle energy. As the particle mean free path (m.f.p.) typically also increases, the diffusive approximation breaks down whenever the m.f.p. exceeds some scale of the problem. The particle transport must be ballistic on that size. These two very simple propagation regimes, diffusive and ballistic, proved challenging to connect. The corresponding transition (transdiffusion) region in the energy spectrum is not small, while the two transport models are very different. The transdiffusive propagation is best approached using Fokker-Plank equation, from which the ballistic and diffusive propagation regimes both derive. By finding an exact solution of this equation, the issue of applicability of either quickly resolves.

Particle propagation dramatically deviates from both diffusive and ballistic regimes when their concentration is sufficient to enhance the turbulence level in the ambient medium. The enhancement is caused by instabilities that particles drive while escaping their acceleration sites, such as supernova remnants. The resulting propagation may technically be considered diffusive, but it is a nonlinear diffusion, spreading particles very differently than test particles. Most importantly, enhanced scattering on the self-excited turbulence leads to reduced particle transport. This effect is also energy-dependent, implicating another transition (break) in the particle energy spectrum. The latter phenomenon is essential whenever the pressure of energetic particles near a source exceeds the ambient magnetic pressure. Since they are similar under average ISM conditions, the particle pressure automatically exceeds the magnetic pressure by orders of magnitude near sources that contribute to the galactic CR population.

E1.5-0026-18 A RANKING OF PRODUCTION CROSS-SECTIONS FOR LIGHT COSMIC RAYS: LI, BE, B, C, AND N.

Yoann Genolini, yoann.genolini@ulb.ac.be Université Libre de Bruxelles, Bruxelles, Belgium David Maurin, david.maurin@lpsc.in2p3.fr France

Stanford University, Stanford, California, United States Michael Unger, michael.unger@kit.edu

Germany

The precision of the new generation of cosmic-ray (CR) experiments, such as AMS-02, PAMELA, CALET, and ISS-CREAM, is now reaching the percent level in a wide energy range from GeV/n (per nucleon) to multi-TeV/n. A precise understanding of cosmic-rays production and propagation as well as stringent constraints on dark matter are guaranty results from a precise interpretation of the measured fluxes. Meanwhile, a major obstacle in doing so is the current uncertainty in the isotopic production cross sections which is often as high as 20-50% or even larger in some channels. This embarrassing situation is gaining momentum in the astrophysics community which call for a dedicated experimental effort. I will first illustrate the impact of the current cross-section models on the interpretation of the data. Measuring the all set of cross-sections needed is of course a huge work that requires an incremental approach. In a recent work my collaborators and I aim at providing the community with the ranking of the cross sections contributing to the production of the most astrophysically important isotopes of Li, Be, B, C, and N. I will present this ranking and give an evaluation of the beam time necessary to reach a 3% precision in the production cross-sections pertinent to the AMS-02 experiment. This first roadmap may become a starting point in the planning of new measurement campaigns that could be carried out in several nuclear and/or particle physics facilities around the world.

The Calorimetric Electron Telescope (CALET) was installed on the International Space Station (ISS) in August 2015 and began to collect data in October 2015. CALET has multiple event trigger modes for measuring high-energy particles and gamma rays, and the effective observations have been successfully performed by scheduling these trigger modes according to the conditions of ISS position and orbital information. The cosmic-ray (CR) electrons (electrons

+ positrons) in the energy region from 10 GeV to 20 TeV, that may provide a possible signature of high-energy electron acceleration at nearby CR origin, have been measured by using a high-energy shower trigger mode. In addition, a low-energy (LE) shower trigger mode working at the polar region can measure the low-energy CR electrons in an energy range of 1 GeV to 10 GeV. By using this LE shower trigger, stable and continuous observations of the low-energy CR electrons have been accomplished for about 2.5 years that is comparable to one quarter of the period of the solar activity cycle.

In this study, we have analyzed flight data obtained by the LE shower trigger for 812 days from October 12, 2015 to December 31, 2017. Using a physics analysis consisting of seven event selections, including a track reconstruction utilizing the Kalman filter method and an electron identification based on the lateral energy-deposit distribution in the TASC first layer with respect to the shower axis, we succeeded to keep electron efficiency of about 50% at 1GeV and that of 70% or more above 2 GeV while removing more than 99% of protons. In this presentation we will show the variations of the energy spectrum of CR electrons in an energy range of 1 GeV to 10 GeV observed by CALET from October 2015 to December 2017, and also discuss the physics implications of the solar modulation of CR electrons.

K. Yoshida

The CALorimetric Electron Telescope, CALET, was launched in August 2015 and has been measuring high-energy cosmic rays on the International Space Station since October 2015. In addition to the high-precision measurements of the all electron spectrum, CALET also performs the precise measurements of the energy spectra of elements from proton to iron, the relative abundances and the secondary-to-primary ratios to the highest energies ever directly observed in space. These will allow for the investigation of the details of their origin and propagation in the galaxy. The CALET instrument consists of two layers of segmented plastic scintillators to identify the individual elements from Z=1 to 40, a fine-grained imaging calorimeter to obtained complementary charge and tracking information, and a total absorption calorimeter to measure the energy with a total 30 radiation lengths and 1.3 nuclear interaction lengths.We will present the details of heavy nuclei (Z>8) analysis including the particle identification capabilities and the analysis of the systematic uncertainties.

E1.5-0029-18 STATUS OF CALET ULTRA HEAVY COSMIC RAY ANALYSIS

UMBC / NASA-GSFC, Greenbelt, Maryland, United States for the CALET Collaboration

The CALorimetric Electron Telescope (CALET) is a Japanese-Italian-US astroparticle observatory operating on the International Space Station (ISS). CALET was launched on August 19, 2015 and continues to return excellent data. The main calorimeter (CAL) was designed to measure the highest energy cosmic ray electrons from 1 GeV to 20 TeV, but it also measures cosmic-ray (CR) nuclei up to 1,000 TeV and gamma-rays above 10 GeV. The energy spectra of the more abundant CR nuclei through 26Fe are measured with the CAL, which also has the dynamic range to measure the abundances of CR nuclei from 1H to 40Zr. CALET has a ultraheavy cosmic-ray (UHCR) trigger based on the two scintillator layers of the charge detector (CHD) module and the four top scintillating fiber planes of the imaging calorimeter (IMC) module that provides an expanded geometric acceptance. Rigidity cutoffs from the earth's geomagnetic field can be used to select higher energy events from this trigger that can be resolved without an energy measurement from the bottom total absorption calorimeter (TASC) module, such that in its approved 5 year mission on the ISS CALET will collect a UHCR data set with statistics comparable to that achieved with the first flight of the SuperTIGER balloon-borne instrument in a similar energy range. Preliminary results of the CALET UHCR data analy- sis show reasonable agreement with SuperTIGER relative abundances of even charge UHCR nuclei, and progress has been made in resolving the odd charge UHCR nuclei as well. The CALET space-based measurements have the benefit that they do not require the corrections for atmospheric interactions that those of SuperTIGER do. They also complement the lower energy space-based UHCR measurements by ACE-CRIS.

E1.5-0030-18 PRELIMINARY RESULTS ON THE MEASUREMENT OF THE PROTON SPECTRUM WITH CALET ON THE ISS

Pier Simone Marrocchesi, marrocchesi@pi.infn.it University of Siena and INFN Pisa, Siena, Italy CALET collaboration etc

The CALorimetric Electron Telescope CALET, located in the JEM-EF external platform of the International Space Station, is collecting science data continuously since mid October 2015. More than 500 million triggers generated by high-energy charged particles and photons of cosmic origin have been recorded to date. CALET is an international space mission led by JAXA with the participation of the Italian Space Agency ASI and NASA. In addition to its primary goal of carrying out direct measurements to explore the electron spectrum in the poorly known energy region above 1 TeV, CALET is investigating the cosmic-ray hadronic component with highprecision measurements of the energy spectra, relative abundances and secondary-to-primary ratios of elements from proton to iron and above (up to atomic number Z=40). Equipped with a thick (30 X0, 1.3 ΛI) calorimeter, including a finely segmented 3 X0 pre-shower section with excellent imaging capabilities followed by a 27 X0 total absorption homogeneous calorimeter, and with two independent sub-systems to identify the charge of the incident particle, CALET provides an excellent energy and angular resolution and electron/proton discrimination of order 10−5. CALET observations extend the range of previous proton measurements in the multi-TeV region confirming a deviation of the proton differential spectrum from a simple power-law, as previously reported by CREAM, PAMELA and AMS-02. In this paper, preliminary results on the proton spectrum as well as details of the analysis will be presented.

E1.5-0031-18 ACCELERATION OF COSMIC RAYS IN SUPERNOVA REMNANT SHOCKS: MASS TO CHARGE SELECTIVITY

Adrian Hanusch, adrian.hanusch@uni-rostock.de University of Rostock, Rostock, Germany

Tatyana Liseykina, tatyana.liseykina@uni-rostock.de University of Rostock, Rostock, Germany

Mikhail Malkov, mmalkov@ucsd.edu

University of California, San Diego, La Jolla, California, United States

The high precision spectrometry of galactic cosmic rays (CR), e.g. the Pamela experiment [1], accurately determined an approximately 0.1 difference between the rigidity spectral indices of protons and Helium ions. Similar deviations have been indicated earlier by other experiments [2] and confirmed by the recent high-fidelity AMS-02 measurements [3]. These findings may shed light on the long standing problem of CR origin. While the CR particles are believed to be accelerated in supernova remnant (SNR) shocks via diffusive shock acceleration (DSA), it is still not understood how different CR elements are extracted from the supernova environments and injected into the DSA. The similarity of He/p, C/p, and O/p rigidity spectra demonstrated by AMS-02 has provided new evidence that injection is a mass-to-charge dependent process. In oder to investigate the elemental selectivity of the injection mechanism and determine the injection efficiency of ion species with different charge-to-mass ratio, A/Z, we performed fully self-consistent hybrid simulations. Our results confirm the earlier theoretical predictions that the efficiency of injection depends on the shock Mach number, M and its increase with A/Z saturates at a level that growth with M. Moreover, they show that for high A/Z the injecton efficiency decreases. By convolving the time-dependent injection rates of p and He, obtained from the simulations, with a decreasing shock strength over the active life of SNRs, we generate the integrated SNR spectra for p and He. These spectra are consistent with the AMS-02 and Pamela data. In particular they correctly predict the decrease in p/He ratio with increasing rigidity at exactly the rate measured in the experiments for > 10 GV. Only at lower rigidities,

;S 10 GV, the difference between the data and our predictions becomes noticeable. Whether this deviation comes from the propagation through the interstellar medium or solar modulation, remains unclear. Except for this uncertainty, the suggested mechanism for A/Z-dependence of the injection fully explains the measured p/He ratio.

E1.5-0032-18 A MULTI-MESSENGER APPROACH TO THE SEARCH FOR THE ORIGIN OF THE POSITRON EXCESS IN COSMIC RAYS

Catia Grimani, catia.grimani@uniurb.it University of Urbino, Urbino, Italy

Pulsed TeV gamma-ray measurements from Crab with the MAGIC experiment and gravitational wave detection with the Earth interferometers (LIGO-Virgo detectors) in the last three years represent two major steps forward for the understanding of young and middle-aged pulsar physics and energy losses at the moment the advanced versions of these last experiments will be operational. Middle-aged pulsars were proposed among the most plausible astrophysical sources of electrons and positrons that may explain the positron excess observed in cosmic rays with respect to the secondary component. It will be shown here that the role of supernova fallback matter on pulsars and circumpulsar disk formation may reconcile within only one scenario cosmic-ray particle observations and electromagnetic and gravitational wave measurements from disks around these compact objects. As a matter of fact, the second generation space interferometers are expected to allow for the detection of circumpulsar disk precession.

Skobeltsyn Insnitute of Nuclear Physics, MSU, Moscow, Russia

Data from the NUCLEON space observatory indicates the existence of a universal cosmic ray “knee”, which is observed in different groups of nuclei (protons, helium, heavy nuclei) near a magnetic rigidity of about 10-20 TV. The knee is estimated to be statistically significant. The position in the magnetic rigidity scale and changes of the spectral indices of the spectra of different nuclei groups are reported. New cosmic-ray knee is similar to the famous cosmic-ray knee near the energy 3 PeV per particle and may be related to a limit of acceleration energy of some sort of cosmic ray source. The location of the knee near the same magnetic rigidity 10 TV points out to such a nature of this spectral break.

E1.5-0035-18 SECONDARY TO PRIMARY RATIOS OF COSMIC RAY NUCLEI IN THE NUCLEON EXPERIMENT

Igor Kovalev, im.kovalev@physics.msu.ru

Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russia Nucleon 2018

E.Atkin, V.Bulatov, V.Dorokhov, N.Gorbunov, S.Filippov, V.Grebenyuk, D.Karmanov, I.Kovalev, I.Kudryashov, A.Kurganov, M.Merkin, A.Panov, D.Podorozhny, D.Polkov, S.Porokhovoy, V.Shumikhin, A.Tkachenko, L.Tkachev, A.Turundaevskiy, O.Vasiliev, A.Voronin

The NUCLEON satellite experiment is aimed at direct measurement of the energy spectra of cosmic ray nuclei and the chemical composition (Z=130) in the energy range of 2-500 TeV. Energy measurements are performed by two different methods (ionization calorimeter and the new Kinematic Lightweight Energy Meter (KLEM) technique). Ratios of secondary to primary nuclei (B/C, N/O, subFe/Fe) are presented. The behavior of the ratios is discussed.

E1.5-0036-18 ORIGIN OF COSMIC RAY METALS: CORE COLLAPSE AND TYPE IA SUPERNOVAE, PLUS BINARY NEUTRON STAR KILONOVAE

Richard Lingenfelter, rlingenfelter@ucsd.edu

University of California, San Diego, La Jolla, California, United States

Analyses of recent cosmic ray abundance measurements from H to U now allow us to quantitatively define the nucleosynthetic and grain-sputtering injection contributions to the elemental abundance enrichment of cosmic rays accelerated in core collapse supernovae in superbubbles. Moreover, they also enable us to address the contributions of Type 1a supernovae and the newly observed binary neutron star merger kilonovae.

E1.5-0037-18 GALPROP CODE FOR GALACTIC COSMIC RAY PROPAGATION AND ASSOCIATED PHOTON EMISSIONS

Igor Moskalenko, imos@stanford.edu

Stanford University, Stanford, California, United States Gudlaugur Johannesson, gudlaugu@hi.is

University of Iceland, Reykjavik, Iceland Troy Porter, tporter@stanford.edu

Stanford University, Stanford, California, United States

Last decade is marked with many breakthroughs in astrophysics of cosmic rays, and more are expected in the nearest future. Their proper interpretation is impossible without a welldeveloped propagation code. The GALPROP project celebrates its 22nd anniversary this year. This project is devoted to the development of a self-consistent model for CR propagation in the Galaxy and associated diffuse emissions (radio, microwave, X-rays, gamma-rays). The project stimulated independent studies of the interstellar radiation field, distribution of the interstellar gas (H2, H I, H II), synchrotron emission and the Galactic magnetic field, and isotopic production cross sections. Version 56 that have many new capabilities has recently become public. I will talk about recent updates to the code and results. As always, the latest release is available through the WebRun, a service to the scientific community enabling easy use of the GALPROP code via web browsers.

E1.5-0038-18 NASA'S SCIENTIFIC BALLOONING PROGRAM

William Vernon Jones, w.vernon.jones@nasa.gov

NASA Headquarters, Washington, DC, District of Columbia, United States

I will talk about progress in NASA's scientific ballooning program and opportunities it will provide in the near future.

E1.5-0039-18 GALACTIC COSMIC RAY ENERGY SPECTRA FOR HEAVY ELEMENTS (NEON TO ZINC) FROM 0.8 TO 10 GEV/NUC AND A SEARCH FOR MICROQUASAR SPECTRAL FEATURES WITH THE SUPERTIGER INSTRUMENT

Allan Labrador, labrador@srl.caltech.edu

California Institute of Technology, Pasadena, California, United States the SuperTIGER Team

A.W. Labrador [1], W.R. Binns [2], R.G. Bose [2], T.J. Brandt [3], P.F. Dowkontt [2], T. Hams [3,4], M.H. Israel [2], J.T. Link [3,4], R.A. Mewaldt [1], J.W. Mitchell [3], R.P. Murphy [2], B.F. Rauch [2], K. Sakai [3,4], M. Sasaki [3,4], E.C. Stone [1], C.J. Waddington [5], N.E. Walsh [2],

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA 91109 USA

SuperTIGER (Trans-Iron Galactic Element Recorder) is a large-area balloon-borne instrument built to measure the galactic cosmic-ray (GCR) abundances of elements from Z=10 (Ne) through Z=56 (Ba) at energies from 0.8 to sim 10 GeV/nuc. SuperTIGER was launched from Antarctica and flew for a record-breaking 55 days, from December 8, 2012 to February 1, 2013. We will report on the status of SuperTIGER energy calibration, using the instrument's aerogel and acrylic Cherenkov detector signals, and on instrumental and atmospheric corrections to obtain cosmic ray energy spectra for abundant elements (e.g. Zle30). Heinz and Sunyaev (2002) suggested that microquasar jets observed in GRS 1915+105 and GRO J1655-40 may be observable as near monoenergetic peaks in heavy ions in the 3-10 GeV/nuc energy range. The large area and long flight duration of SuperTIGER is particularly suited to looking for these microquasar signatures with good statistics. We will compare our SuperTIGER spectra (extrapolated to the top of the atmosphere) with ACE/CRIS spectra from the same time period, and with spectra from a solar modulated GCR model, in order to search for features that may be produced by microquasar jets. We will also compare SuperTIGER spectra with those of the earlier TIGER experiment, using data from its 2001-2002 Antarctic flight.

E1.5-0040-18 SUPERTIGER ABUNDANCES OF GALACTIC COSMIC-RAYS FOR THE CHARGE INTERVAL Z=41-56

Nathan Walsh, newalsh@wustl.edu

Washington University in Saint Louis, St. Louis, Missouri, United States SuperTIGER

Walter Binns (Washington University), Martin Israel (Washington University), Ryan Murphy (Washington University), Brian Rauch (Washington University), Nathan Walsh (Washington University), John Ward (Washington University), Terri Brandt (NASA Goddard Space Flight Center), Jason Link (NASA Goddard Space Flight Center), John Mitchell (NASA Goddard Space Flight Center), Thomas Hams (NASA Goddard Space Flight Center), Kenichi Sakai (NASA Goddard Space Flight Center), Makoto Sasaki (NASA Goddard Space Flight Center), Allan Labrador (California Institute of Technology), Richard Mewaldt (California Institute of Technology), Edward Stone (California Institute of Technology), Mark Wiedenbeck (Jet Propulsion Laboratory), Cecil Waddington (University of Minnesota)

On December 8, 2012 the SuperTIGER (Trans-Iron Galactic Element Recorder) instrument was launched from Williams Field, Antarctica on a long-duration balloon flight lasting 55 days and maintaining a mean altitude of 125,000 feet. SuperTIGER made measurements of the relative abundances of Galactic cosmic-ray nuclei from Neon to Zirconium (charges Z=10-40) with high statistical precision and well resolved individual element peaks. SuperTIGER also made exploratory measurements of the relative abundances up to Barium (Z=56). Although the statistics are low for elements heavier than Zirconium (Z=40), we will show how the relative abundances of charges Z=40-56 compare to those reported by HEAO3-HNE during 1979-81. The relative abundances of elements Zirconium through Neodymium (Z=40-60) are of particular interest because they are formed both by supernova explosions and by binary neutron star mergers. A well resolved measurement of this range of elements can show us how much the composition of the Galactic cosmic-rays is affected by contributions from both of these possible sources. SuperTIGER 2 was originally scheduled for a 2017-18 Austral summer launch from Williams Field, Antartica. The 2017-18 campaign was cancelled, however, due to consistently unfavorable weather. A fully integrated SuperTIGER 2 will remain in Antarctica in anticipation of a possible rescheduled flight during the Austral summer of 2018-19. As solar minimum should persist through next season, we estimate that SuperTIGER 2 will experience a 50% increase in the particles collected per unit time as compared to SuperTIGER 1. With the combined data sets of SuperTIGER 1 and 2, we will improve the statistics of our relative abundance measurements of the Z=30-56 range.

We present measurements of the abundances of ultra-heavy (Z>29) cosmic rays made by the

CRIS instrument on NASA's ACE satellite. The data set corresponds to >7000 days of data collection beginning December 4, 1997 through January 10, 2018. The charge resolution shows essentially complete separation of charges in the Z>28 range. We have detected more than 1100 events over the charge range of Z=30-40. Our measurements show that the ordering of refractory and volatile elements with atomic mass is greatly improved when compared to a mix of massive star outflow and SN ejecta with normal interstellar material (ISM), rather than with pure ISM. In addition, the refractory and volatile elements have similar slopes and refractory elements are preferentially accelerated by a factor of 4. The measured abundances support a model in which cosmic-ray source material is a mix of material from massive star outflow and ejecta and normal ISM. This research is supported by NASA under Grant NNX13AH66G.

E1.5-0042-18 THE GAPS EXPERIMENT TO SEARCH FOR DARK MATTER USING LOWENERGY ANTIMATTER

Ralph Bird, ralph.bird.1@gmail.com

University of California, Los Angeles, Los Angeles, California, United States

The General Antiparticle Spectrometer (GAPS) is designed to carry out a sensitive dark matter search by measuring low-energy cosmic ray antiparticles. GAPS will open a new window to explore a wide range of dark matter models and masses in a complementary manner to existing direct, indirect and collider searches. At low energies the secondary antideuteron flux is very low, and well-motivated, beyond the standard model theories predict a detectable flux of antideuterons significantly above this level. GAPS will also conduct a low-energy antiproton search. Combined, these observations will provide stringent constraints on dark matter, and provide the best limits to date on primordial black hole evaporation on Galactic length scales.

GAPS is planned to fly on a long-duration balloon over Antarctica in the austral summer of 2020. The primary detector is a one cubic meter central volume containing planes of Si(Li) detectors. This volume is surrounded by a time-of-flight system to both trigger the Si(Li) detector and better reconstruct particle tracks. After slowing down in the Si(Li) target, an incident antiparticle is captured and autoionizes the shell electrons to form an excited exotic atom. This atom de-excites via characteristic X-ray transitions before producing a pion/proton star when the antiparticle annihilates with a portion of the nucleus of the atom. This unique event topology will give GAPS the nearly background-free detection capability that is critical in a rare-event search.

This presentation will address the motivation for this low-energy antiparticle search, discuss the current status of the GAPS experiment and give an update on the design of the payload.

E1.5-0043-18 GALACTIC COSMIC RAY OBSERVATIONS FROM VOYAGERS 1 AND 2

New Mexico State University, Las Cruces, New Mexico, United States

Voyager 1 crossed into interstellar space on 25 August 2012 at 121.6 AU from the Sun. At the time of the conference, it will have collected nearly 6 years of low-energy galactic cosmic ray (GCR) data from the nearby interstellar medium. We will report the latest results on topics ranging from the radial gradient of GCRs just outside the heliosphere to energy spectra and composition of the arriving cosmic rays. Voyager 2 is still in the inner heliosheath but appears to be rapidly approaching the heliopause. We will show observations that yield rough estimates of when it might cross into interstellar space.

This research was supported by NASA Grant NNN12AA01C.

E1.5-0044-18 SOLAR MODULATION, FORBUSH DECREASES AND SOLAR ENERGETIC PARTICLES WITH AMS

Veronica Bindi, bindi@hawaii.edu

University of Hawaii, Honolulu, Hawaii, United States AMS

AMS collaboration

The Alpha Magnetic Spectrometer (AMS), on the International Space Station (ISS) since May 2011, has acquired the largest number of particles ever measured in space by a single experiment, performing the most precise measurement of galactic cosmic rays (GCR) to-date. The detailed time variation of multiple particle species fluxes measured in the first years of operations, during the ascending phase of solar cycle 24 and reversal of the Sun's magnetic field polarity (from negative $A < 0$ to positive $A > 0$). For all particles, the high energy spectrum remains stable versus time, while the low-energy range is strongly modulated by the solar activity. In addition, AMS measured several Forbush decreases (FD) and solar energetic particles (SEP) associated with the short term solar activity. AMS data allows us to study the time evolution of the rigidity dependence of these type of events for multiple particle species. Selected FD and SEP events observed by AMS, since the beginning of its mission, will be presented.

E1.5-0045-18 HELMOD MODEL AND COSMIC RAY PROPAGATION IN THE HELIOSPHERE

Pier Giorgio Rancoita, piergiorgio.rancoita@mib.infn.it INFN Milano-Bicocca, Milano, Italy

Matteo Boschini, matteo.boschini@mib.infn.it INFN Milano-Bicocca, Milano, Italy

Stefano Della Torre, stefano.dellatorre@mib.infn.it INFN Milano-Bicocca, Milano, Italy

Massimo Gervasi, massimo.gervasi@mib.infn.it University and INFN - Milano Bicocca, Milano, Italy Giuseppe La Vacca, giuseppe.lavacca@mib.infn.it INFN Milano-Bicocca, Milano, Italy

HelMod is a 2-D Monte Carlo capable to describes the transport of Galactic cosmic rays through the heliosphere down to and at several distances from Earth. The model includes the symmetric and antisymmetric part of the diffusion tensor, thus, properly treating particle drift effects. The model was been tuned in order to fit the data observed outside the ecliptic plane at several distances from the Earth and, also, the spectra observed near the Earth during high and low solar activity periods. HelMod was proved to reproduce light and heavy cosmic rays observed during solar cycle 23-24 by several detectors, for instance, PAMELA, BESS and AMS-02. A new set of local interstellar spectra were obtained in conjunction with GALPROP model.

E1.5-0046-18 NEW SELF-CONSISTENT LOCAL INTERSTELLAR SPECTRA FOR ELECTRONS, POSITRONS, PROTONS, HELIUM AND CARBON

Driaan Bisschoff, 20056950@nwu.ac.za

North-West University, Potchefstroom, South Africa Marius Potgieter, marius.potgieter@nwu.ac.za North-West University, Potchefstroom, South Africa

The observations made by the Voyager 1 spacecraft outside the dominant modulating influence of the heliosphere allows the comparison of computed galactic spectra with in situ experimental data at lower energies (less than 100 MeV/nuc). Using a galactic propagation model, such as the GALPROP code, galactic spectra can be computed and taken as local interstellar spectra (LIS's). By implementing the GALPROP code we set out to simultaneously reproduce the cosmic ray electron, proton, Helium and Carbon observations made by Voyager 1 beyond the heliopause. These LIS's are also compared to the observations made by the PAMELA space detector at the Earth using a comprehensive 3D solar modulation model. Using these models and observations we can also infer a positron LIS and present a set of self-consistent LIS's for the energy range of 3 MeV/nuc to 100 GeV/nuc.

E1.5-0047-18 THE HEAVY NUCLEI EXPLORER

John Mitchell, john.w.mitchell@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States HNX Collaboration

T. Anderson, W.R. Binns, S. Coutu, G.A. De Nolfo, P. Dowkontt, M.H. Israel, J.F. Krizmanic,

J. T. Link, S. Nutter, B. Rauch, K. Sakai, M. Sasaki, C.J. Waddington, A. Westphal

The HNX (Heavy Nuclei eXplorer) is a new mission to measure the abundances of ultra-heavy galactic cosmic ray (UHGCR) nuclei, that will be proposed as a NASA Small Explorer (SMEX) at the next opportunity (expected early 2019) by NASA Goddard Space Flight Center, University of California, Berkeley, Washington University in St. Louis, the Jet Propulsion Laboratory, the University of Minnesota, Pennsylvania State University and the Northern Kentucky University. The planned effort builds on very successful proposals in 2001 and 2014, that, unfortunately, did not result in a flight selection. HNX will complement and extend measurements by TIGER/SuperTIGER, ACE, and HEAO and will investigate the nature of the reservoirs of nuclei at the cosmic-ray sources, the mechanisms by which nuclei are removed from the reservoirs and injected into the cosmic accelerators, and the GCR acceleration mechanism. HNX will measure, for the first time, the abundance of every individual element in the periodic table from carbon through the actinides, providing the first fully resolved measurement of many of these elements. These measurements are especially timely and interesting to the broader astrophysics community in light of the recent detection of a binary neutron star merger in gravitational radiation, gamma-rays and radio. HNX will record several thousand UHGCR nuclei with atomic number Z30, including about 50 actinides. This will enable sensitive tests of the relative importance to the nucleosyntheis of UH elements of R and S neutron capture processes and the relative contributions of supernovae and binary neutron star mergers. To measure UHGCR with unprecedented statistics and individual element resolution over its full measurement range, HNX will use two large instruments, the Extremely-heavy Cosmic-ray Composition Observer (ECCO) using sophisticated glass detectors and the Cosmic-ray TransIron Galactic Element Recorder (CosmicTIGER) using electronic detectors evolved from the SuperTIGER (Super Trans-Iron Galactic Element Recorder) long-duration balloon instrument. HNX will be accommodated in the SpaceX DragonLab orbiting laboratory that will also return it to Earth for post-flight processing of the ECCO detectors. The scientific motivations of HNX and details of the planned mission and instruments will be discussed, including the results of CERN accelerator tests.

E1.5-0048-18 THREE-DIMENSIONAL MODELS OF THE INTERSTELLAR MEDIUM FOR THE PROPAGATION OF COSMIC RAYS AND THEIR NON-THERMAL INTERSTELLAR EMISSIONS

Troy Porter, tporter@stanford.edu

Stanford University, Stanford, California, United States Gudlaugur Johannesson, gudlaugu@hi.is

University of Iceland, Reykjavik, Iceland Igor Moskalenko, imos@stanford.edu

Stanford University, Stanford, California, United States

High-energy gamma rays of interstellar origin are produced by the interaction of cosmic-ray (CR) particles with the diffuse gas and radiation fields in the Galaxy. The main features of this emission are well-understood and are reproduced by existing CR propagation models employing 2D Galactocentric cylindrically symmetrical geometry. However, the high-quality data from instruments like the Fermi Large Area Telescope reveal significant deviations from the model predictions on few to tens of degree scales indicating the need to include the details of the Galactic spiral structure and thus require 3D spatial modelling. In this contribution the propagation of CRs and generation of high-energy interstellar emissions from the Galaxy are calculated using the latest release of the GALPROP code employing 3D spatial models for the CR source, interstellar gas, and interstellar radiation field (ISRF) densities. The interstellar emission models that include arms and bulges for the CR source and ISRF densities provide plausible physical interpretations for features found in the residual maps from high-energy gamma-ray data analysis. The 3D models for the CR and interstellar medium densities provide a more realistic basis for interpretation of the direct CR measurements and for their non-thermal interstellar emissions including the directions toward the inner Galaxy and about the Galactic centre.

E1.5-0049-18 COSMIC-RAY SOURCES AS GAMMA-RAY SOURCES

Ramanath Cowsik, cowsik@physics.wustl.edu

Washington University in St. Louis, St. Louis, Missouri, United States Tsitsi Madziwa-Nussinov, tsitsi@wustl.edu

Washington University in St. Louis, St. Louis, Missouri, United States Martin Israel, mhi@wuphys.wustl.edu

Washington University in St. Louis, St. Louis, Missouri, United States

Galactic cosmic rays are accelerated in sources situated in the disc of the Galaxy, and thereafter move along spiral trajectories, scatter on magnetic inhomogeneities, and consequently diffuse through the interstellar medium and leak away into the intergalactic medium. This process of diffusion essentially erases almost all traces of the direction to their origins. Thus the expectation from the early years of cosmic-ray astrophysics was that gamma-ray astronomy would help in identifying the sources: The cosmic rays subsequent to acceleration to high energies would interact with matter in the source regions, produce neutral pions, which decay and generate gamma rays. Observation of such gamma rays would point directly towards the sources of cosmic rays. This expectation of identifying the sources of cosmic rays is only partially fulfilled - gamma-ray astronomy in recent decades has been able to identify a very large number of sources in the Galaxy, but it has not been possible to unequivocally identify them as the sources of cosmic rays that have been observed. In this paper we identify the amount of material that cosmic rays traverse in the source regions, as this has a direct bearing on their gamma-ray emissivity and spectra. To this end we make use of all the available data on cosmic rays, especially the recent results on the spectra and composition measured with great energy resolution and statistical significance by the Alpha Magnetic Spectrometer aboard the International Space Station. The analysis shows that a significant amount of material is indeed traversed by cosmic rays in the source regions allowing these regions to function as gamma-ray sources.

E1.5-0050-18 ORIGIN OF COSMIC RAYS IN LIGHT OF 10 YEARS OF FERMILAT MISSION

Mattia Di Mauro, mdimauro@slac.stanford.edu

Stanford University, REDWOOD CITY, California, United States

The Large Area Telescope (LAT) on board the Fermi Gamma-ray Space Telescope has continuously taken data data since 2008. In 10 years of the mission, the Fermi-LAT team has provided gamma-ray measurements from 10 MeV to 2 TeV as well as the flux and dipole anisotropy of electrons, positrons and protons from GeV to multi TeV energies. I will review the main results on the origin of cosmic rays that the LAT team has published using gamma-ray, electron and positron and preliminary proton data. My presentation will include evidence of the acceleration of protons in Supernova Remnants (SNRs) through the measurement of hadronic gamma-ray emission and the detection of the gamma-ray emission from the Fermi Bubbles, molecular clouds and star forming galaxies. Finally, I will show possible interpretations for the electron and positron flux in terms of SNRs, Pulsar Wind Nebulae and secondary production.

E1.5-0051-18 RECENT RESULTS FROM THE HAWC GAMMA-RAY OBSERVATORY

Jordan Goodman, goodman@umdgrb.umd.edu

University of Maryland, College Park, College Park, Maryland, United States

The High Altitude Water Cherenkov (HAWC) Gamma-ray Observatory in the high mountains of Mexico was completed in March of 2015 and is now giving us a new view of the TeV sky. HAWC is 15 times more sensitive than the previous generation of wide-field EAS gamma-ray instruments and is able to detect the Crab nebula at >5 with each daily transit. Unlike Imaging Atmospheric Cherenkov Telescopes (IACTs), HAWC operates 24hrs/day with over a 95% ontime and observes the entire overhead sky (8sr over the course of the day). This talk will present recent results showing our updated sky catalog, including our view of the sky above 50 TeV and first observations of the jets of a micro-quasar. We will also show recent results on how our observation of nearby middle-aged pulsars impact our understanding of their contribution to the positron flux at earth.

E1.5-0052-18 HAWC OBSERVATIONS ON TWO NEARBY PULSAR WIND NEBULAE CONSTRAIN THE ORIGIN OF LOCAL POSITRONS

Hao Zhou, hzhou1@mtu.edu

Los Alamos National Laboratory, Los Alamos, New Mexico, United States

Nearby electron and positron accelerators, especially Pulsar Wind Nebulae, have been proposed as potential origins of the local positron excess above 10 GeV. The HAWC Gamma-Ray Observatory has reported the discovery of TeV gamma-ray emission extending several degrees around two nearby middle-aged pulsars Geminga and B0656+14, suggesting ultra-relativistic electrons and positrons accelerated in our backyard. By performing morphological studies, we determine the diffusion of electrons and positrons in the interstellar medium around the two pulsars. We will present the morphological and spectral studies on these two TeV gamma-ray sources and the derived positron contribution at Earth.

In the 15 years since its construction, the H.E.S.S. gamma-ray observatory has allowed the study of the VHE gamma-ray sky at resolutions and sensitivities which were never before possible. During this period H.E.S.S. has discovered a rich zoo of both galactic and extra galactic source classes, made measurements of the galactic cosmic ray spectrum and placed limits on fundamental physical processes.

We will present a summary of the latest H.E.S.S. results for these source classes, describing the most interesting new observations and their physical interpretation. Additionally we will detail the latest upgrades and improvements to the H.E.S.S. hardware and data analyses and the future science prospects for the experiment.

E1.5-0054-18 GALACTIC GAMMA-RAY ASTROPHYSICS WITH VERITAS

Brian Humensky, humensky@nevis.columbia.edu Columbia University, New York, New York, United States VERITAS

Brian Humensky

The Galaxy carries a small but quite significant population of highly energetic denizens: supernova remnants with fast shocks, pulsars with powerful winds, intensely-interacting binary systems built from a compact object and a massive star. All of these environments conspire to generate nonthermal populations of particles, and radiation produced by these particles is gradually revealing the methods by which Nature accelerates cosmic rays, as well as the ways in which those cosmic rays escape and diffuse into the interstellar medium. In this talk, we discuss advances in our understanding of these environments and processes provided by recent results from VERITAS, an array of ground-based imaging air-Cherenkov telescopes located at the Whipple Observatory in southern Arizona and sensitive to gamma rays in the energy range from 85 GeV to > 30 TeV. These results include studies of cosmic-ray acceleration in the supernova remnants Cassiopeia A and IC 443, as well as the remarkable Fall 2017 periastron passage of VER J2032+4127, the binary system containing PSR J2032+4127 and the Be star MT91 213 with a 50-year period.

E1.5-0055-18 THE ALPACA EXPERIMENT: OVERVIEW AND CURRENT STATUS

Takashi Sako, tsako@icrr.u-tokyo.ac.jp

Institute for Cosmic Ray Research, Chiba, Japan The ALPACA Collaboration

T. Asaba, K. Hibino, N. Hotta, M. Kataoka, Y. Katayose, C. Kato, K. Kawata, H. Kojima,

R. Mayta, P. Miranda, K. Munakata, Y. Nakamura, M. Nishizawa, S. Ogio, M. Ohnishi, A. Oshima, M. Raljevich, H. Rivera, T. Saito, T. K. Sako, T. Sasaki, S. Shibata, A. Shiomi, M. Subieta, M. Suzuki, N. Tajima, M. Takita, Y. Tameda, K. Tanaka, R. Ticona, H. Tsuchiya, Y. Tsunesada, S. Udo, M. Wakamatsu

ALPACA (Andes Large area PArticle detector for Cosmic ray physics and Astronomy) is a highaltitude air-shower experiment at 4,740m of Mt. Chacaltaya near La Paz, Bolivia. ALPACA aims at observing 10 TeV gamma rays in the southern hemisphere with 100elucidate sub-PeV high-energy astrophysics. ALPACA consists of a 83,000m2 surface air-shower array to measure energies and arrival directions of air showers, and a 5,400m2 underground muon detector array to discriminate gamma-ray and cosmic-ray primaries based on the muon content of air showers. A 1/10-scale prototype array is currently being constructed and data taking will be started in mid 2018. The overview and current status of the project will be presented in the talk.

E1.5-0056-18 TUNKA ADVANCED INSTRUMENT FOR COSMIC RAYS AND GAMMA ASTRONOMY

Leonid Kuzmichev, kuz@dec1.sinp.msu.ru

Scobeltsyn Institute of Nuclear Physics, Moscow, Russia

We present the current status of high-energy cosmic-ray physics and gamma-ray astronomy at the Tunka Astrophysical Center. This complex is located in the Tunka valley, about 50 km from the Baikal lake. At present, three arrays of the complex to study charged cosmicrays are operated: Tunka-133, Tunka-REX and Tunka-Grande. Their measurement of energy spectrum and mass composition is important in order to understand the acceleration limit of the Galactic cosmic-ray sources and the transition from Galactic to extragalactic sources. Most of the ongoing efforts are focused on the construction of the first stage of the gamma-ray observatory TAIGA. TAIGA (Tunka Advanced Instrument for cosmic ray physics and Gamma Astronomy) is designed for the study of gamma-rays and charged cosmicrays in the energy range of 1013 eV - 1018 eV. The TAIGA prototype will consist of 100 wide angle timing Cherenkov stations (TAIGA-HiSCORE) and three IACTs deployed over an area of 1 km^2. The installation of the array will be finished in 2019 while data-taking already proceeds during the commissioning phase. The combined reconstruction of energy, direction, and core position of the imaging and non-imaging detectors allow to increase the distance between the IACTs up to 600 -800 m, therefore reducing the costs dramatically. The low investments together with the high sensitivity for energies 30-50 TeV make this pioneering technique very attractive for exploring the galactic PeVatrons and cosmic rays. In addition to the Cherenkov light detectors we intend to deploy a muon detectors over an area of 1 km^2 with a total area of muon detectors of about 1000 m2. The results of the fist season of common operation of IACT with 40 stations of TAIGA-HiSCORE will be presented

E1.5-0057-18 PROBING COSMIC-RAY PHYSICS IN STARBURST GALAXIES WITH FUTURE HIGH-ENERGY MISSIONS

Tonia Venters, tonia.m.venters@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States HEX-P Science Working Group on Starburst and Local Group Galaxies

Ann Hornschemeier, Mihoko Yukita, Valsamo Antoniou, Megan Argo, Keith Bechtol, Brian Grefenstette, Fiona Harrison, Roman Krivonos, Bret Lehmer, Thomas Maccarone, Kristin Madsen, Jeremy Perkins, Andrew Ptak, Daniel Stern, Tonia Venters, Neven Vulic, Daniel Wik, Andreas Zezas, Will Zhang

Cosmic ray feedback on a galaxy's interstellar medium (ISM) can substantially influence the galaxy's formation and evolution. Cosmic rays ionize and heat the ISM, regulating star formation. Cosmic-ray transport can also result in galactic winds that will drive material out of galaxy disks and enrich the intergalactic medium. In order to assess the influence of cosmic ray feedback (relative to other types of feedback) in driving the conditions for galaxy formation and evolution, we need to better understand the complex interplay among cosmic rays, galaxy magnetic fields, and the ISM (the CR-B-ISM relationship) in a variety of interstellar environments.

The sole means for probing cosmic-ray physics in other galaxies is through the byproducts of their interactions with gas and radiation in their environments, including the broadband nonthermal diffuse spectrum observable from hard X-rays to TeV gamma rays. Observations of nearby galaxies by Fermi in the GeV band and Imaging Atmospheric Cherenkov Telescopes in the TeV band have resulted in the first detections of non-AGN galaxies outside of the Milky Way. Recent NuSTAR observations of starburst galaxies such as NGC 253 and M82 enable the most sensitive search to date for their diffuse inverse Compton emission in the hard X-ray band (10-30 keV). Such extremely deep observations are made with very long exposures and are currently only available for very nearby galaxies; however, they provide a glimpse of what we may expect from next-generation facilities. In this talk, I will discuss the latest results from high-energy observations of nearby star-forming galaxies, including the connection between the gamma-ray, radio, and far-infrared emission. I will discuss the implications of these results for these galaxies' cosmic ray populations. Finally, I will set the stage for next generation high-energy facilities, including (but not limited to) HEX-P, FORCE, AMEGO, CTA, and IceCube-Gen2.

E1.5-0058-18 CHERENKOV TELESCOPE ARRAY: OVERVIEW AND GALACTIC SCIENCE PROGRAM

Rene Ong, rene@astro.ucla.edu

UCLA, Los Angeles, California, United States Cherenkov Telescope Array (CTA) Consortium

See https://www.cta-observatory.org/consortium_authors/authors_2018_07.html for full author list

The Cherenkov Telescope Array (CTA) will be the next-generation gamma-ray observatory, investigating gamma-ray and cosmic ray astrophysics at energies from 20 GeV to more than 300 TeV. The observatory, consisting of large arrays of imaging atmospheric Cherenkov telescopes in both the southern and northern hemispheres, will provide full-sky coverage and will achieve a wider energy range and a significantly improved sensitivity compared to existing instruments such as H.E.S.S., MAGIC and VERITAS.

The development of CTA is being carried out by a worldwide consortium of scientists from 32 countries. This talk will provide an overview of CTA and will review the scientific motivation for CTA, with a focus on the key science projects that relate to the study of Galactic sources of very high-energy emission and to the long-standing question on the origin of cosmic rays.

E1.5-0059-18 RECENT RESULTS FROM THE PIERRE AUGER OBSERVATORY

James Matthews, jmatth5@lsu.edu

Louisiana State University, BATON ROUGE, Louisiana, United States

I will review recent results from the Pierre Auger Observatory, especially studies of the anisotropy of the highest energy cosmic rays.

E1.5-0060-18 RESULTS FROM THE TELESCOPE ARRAY EXPERIMENT

Pierre Sokolsky, ps.protopop@gmail.com

University of Utah, Salt Lake City, Utah, United States

We present recent results on the spectrum, composition and anisotropy of VHE and UHE cosmic rays based on data from the Telescope Array (TA) and Telescope Array Low Energy Extension (TALE) experiments. TA and TALE are hybrid air-fluorescence/Cherenkov and surface array experiments covering the energy range from 1015.2 to greater than 1020 eV with overlapping techniques. New results on spectral features including the first and second knee, ankle and GZK cutoff will be presented as well as updates on the hybrid composition measurements using the Xmax technique above 1018.2 eV. A new analysis of energy spectrum anisotropy above 1019.2 eV around the previously reported hot spot near Ursa Major will also be presented. We also report on the status of the TAx4 project currently under construction.

E1.5-0061-18 ON THE ACCELERATION OF ULTRA HIGH ENERGY COSMIC RAYS AT RICH CLUSTER ACCRETION SHOCKS - PROGRESS, PROBLEMS AND PROPOSED TESTS

Roger Blandford, rdb3@stanford.edu

Stanford University, Stanford, California, United States Paul Simeon, paulsimeon@gmail.com

Stanford University, Stanford, California, United States Noemie Globus, noemie.globus@mail.huji.ac.il

Hebrew University of Jerusalem, Jerusalem, Israel

Longstanding, proposed sites for the acceleration of Ultra High Energy Cosmic Rays are accretion shocks surrounding nearby, rich clusters of galaxies. These can form with large Mach numbers and subject a seed population of PeV cosmic rays that escape normal galaxies to diffusive shock acceleration. This explanation probably requires the highest energy particles to be medium to heavy nuclei and the intergalactic propagation to be quite rapid. We will outline the modern basis of this model in the context of recent observations of this particles and supernova remnants, address some difficulties that these observations may present and propose some observational tests. Special attention will be paid to the associated luminosity densities of the various cosmic ray populations.

E1.5-0062-18 HIGH ENERGY INTERACTIONS OF COSMIC RAYS

Sergey Ostapchenko, sergei@tf.phys.ntnu.no

Frankfurt Institute for Advanced Studies (FIAS), Frankfurt Am Main, Germany

I'll review the state of the art concerning modelling of high energy cosmic ray interactions. A special attention will be devoted to novel theoretical approaches employed in models-generators of hadronic interactions and to the impact of experimental data from the Large Hadron Collider (LHC). In relation to studies of ultra-high energy cosmic rays (UHECRs), the differences between models' predictions for basic characteristics of UHECR-induced extensive air showers in the atmosphere will be analysed and traced down to the differences in the respective interaction treatments. Possibilities to discriminate between the alternative approaches, based on LHC and UHECR data, will be demonstrated and the relation to UHECR primary composition will be outlined. Finally, in relation to direct studies of charged cosmic rays, potential improvements of the treatment of cosmic ray interactions at low and intermediate energies will be discussed.

E1.5-0063-18 PRELIMINARY RESULTS OF THE TUS ORBITAL DETECTOR OF ULTRAHIGH ENERGY COSMIC RAYS

Pavel Klimov, pavel.klimov@gmail.com

Lomonosov Moscow State University, Moscow, Russia Mikhail Panasyuk, panasyuk@sinp.msu.ru

Moscow State University, Skobeltsyn Institute of Nuclear Physics, Moscow, Russia Lomonosov-UHECR/TLE Collaboration

G.K. Garipov, V.E. Eremeev, M.A. Kaznacheeva, B.A. Khrenov, P.A. Klimov, M.I. Panasyuk,

V.L. Petrov, S.A. Sharakin, A.V. Shirokov, I.V. Yashin, M.Yu. Zotov, S.V. Biktemerova, A.A. Grinyuk, V.M. Grebenyuk, M.V. Lavrova, L.G. Tkachev, A.V. Tkachenko, O.A. Saprykin, A.A. Botvinko, A.N. Senkovsky, A.E. Puchkov, I.H. Park, J. Lee, S. Jeong, O. Martinez, H. Salazar,

E. Ponce

The first orbital detector of ultra-high energy cosmic rays (UHECR) TUS was launched on board the Lomonosov satellite on April 28, 2016. The detector is a UV telescope with a mirrorconcentrator of 2 m2 area and a photodetector composed of 256 photo multiplier tubes for measuring fluorescent radiation of extensive air showers (EAS) produced in the atmosphere by UHECR particles. The field of view of the detector is 80 80 km^2 at sea level providing an instant exposure comparable with that of the largest ground-based arrays (Pierre Auger Observatory and the Telescope Array). We report preliminary results of a search for EAS-like events in the TUS data and their analysis, including a strong UHECR candidate registered on October 3, 2016. We also present a rich variety of atmospheric phenomena measured during the mission, among them UV background and airglow, anthropogenic radiation, aurora lights, lightning discharges and transient luminous events, meteors. The experience of the TUS detector gives unique data on the transient UV radiation from the atmosphere and proves the capability of EAS measurements from space. This is an important step for future UHECR orbital missions like KLYPVE-EUSO.

E1.5-0064-18 RESULTS FROM THE THIRD FLIGHT OF THE ANTARCTIC IMPULSIVE TRANSIENT ANTENNA (ANITA) PAYLOAD

Peter Gorham, gorham@phys.hawaii.edu

University of Hawaii, Honolulu, Hawaii, United States ANITA collaboration

C. J. Naudet, R. J. Nichol, M. Olmedo, R. Prechelt, B. F. Rauch, J. Roberts, A. Romero-Wolf,

J. Russell, D. P. Slatzberg, D. Seckel, H. Schoorlemmer, S. Stafford, J. Stockam, M. Stockam,

B. Strutt, G. S. Varner, A. G. Vieregg, S. A. Wissel

ANITA is a long-duration balloon payload which searches for impulsive radio signals in the 200-1200MHz band arising from the Askaryan effect in neutrino interactions in the Antarctic ice sheets, and via air-shower radio signals from cosmic-ray-like events in the atmosphere above the ice. Because of the wide synoptic view of Antarctic ice that is obtained from stratospheric balloon altitudes, ANITA has a very large instantaneous acceptance for neutrino signals. We report here on results of the third flight of ANITA, taking place in December 2014-January 2015. We also present preliminary performance results from the fourth ANITA flight, which flew in the last weeks of 2016, and for which the data was retrieved in early 2017.

E1.5-0065-18 POEMMA: PROBE OF MULTI-MESSENGER ASTROPHYSICS

Angela V Olinto, aolinto@uchicago.edu

University of Chicago, Chicago, Illinois, United States

The Probe Of Multi-Messenger Astrophysics (POEMMA) mission is being designed to identify the sources of the most extreme particles ever observed, the ultra-high energy cosmic rays (UHECRs), and to discover cosmic neutrinos above 10 PeV. POEMMA will consist of two satellites, flying in loose formation, each with a wide field-of-view UV photodetector, using an innovative Schmidt camera, optimized to observe both air fluorescence and air Cherenkov signals from UHECRs and neutrinos. POEMMA will measure the spectrum, composition, and sky distribution of the UHECRs above 10 EeV and the Cherenkov signals from upward-moving air showers induced from tau neutrino interactions in the Earth. POEMMA's goal is to obtain orders of magnitude higher sensitivity to the highest energy cosmic messengers compared to what is achieved by ground-based experiments in order to identify the most energetic cosmic accelerators in the universe, study the acceleration mechanism(s), and probe particle interactions at energies well-above those achieved by man-made accelerators.

E1.5-0066-18 THE JEM-EUSO PROGRAM TO STUDY ULTRA-HIGH ENERGY COSMIC RAYS FROM SPACE.

Marco Ricci, marco.ricci@lnf.infn.it INFN-LNF, Frascati (RM), Italy

The origin and nature of Ultra-High Energy Cosmic Rays (UHECRs) remains as one of the still unsolved problems in the current scenario of Astroparticle Physics. To give an answer to these questions is rather challenging because of the extremely low flux of a few per km^2 per century at extreme energies such as $E > 5 \times 1019$ eV and beyond. In order to obtain a significant statistics in the data, very large arrays of surface telescopes on ground are required (like Auger and Telescope Array, operating in Argentina and Utah, respectively). A complementary way to tackle the problem is to employ wide-field telescopes to look down from space onto the night sky to detect UV photons emitted from air showers generated by UHECRs in the atmosphere. The observation of UHECRs from space offers several advantages such as large exposure, uniform observation of both celestial hemispheres, uniform detector response. The main objective of the JEM-EUSO program (Extreme Universe Space Observatory) is the realization of a space mission devoted to the scientific research of cosmic rays of highest energies. In order to make a proof-of-principle of the UHECR observation from space, to meet the science requirements and the constraints (mass, power, hardness) of space-borne detectors, and to raise the technological level of the instrumentation to be employed in a space mission, different test experiments using fluorescence detectors systems have been developed and performed by the JEM-EUSO Collaboration. These systems have been extensively tested and calibrated in different phases: the installation of a ground based telescope at the Telescope Array site (EUSO-TA, operating since 2013) and a first Stratospheric Balloon flight from Canada (EUSO-Balloon, 2014). A second generation of greatly improved detectors has been developed, the first on a Super Pressure Balloon (EUSO-SPB) which flew from New Zealand in Spring 2017, the second - Mini-EUSO - a small telescope to be placed on the Russian Module of the International Space Station (ISS) in late 2018 - early 2019. A second Super Pressure Balloon flight (EUSO-SPB2) is planned to be launched in 2021 from New Zealand. Scientific, technical and programmatic aspects will be discussed also in the context of future missions like K-EUSO (in Russia) and POEMMA (in USA).

E1.5-0067-18 USING THE SQUARE KILOMETRE ARRAY TO DETECT HIGH ENERGY COSMIC PARTICLES

Clancy James, clancy.james@curtin.edu.au Curtin University, Perth, WA, Australia

SKA High Energy Cosmic Particles Focus Group

Justin Bray Clancy James Jaime Alvarez-Muniz Stijn Buitink Rustam Dagkesamanskii Richard Dallier Ron Ekers Torsten Ensslin Heino Falcke Ken Gayley Nadir Hashim Tim Huege Katherine Mack Lilian Martin Maaijke Mevius Robert Mutel Anna Nelles Julian Rautenberg Benoit Revenu Olaf Sholten Frank Schroeder Ralph Spencer Steven Tingay Sander ter Veen Anne Zilles

The Square Kilometre Array (SKA) will be a giant array of radio telescopes to be built in Australia and Southern Africa over the next ten years. The SKA's High Energy Cosmic Particles Focus Group aims to use this instrument to study cosmic ray interactions in the atmosphere above the detector with 'ultimate precision', and use the Moon as a 20 million km² target for the highest-energy flux.

This contribution describes these two proposed experiments. It gives an update on the current status of the SKA, and describes the efforts of the HECP Focus Group to harness its power to detect sub-microsecond cosmic ray pulses. The ultimate aim is to use the SKA to study air shower physics with high-precision near-field interferometry, the cosmic-ray composition near the knee, and perform directional studies in the highest-energy regime, above 1019 eV.

E1.5-0068-18 A VISION FOR THE FUTURE OF MULTIMESSENGER ASTRONOMY WITH NEUTRINOS: THE ICECUBE GEN2 OBSERVATORY

Kael Hanson, kael.hanson@icecube.wisc.edu

University of Wisconsin - Madison, Madison, Wisconsin, United States

Neutrinos are ideal astronomical messengers that bring information across vast cosmological distances. Neutral, they are not deflected by galactic and intergalactic magnetic fields. Weakly interacting, they are not diffused by interstellar matter nor photon fields nor even by thick shrouds of material surrounding the exotic, high energy astrophysical particle accelerators where they are produced. They arrive at the observer in pristine form. Catching these ghostly particles, however, is an enterprise: cubic kilometers of target material must be instrumented to yield a handful of events per year. The IceCube detector has turned a billion tons of ice at the South Pole into a neutrino telescope. In 2013, IceCube reported the discovery of a flux of neutrinos of astrophysical origin consistent with isotropic sources, establishing the existence of hadron accelerators and the detectability of the neutrino flux from them. In 2017, the new real-time alerting system of IceCube released an ATEL following the appearance of a high-energy neutrino event in the detector. Follow up observations confirm emission of high energy gamma rays from the blazar TXS0506+056. This latter event marks the beginning of neutrino multimessenger astronomy. The IceCube collaboration plans to deploy additional instrumentation to expand the science achievable by this unique observatory. In the near term, the addition of 7 infill strings with advanced photodetectors will extend IceCube's sensitivity to GeV atmospheric neutrinos. The sheer tonnage of this upgraded detector will allow the detection of an unprecedented number of tau neutrinos created in transit through the Earth by the phenomenon of neutrino oscillations and will enable measurements of the tau mixing parameters to greater precision than any planned astrophysical or accelerator based detector. Further in the future will be the IceCube Gen2 Observatory, a revolutionary new observatory which will combine optical and radio detection techniques to detect neutrinos spanning ten decades in energy and presenting an order of magnitude more neutrino effective area at high energies.

E1.5-0069-18 MEASUREMENT OF COSMOGENIC NEUTRINOS WITH THE ARIANNA EXPERIMENT

Christian Glaser, christian.glaser@uci.edu

University of California Irvine, Irvine, California, United States

The detection of cosmogenic neutrinos offers the potential to reveal the sources of ultra-high energy cosmic rays. Cosmogenic neutrinos are expected to be produced via the GZK effect during the propagation of cosmic rays or by the interaction of cosmic rays with surrounding media directly at the source. In particular, a coincident detection of neutrinos and recently discovered gravitational waves signals from neutron star mergers offers a unique opportunity to directly probe a cosmic-ray source.

The ARIANNA detector aims to detect neutrinos with energies above 1016 eV with a surface array of a thousand independent radio detector stations in Antarctica. Radio signals are produced via the Askaryan effect from particle cascades generated in the ice by interactions of these neutrinos. The Antarctic ice is transparent to MHz - GHz radio signals which allows for a cost-effective instrumentation of large volumes. A pilot array of 10 stations is currently operating successfully at the Moore's Bay site (Ross Ice Shelf) in Antarctica. In addition, one station was installed at the South Pole to test the suitability of this site. We will report on the current status of the ARIANNA detector. Furthermore, we will present techniques to reconstruct neutrino properties from our radio measurements which we probe experimentally by the detection of the more abundant cosmic-ray air showers.

E1.5-0070-18 PHAESTOS: USING GALACTIC MAGNETIC TOMOGRAPHY TO ENABLE CHARGE PARTICLE ASTRONOMY AND ELECTROMAGNETICALLY PROBE COSMIC-RAY COMPOSITION AT THE HIGHEST ENERGIES

Vasiliki Pavlidou, pavlidou@physics.uoc.gr University of Crete, Heraklion, Greece

The sources of the highest-energy particles in the Universe remain an unresolved mystery. The reason is that charged-particle astronomy is severely complicated by magnetic deflections. I will discuss the PHAESTOS project - a radically new approach to charged-particle astronomy: constructing a 3-dimensional map of the Galactic magnetic field through optopolarimetric magnetic tomography, and backtracking the paths that UHECR traverse through the Galaxy before reaching us, to improve agreement between their (corrected) arrival directions and the location of their sources on the sky. Effectively, this technique aims to improve the charged-particle point-spread-function by a factor of several, boosting the sensitivity to individual sources by a similar factor, and allowing us to probe the cosmic-ray composition at the highest energies without reference to the development of extensive air showers in the atmosphere. This approach is becoming possible for the first time thanks to two experimental breakthroughs: the unparalleled wealth of stellar distances that the Gaia mission is in the process of providing; and recent advances in optopolarimetry of point sources that make possible systematic large-area surveys of stars. This technique would act multiplicatively on the return from current and future cosmic-ray observatories, groundand space-based.

E1.5-0071-18 ULTRA HIGH ENERGY COSMIC RAYS BY LIGHT NUCLEI IN NEAREST UNIVERSE: THE CONFIRMED CEN A, M 82, NGC 253 IMPRINT.

Daniele Fargion, daniele.fargion@roma1.infn.it

Physics Department, Rome University 1, INFN Rome 1,, Rome, Italy

Ultra High Energy Cosmic Rays UHECR had probed (by the Virgo absence, the best candidate source of galaxy cluster inside a 40 Mpc GZK volumes) to be screened at least from Virgo 20 Mpc volumes: that hint forced us ten years (2008) ago to claim and to point toward light nuclei as the main currier: consistently only Cen A AGN (at 2 Mpc distance) was and it still shines as a main clustered region in UHECR south sky. Only a few years later (2014-2015) this result on composition for UHECR had been achieved independently by AUGER via air shower morphology composition models. Last years (2014-2015) we noted that also NGC 253 in AUGER and M82 in Telescope Array anisotropy, (both nearby star bust galaxy or AGN) were crowding UHECR events, confirming the local UHECR understanding by sources as Cen A, M82, NGC 253. Most of these results had been achieved once again later and shown only recently, 2018, by AUGER collaboration. We claim therefore that there is a new reading key for UHECR and also CR. Additional new views for the tens EeV dipole anisotropy will be shown for the first time. E1.5-0072-18 COSMIC RAY ORIGIN: WHY COSMIC RAY PHENOMENON IS UNIVERSAL IN THE UNIVERSE?

Lev Dorman, lid010529@gmail.com

Tel Aviv University, Moscow, Tel Aviv, Russia

Usually, when are talking on the origin of Cosmic Rays (or Astroparticles), have in view protons, nucleus of different Z, electrons, gamma-quants, and neutrino of high and very high energy generated in our Galaxy and in different astrophysical objects in the Universe, outside the Galaxy. Moreover, during many years energetic particles generated on the Sun were called as Solar Cosmic Rays (SCR), but now increased the tendency to rename this phenomenon as Solar Energetic Particles (SEP) event. We will show that SEP, energetic particles generated in magnetospheres of the Earth, Jupiter, Saturn and other planets, in interplanetary space, and in atmospheres of stars have the same nature as Galactic and Intergalactic CR: they are all runaway particles from the MaxwellBoltzmann distribution of background plasma where they were generated. Energy of these run-away particles is much higher than average energy of background thermal particles. We will show in our report that the energy of all these run-away particles have the same general nature: it is always transfer energy from the Macro-objects and Macroprocesses directly to charged particles. This transfer energy is formatted in dynamic plasma with frozen in magnetic fields: really magnetic fields 'glues' thermal background particles in Macro-objects and Macro-processes involved milliards thermal particles. Through magnetic fields run-away particles can interact not only with thermal background particles (and loose energy), but also directly with Macro-objects and Macro-processes with very high macro-energy (many order higher than energy of run-away particle). We come to conclusion that main cause of origin of all types of Cosmic Rays in the Universe is the transform energy from Macroworld directly to Micro-world through frozen in magnetic fields in plasmas. At the stage when in early Universe were formatted small density plasmas objects with magnetic fields, where formatted also Cosmic Rays of different types. We consider also the problem of formatting energy spectrum of different types of CR.

E1.5-0074-18 SOLUTION OF INVERSE PROBLEM FOR TRANSPORT OF ULTRA-HIGH ENERGY COSMIC RAYS IN THE INTERGALACTIC SPACE: DETERMINATION OF SOURCE SPECTRUM AND COMPOSITION

Vladimir Zirakashvili, zirak@izmiran.ru

Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation of the Russian Academy of Sciences (IZMIRAN), Troitsk, Moscow Region, Russia

Vladimir Ptuskin, vptuskin@hotmail.com

Pushkov Institute of Terrestrial Magnetism, Ionosphere and Radio wave propagation of Russian Academy of Sciences, Moscow, Russia

Svetlana Rogovaya, rogovaya@izmiran.ru

Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation of the Russian Academy of Sciences (IZMIRAN), Troitsk, Russia

Evgeny Klepach, eklepach@trtk.ru

Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation of the Russian Academy of Sciences (IZMIRAN), Russia

The inverse problem of cosmic ray transport of ultra-high energy cosmic rays is considered. The source spectrum and composition is derived based on the Auger data on energy spectrum, energy dependence of mean logarithm of atomic mass number and its variance. The regularization procedure for considered ill-posed problem and the statistical analysis of experimental data are employed.

E1.5-0075-18 ANOMALIES IN POSITRON AND ANTIPROTON SPECTRA OF GALACTIC COSMIC RAYS: POSSIBLE EXPLANATIONS

Mikhail Malkov, mmalkov@ucsd.edu

University of California, San Diego, La Jolla, California, United States Patrick Diamond, pdiamond@ucsd.edu

UCSD, 92093-0424, United States Roald Sagdeev, rsagdeev@gmail.com

University of Maryland, College Park, Chevy Chase, Maryland, United States

The unexpected energy spectrum of the positron/electron ratio is interpreted astrophysically, with a possible exception of the 100-300 GeV range. The data indicate that this ratio, after a decline between 0.5-8 GeV, rises steadily with a trend towards saturation at 200-400GeV. These observations (except for the trend) appear to be in conflict with the diffusive shock acceleration (DSA) mechanism, operating in a single supernova remnant (SNR) shock. We argue that positron/electron ratio can still be explained by the DSA if positrons are accelerated in a subset of SNR shocks which: (i) propagate in clumpy gas media, and (ii) are modified by accelerated CR protons. The protons penetrate into the dense gas clumps upstream to produce (secondary) positrons and, charge the clumps positively. The induced electric field expels positrons into the upstream plasma where they are shock-accelerated. Since the shock is modified, these positrons develop a harder spectrum than that of the CR electrons accelerated in other SNRs. Mixing these populations explains the increase in the positron/electron ratio at $E>8$ GeV. It decreases at $E<8$ GeV because of a subshock weakening which also results from the shock modification. Contrary to the expelled positrons, most of electrons are left unaccelerated inside the clumps. Antiprotons, generated at the cloud edges are not retained in the cloud, contrary to the light electrons. Scenarios for the 100-300 GeV AMS-02 fraction exceeding the model prediction, including, but not limited to, possible dark matter contribution, are also discussed.

E1.5-0076-18 NEW INSIGHTS IN THE PROPAGATION MODELS IN THE LIGHT OF AMS02 SECONDARY FLUXES.

Yoann Genolini, yoann.genolini@ulb.ac.be Université Libre de Bruxelles, Bruxelles, Belgium CRAC (Cosmic Rays Alpine Colaboration)

Yoann Génolini, Pasquale D. Serpico, Mathieu Boudaud, Sami Caroff, Vivian Poulin, Laurent Derome, Julien Lavalle, David Maurin, Vincent Poireau, Sylvie Rosier, Pierre Salati and Manuela Vecchi.

Secondary to primary ratios, freshly published by AMS-02 are decisive for the understanding of Galactic cosmic-rays propagation mechanisms. In turn, the propagation models are a crucial ingredient for testing astrophysical scenarios as well as indirect dark matter searches. Focusing on the boron to carbon ratio (B/C) at high-energy we find indications (decisive evidence, in Bayesian terms) in favor of a diffusive propagation origin for the broken power-law spectra found in protons (p) and helium nuclei (He). I will show that this result is robust with respect to currently estimated uncertainties in the cross sections, and in the presence of a small component of primary boron, expected because of spallation at acceleration sites. At lower energies, around 1GeV/nuc, several effects are competing. I will discuss the different models allowed by the data, and the emerging indications which call for refinements of the standard cosmic-rays production and diffusion models. Theoretical uncertainties and limitations affecting the interpretation of the data will be highlighted.

E1.5-0077-18 COSMIC RAYS AND ASSOCIATED MULTIFREQUENCY OBSERVATIONS OF THE INTERSTELLAR EMISSION

Elena Orlando, orlandele@gmail.com

Stanford University, Stanford, California, United States

The interactions of cosmic rays with the interstellar medium and magnetic field produce diffuse emissions that span the electromagnetic spectrum from radio to gamma rays. Observations of this diffuse emission are an invaluable tool for understanding densities and spectra of CRs in different places of our Galaxy.

We present our results on cosmic-ray properties by combining multi-frequency observations of the interstellar emission, from radio to gamma rays, and latest cosmic-ray direct measurements with propagation models.

E1.5-0078-18 ARE RUNAWAY O-STAR BOW SHOCKS CAPABLE OF ACCELERATING COSMIC RAYS?

Blagoy Rangelov, rangelov@txstate.edu

Texas State University, San Marcos, Texas, United States Thierry Montmerle, thierry.montmerle@iap.fr

Institut d'Astrophysique de Paris, Paris, France Steven Federman, steven.federman@utoledo.edu University of Toledo, Toledo, Ohio, United States Patrick Boisse, boisse@iap.fr

IAP, Paris, France

Stefano Gabici, stefano.gabici@apc.univ-paris7.fr Laboratoire APC, Paris, France

In the long-standing quest to understand the origin of cosmic rays and how they can acquire their enormous energies, particle acceleration by shock waves is thought to play a central role. Massive runaway stars moving supersonically through the interstellar medium (ISM) are known to produce bow shocks detected through their associated infrared (IR) emission, and it has been speculated that these bow shocks can accelerate particles to very high energies, even producing cosmic rays. Here, we present preliminary results of our Chandra observations of the field centered on the runaway star AE Aur and its well characterized bow shock. Previous XMMNewton observations revealed an X-ray "blob", located near the well-known IR arc, possibly a nonthermal source consistent with models of inverse Compton scattering of dust IR photons by electrons accelerated within the bow shock. The previous conclusions for AE Aur were based on relatively poor spatial coincidence between the X-ray "blob" and the IR arc. In contrast, our Chandra data, while confirming the XMM-Newton results, neither show a spatial coincidence with the bow shock, nor confirm a non-thermal spectrum. We conclude that in the AE Aur case, there is no observational evidence for cosmic-ray (electron) acceleration by the shock.

E1.5-0079-18 COSMIC-RAY ACCELERATION IN ETA CARINAE

Roland Walter, roland.walter@unige.ch ISDC, Versoix, Switzerland

Matteo Balbo, matteo.balbo@unige.ch ISDC, Versoix, Switzerland

Christos Panagiotou, christos.panagiotou@unige.ch ISDC, Versoix, Switzerland

Galactic cosmic-rays are likely produced through Fermi acceleration processed in supernova remnant shocks and other exotic sources. Identifying the different contributors to cosmic ray acceleration in galaxies is fundamental to understand galactic processes, how Fermi acceleration works in various environments, and the feed-back between cosmic-ray acceleration, galactic magnetic fields and the dynamics of the interstellar medium. Variable sources are interesting targets to study particle shock acceleration as the correlated observations in various energy bands provide key signatures of the physical processes at play and allow to understand how particle acceleration takes place and the luminosity of the source in the different particle species. Particle acceleration in stellar wind collision can be particularly well studied in η Carinae, the most luminous massive colliding wind binary system of our Galaxy and the first one to have been detected at very high energies without hosting a compact object. Most of the shock power is released on both sides of the wind collision zone downstream of the wind-collision region.

The photon-photon opacity could also be estimated as < 10−2, excluding a significant effect on the observed GeV spectrum. γ-ray observations can probe the magnetic field and shock acceleration in details. The quality of the current data below 100 MeV and above 1 GeV does not yet provide enough information to test hydrodynamical models including detailed radiation transfer (inverse-Compton, pion emission, photo-absorption). eAstrogam and CTA will provide a wealth of information and allow to test the conditions and the physics of the shocks at a high level of details. η Carinae could yield to 1048−49 erg of cosmic-ray acceleration, a number close to the expectation for an average supernova remnant.

E1.5-0081-18 INTENSE ELECTROMAGNETIC WAVE EMISSION IN RELATIVISTIC MAGNETIZED SHOCKS

Masanori Iwamoto, iwamoto@eps.s.u-tokyo.ac.jp University of Tokyo, Tokyo, Japan

Takanobu Amano, amano@eps.s.u-tokyo.ac.jp University of Tokyo, Tokyo, Japan

Yosuke Matsumoto, ymatumot@chiba-u.jp Chiba University, Chiba, Japan

The origin of high energy cosmic rays (>1015.5eV) has not been fully understood, and the acceleration mechanism is still controversial. Recently Chen et al. (2002) proposed the particle acceleration by the large-amplitude Alfvén waves at gamma-ray bursts as a model of the generation of ultra-high energy cosmic rays (>1018eV), based on the wakefield acceleration (WFA) mechanism which was initially proposed by Tajima and Dowson (PRL, 1979) in the context of laser-plasma interactions in the laboratory. The WFA in laboratory is induced by an intense laser pulse (or transverse electromagnetic waves) propagating in a plasma. The mechanism may also operate in relativistic shocks in nature because it is known that large-amplitude electromagnetic precursor waves are excited by synchrotron maser instability (SMI) driven by the particles reflected off the shock-compressed magnetic field in relativistic shocks (Hoshino and Arons, 1991). In fact, Hoshino (2008) demonstrated the generation of the non-thermal electrons by the wakefield induced by the ponderomotive force of the electromagnetic precursor waves in relativistic magnetized shocks by means of 1D PIC simulation.

In multidimensional systems, it is well known that Weibel instability (WI) develops in the transition region of weakly magnetized shocks. Previous PIC simulation studies in multiple dimensions indeed showed that the shock transition is dominated by the WI at low magnetization. Since both WI and SMI are excited from the same free energy source in the same region and the growth rate of the WI is larger than that of the SMI at low magnetization, it was believed that the WI dominates over the SMI and the precursor wave emission could be shut off in multidimensional shocks.

Recently, by using 2D PIC simulations, we have shown that the SMI can coexist with the WI and that the precursor wave emission continues to persist to the Weibel-dominated regime (Iwamoto et al. 2017). We also showed that the wave power is sufficient enough to induce wakefield for a wide range of magnetization parameter. However, the WFA did not operate in our previous simulation in pair plasmas because the finite mass ration between positive and negative charges is essential for the WFA. To investigate the feasibility of the WFA in relativistic shocks, we carried out 2D simulations in ion-electron plasmas. We found that the wakefield is indeed induced in the upstream. In this presentation, we discuss the acceleration mechanism.

E1.5-0082-18 THE STRONG SURFATRON ACCELERATION OF RELATIVISTIC ELECTRONS BY ELECTROMAGNETIC WAVE PACKET IN CLOSEST INTERSTELLAR CLOUDS

Rumen Shkevov, shkevov@space.bas.bg

Space Research Institute, Russian Academy of Sciences, Moscow, Russia

The Cherenkov resonant interaction between an electromagnetic wave packet and relativistic electrons in the space plasma based on digital calculations is investigated. The strong surfatron acceleration of electrons (having their initial energies about GeV) up to energies at the cosmic rays knee in the particles energy spectrum is considered. The electric field amplitude in the central area of the wave packet must be above the threshold value. Thereby, if Cherenkov resonance conditions are met, it becomes possible for the wave packet to capture electrons in the surfing acceleration mode. The research is carried out by numerically solving second order nonlinear, nonstationary equations for the wave packet phase on the particle's trajectory at the packet carrying frequency. For small enough difference between the component of particle velocity along the wave packet direction of propagation and the wave phase velocity, the numerical calculations reveal that the trapping of relativistic electrons in strong surfatron acceleration occurs immediately for a wide enough range of favorable initial wave phase values at the particle's trajectory. It has been demonstrated that the combination of ranges of the particle's initial parameters corresponding to the capturing in surfatron acceleration mode is large enough, so the possibility for important practical applications become real. The temporal dynamics of momentum components and velocities for accelerated particles, the particularities of their trajectories, taking into account the possibility of cyclotron rotation at the initial stage and the phase plane structure for digitally solved nonlinear equation are considered for selected initial sets of parameters. Simulation results allow us to draw conclusions about the possibility of ultrarelativistic surfatron acceleration of electrons in space plasma by an electromagnetic waves packet in the closest plasma interstellar clouds up to 'knee' energy. It is obvious that such strong acceleration may cause large enough variations of the cosmic rays spectrum observed in the solar system.

E1.5-0083-18 PRODUCTION OF ULTRA-HIGH-ENERGY PARTICLES IN THE VICINITY OF SUPERMASSIVE BLACK HOLES.

Arman Tursunov, arman.tursunov@fpf.slu.cz

Silesian University in Opava, Opava, Czech Republic

Origin and mechanism of production of ultra-high-energy (UHE) particles with energies above 1020 eV in cosmic rays detected by several cosmic ray observatories still remain the subject of discussion. It is generally believed that the sources of such particles should be of extragalactic origin. I will show that UHE particles can be produced in the dynamical environment and close vicinity of supermassive black holes (SMBH) located at the centers of galaxies by extracting out the rotational energy of the central SMBH within a neutron beta-decay. Assuming the presence of astrophysically relevant magnetic fields and taking into account the back-reaction force of individual charged particles, we put constraints on the mass of SMBH and magnetic fields in its vicinity to produce UHE particles within the model. From this, it follows that these are more likely protons, which may escape from SMBH, while Sgr A* at the Galactic center cannot serve as a source of such UHE particles, mainly due to its relatively low mass.

The NUCLEON satellite experiment is aimed to directly measure the energy spectra of cosmicray nuclei and the chemical composition (Z=130) in the energy range of 2-500 TeV. Energy measurements are performed by two different methods (ionization calorimeter and the new Kinematic Lightweight Energy Meter (KLEM) technique). Energy spectra of different abundant nuclei are presented. Spectral peculiarities are found and discussed.

HERD(High Energy Cosmic Radiation Detection) facility is one of the Cosmic Lighthouse Programs onboard China's Space Station. The main science objectives of HERD are indirect dark matter particles search, cosmic ray spectrum and composition measurements and high energy gamma-ray observations. The Silicon TracKer (STK) inherited from DAMPE is one of the main payloads of HERD. A new readout electronics system based on ASIC-IDE1162 is developed for charge measurement of STK. Here, we present the performance measurements and the preliminary ion beam test results.

E1.5-0090-18 STATUS AND TRIGGER EFFICIENCY OF THE TOP AND BOTTOM COUNTING DETECTORS OF THE ISS-CREAM EXPERIMENT ON THE INTERNATIONAL SPACE STATION

The Cosmic Ray Energetics And Mass (CREAM) instrument on the International Space Station (ISS) is designed to study the origin, acceleration and propagation mechanism of high energy cosmic rays. The ISS-CREAM detector was launched on the 14th of August 2017 to the ISS aboard the SpaceX-12 Dragon spacecraft. The Top Counting Detector (TCD) and Bottom Counting Detector (BCD) are parts of the detector suite of the ISS-CREAM instrument and they are designed to separate electrons and protons for studying electron and gamma-ray physics. The TCD/BCD separate electrons from protons using differences in shapes between electromagnetic and hadronic showers. In addition, the TCD/BCD provide a redundant trigger to that from the calorimeter and a low energy trigger to the ISS-CREAM instrument. We can trigger on cosmic ray events from He to high-Z nuclei. At the ISS, the TCD/BCD status is stable, and the pedestal values are almost the same as those measured in ground tests. In this presentation, we will present the status and trigger efficiency of the TCD/BCD on the ISS.

E1.5-0091-18 SEARCH AND STUDY OF EXTENSIVE AIR SHOWER EVENTS WITH THE TUS SPACE EXPERIMENT.

Andrey Grinyuk, andrei.grinyuk@gmail.com

Joint Institute for Nuclear Research, Dubna, Moscow Region, Russia Lomonosov - UHECR/TLE

The TUS experiment is designed to investigate the ultra high energy cosmic rays (UHECR) at energy 100 EeV from the space orbit by the UV radiation measurement of extensive air showers (EAS). It is the first orbital telescope aimed for such measurements and is taking data since April 28, 2016. TUS detector consists of a modular Fresnel mirror and a photo receiver matrix with a field of view 4.5° and the number of PMT pixels 16x16. The DAQ electronics has a main mode of operation with 0.8 µs temporal resolution and a 200 µs duration of measured waveforms. Spatial resolution in the atmosphere is 5 km with a total field of view of about 80x80 km^2. The TUS apparatus structure, methods of UHECR on-line selection and off-line data analysis are described. A few UHECR EAS candidates were found. Preliminary results of their investigation and comparison with the corresponding Monte-Carlo events are presented.

Institute of High Energy Physics, CAS, China, Beijing, China

The DArk Matter Particle Explorer (DAMPE) is one of the four satellites within the Strategic Pioneer Research Program in Space Science of the Chinese Academy of Science (CAS). The Silicon-Tungsten Tracker (STK), which is composed of 768 singled-sided silicon microstrip detectors, is one of the four subdetectors in DAMPE, providing track reconstruction and charge identification for relativistic charged particles. The charges sharing effect of STK was studied by charges-injection, SPICE simulation, test beam data and on-orbit data analysis. Based on this charges sharing effect, the on-orbit STK charge spectrum was reconstructed and shown.

E1.5-0093-18 ON PAIRED EVENTS OBSERVED BY YAKUTSK EAS ARRAY

Yu.G. Shafer Institute of Cosmophysical Research and Aeronomy of SB RAS, Yakutsk, Russia

The ultra-high energy cosmic ray database of Yakutsk extensive air shower array is analyzed. Attention is drawn to showers from particles with energy greater than 5 EeV coming one after another at intervals less than 20 hours and having approximately the same energy and arrival direction ("doublets"). The significant excess of the number of such events over the random distribution is found. The mass compositions and arrival directions of doublets are analyzed. Possible mechanisms for the origin of such doublets are discussed.

E1.5-0094-18 SEARCH DARK MATTER OF THE GALAXY

Aleksei Mikhailov, mikh@ikfia.sbras.ru

Institute of Cosmophysical Research and Aeronomy SB RAS, Yakutsk, Russia

We analyzed distribution particles in celestial sphere by data Yakutsk array at energy E 8×1018 eV. It is consider arrival directions of extensive air shower (EAS) or particles with zenith angles $\vartheta<60°$ and cores located inside the array perimeter. We consider primary particles with energies

E 5.7×1018 eV. Energy of particles determined by registration Cherenkov light with accuracy's 30% and angles 5-7°. We have found correlation arrival directions of ultrahigh energy E<4×1019

eV particles with the positions of pulsars and anisotropy of arrival directions of these particles from side of the galactic plane by Yakutsk array data and Telescope array data at energy E>5.7×1019 eV at high galactic latitudes. 0ur analyses of data show that observed cosmic rays up to 4×1019 eV are galactic and above this energy most likely extragalactic. Detectors which registered particles each had area 2 m2 and they are situated at area S<10 km^2 and we choice EAS (extensive air showers) inside this area 10 km^2 and at energy above E>1018 eV.

E1.5-0095-18 MINI-EUSO: A MISSION ON THE INTERNATIONAL SPACE STATION FOR THE STUDY OF TERRESTRIAL AND COSMIC UV EMISSION

Valentina Scotti, scottiv@na.infn.it INFN, Napoli, Italy

Giuseppe Osteria, osteria@na.infn.it INFN - Napoli, Naples, Italy

The Mini-EUSO space experiment ("UV atmosphere" in Russian Space Program) aims to perform observations of the UV-light night emission from Earth.

The scientific goal of the experiment is to map the earth in the UV range (300 - 400 nm) with a spatial resolution of 6.11 km and a temporal resolution of 2.5 s, offering the opportunity to study a variety of atmospheric events such as transient luminous events (TLEs) and meteors, as well as searching for strange quark matter and bioluminescence.

The mission is approved by the Italian Space Agency and the Russian Space Agency. Launch is foreseen between Autumn 2018 and beginning 2019.

The Mini-EUSO instrument is a UV telescope to be placed inside the International Space Station (ISS), looking down on the Earth from a nadir-facing, UV-transparent window in the Russian Zvezda module.

The instrument comprises a compact telescope with a large field of view, based on an optical system employing two Fresnel lenses for increased light collection. The light is focused onto an array of photo-multipliers and the resulting signal is converted into digital, processed and stored via the electronics subsystems on-board. The instrument is designed and built by the members of the JEM-EUSO collaboration.

In this paper, scientific, technical and programmatic aspects of this project will be described.

A new balloon experiment with small optical detector for registration of the Vavilov-Cherenkov radiation and the fluorescence light from the extensive air showers with energies 5 ∗ 1018 –

5 1019eV is proposed. The flights are planned in the polar night period at an altitude up to 30km above snow covered surface of Antarctica. Scientific novelty of this project is in the methodology

of the extensive air showers registration over a large area up to 600km^2, that allows to measure the two optical components of the shower - Vavilov-Cherenkov radiation and fluorescence light by the same sensitive element of the detector simultaneously. To obtain the most reliable data about the energy spectrum and mass composition of primary cosmic rays in the energy region 5 1018 5 1019eV is especially important in connection with the planned orbital experiments.

E1.5-0099-18 ARRRAY IN SATELLITES AND BALLOONS TO DETECT UHECR AND UHE UPGOING TAU NEUTRINO SKIMMING AIRSHOWERS, OFFERING ALSO STATIONS FOR INFRARED COSMIC RADIATION INTERFEROMETRY.

Daniele Fargion, daniele.fargion@roma1.infn.it

Physics Department, Rome University 1, INFN Rome 1„ Rome, Italy

The discover of UHECR and UHE neutrino it is widely approched in ground and underground (respectively) detector. However the Ultra High Energy Cosmic Ray (UHECR) and UHE neutrino tau may shine in Space too. Indeed there are several experiment like Jem-EUSO searching for the upgoing view of luminescent UHECR trail in air at night. We propsed since 1999-2002 to reveal UHE tau neutrino by their induced tau airshower upgoing the horizons. The same UHECR might be tested at different angles as skimming airshower and blazing at Earth boundaries observable by mountains, balloons or satellites. The UHECR composition reflects into the angular distribution and their corresponding slanth depth, offering a filter and a spetroscopy of UHECR events. We suggested the ISS with several detector elements in its extreme edges as a main location for such an array detector. However also nano satellite cooperative and in array flight possibly along ISS may test wide area airshower signals by their gamma, X, radio correlated triggered signals. Rate for future array in Space and in ISS will be shown in detail. Also a new Cherenkov optical array telescope geometry detector, ideal for crown detection in space, will be shown for the first time. The UHECR filtered sinals at different angle and different slanth depth might better calibrate the UHECR composition, while the upgoing air shower below the Earth horizons and its polarization will probe for the first time tau airshower (tens PeV-EeV) existence. The same satellite or ISS element array system may be also used for an interferometric radio detection of Cosmic Background leading to highest angular resolution of cosmic millimeter Big Bang radiation.

E1.5-0100-18 SUBARU OBSERVATIONS OF H-ALPHA FILAMENTS OF THE CYGNUS LOOP AND TYCHO'S SUPERNOVA REMNANTS

Satoru Katsuda, katsuda@phy.saitama-u.ac.jp Saitama University, Saitama, Japan

Subaru Supernova-Remnant Team

Keiichi Maeda, Yutaka Ohira, Yoichi Yatsu, Koji Mori, Wako Aoki, Kumiko Morihana, John Raymond, Parviz Ghavamian, Jae-Joon Lee, Jiro Shimoda, Ryo Yamazaki, Yasuyuki Tanaka, Sladjana Knezevic, John Martin Laming

We present high-resolution long-slit spectroscopy of a Balmer-dominated shock in the northeastern limb of the Cygnus Loop with the Subaru HDS (Katsuda et al. 2016, ApJ, 819, L32). By setting the slit angle along the shock normal, we investigate variations of the flux and profile of the H-alpha line from preshock to postshock regions with a spatial resolution of about 4e15 cm. The H-alpha line profile can be represented by a narrow (28.9 +/- 0.7 km/s) Gaussian in a diffuse region ahead of the shock, i.e., a photoionization precursor, and narrow (33.1 +/0.2 km/s) plus broad (130–230 km/s) Gaussians at the shock itself. We find that the width of the narrow component abruptly increases up to 33.1 +/- 0.2 km/s, or 38.8 +/- 0.4 km/s if we eliminate projected emission originating from the photoionization precursor, in an unresolved thin layer (4e15 cm at a distance of 540 pc) at the shock. We show that the sudden broadening can be best explained by heating via damping of Alfven waves in a thin cosmic-ray precursor, although other possibilities are not fully ruled out.

We also recently performed spectrally resolved polarimetry of Tycho's knot g with Subaru FOCAS. Our observation is similar to the pioneering work by Sparks et al., 2015, ApJL, 815, L9 who measured 2% polarization at the H-alpha filament (narrow component) in the northwestern limb of SN 1006. Given that the cosmic-ray acceleration efficiency at Tycho's knot g appears to be higher than that in the northwestern limb of SN 1006, we expect a higher polarization in Tycho's knot g (Shimoda et al. 2015, MNRAS, 473, 1349). We will present our preliminary results.

E1.5-0101-18 AN INVESTIGATION OF THE INTERSTELLAR ENVIRONMENT OF SUPERNOVA REMNANT CTB 87

Qian-cheng Liu, qcliu@smail.nju.edu.cn

Department of Astronomy, Nanjing University, Nanjing, China

We present a new millimeter CO-line observation towards supernova remnant (SNR) CTB 87, which was regarded purely as a pulsar wind nebula (PWN), and an optical investigation of a coincident surrounding superbubble. The CO observation shows that the SNR delineated by the radio emission is projectively covered by a molecular cloud (MC) complex at VLSR = 60

54km s−1. Both the symmetric axis of the radio emission and the trailing X-ray PWN

appear projectively to be along a gap between two molecular gas patches at 58- 57km s−1. Asymmetric broad profiles of 12CO lines peaked at 58km s−1 are found at the eastern and southwestern edges of the radio emission. This very probably represents a kinematic evidence of the SNR-MC interaction. We also find that a superbubble, 371 in radius, appears to surround the SNR from HI 21cm (VLSR 61- 68km s−1), WISE mid-IR, and optical extinction data.

We build a multi-band photometric stellar sample of stars within the superbubble region and find 82 OB star candidates. The likely peak distance in the stars' distribution seems consistent with the distance previously suggested for CTB 87. We suggest the arc-like radio emission is mainly the relic of the part of blastwave that propagates into the MC complex and is now in a radiative stage while the other part of blastwave has been expanding into the low-density region in the superbubble. This scenario naturally explains the lack of the X-ray emission related to the ejecta and blastwave. The SNR-MC interaction also favours a p-p hadronic contribution to the gamma-ray emission from the CTB 87 region, as the GeV-TeV gamma-ray spectrum could be well fitted with the molecular gas density estimated in this work (~ 80cm−3).

E1.5-0102-18 MEASUREMENT OF LOW-ENERGY COSMIC RAYS IN SUPERNOVA REMNANTS VIA NEUTRAL IRON LINE

Kumiko Nobukawa, kumiko@cc.nara-wu.ac.jp Nara Women's University, Nara, Japan Shigetaka Saji, s_saji@u.phys.nagoya-u.ac.jp Nagoya University, Nagoya, Japan

Katsuji Koyama, koyama@cr.scphys.kyoto-u.ac.jp Kyoto University, Kyoto, Japan

Supernova remnants (SNRs) have been prime candidates for Galactic cosmic-ray accelerators. Gamma-ray observations have revealed that protons and/or electrons are accelerated to energies up to 100 TeV in SNRs. In diffusive shock acceleration, suprathermal particles (low-energy cosmic rays; LECRs) are accelerated to relativistic energy through multiple crossings of the shock front. Thus, the energy spectra and fluxes of the LECRs in SNRs provide a key link to generation of the GeV and TeV cosmic rays in SNRs. However, there has been very few observation of LECRs below the MeV band due to the lack of an effective probe to investigate them. When LECRs collide with interstellar gas, they ionize neutral iron atoms and emit the neutral iron line at 6.4 keV. We have started a campaign to search for the 6.4 keV line in SNRs with the Suzaku archive data. We have already discovered the line emission from more than 10 SNRs [1-3]. The spectra and morphologies suggest that the 6.4 keV line is produced by interactions between LECR protons and the adjacent cold gas. The proton energy density is estimated to be 10–100 eV/cc, which is more than 10 times higher than that in the ambient interstellar medium. In this presentation, we also discuss an association between the 6.4 keV line and gamma rays.

[1] Nobukawa et al. 2018, ApJ, 854, 87 [2] Saji et al. 2018, PASJ, in press, [3] S. Saji, Ph.D. thesis, Nagoya University, 2018

E1.5-0103-18 DISCOVERY OF A 6.4 KEV EMISSION LINE IN THE SUPERNOVA REMNANT IC 443: FLUORESCENCE INDUCED BY LOW-ENERGY COSMIC RAYS?

Arisa Hirayama, raa_hirayama@cc.nara-wu.ac.jp Nara Women's University, Nara, Japan

Kumiko Nobukawa, kumiko@cc.nara-wu.ac.jp Nara Women's University, Nara, Japan Shigeo Yamauchi, yamauchi@cc.nara-wu.ac.jp Nara Women's University, Nara, Japan

Katsuji Koyama, koyama@cr.scphys.kyoto-u.ac.jp Kyoto University, Kyoto, Japan

Masayoshi Nobukawa, nobukawa@nara-edu.ac.jp Nara University of Education, Nara, Japan

Hideki Uchiyama, uchiyama.hideki@shizuoka.ac.jp Shizuoka University, Shizuoka, Japan

Akiko Ono, raa_ono@cc.nara-wu.ac.jp Nara Women's University, Nara, Japan

IC 443 is a middle-aged supernova remnant (SNR) in our galaxy. A gamma-ray spectrum of IC 443 shows a pion-decay signature, which means that cosmic-ray protons are accelerated in the SNR (Ackermann et al. 2013, Sci, 339, 807). Since pion production requires cosmic-ray protons with > 280 MeV, gamma-ray observations cannot constrain low-energy cosmic rays (LECRs). Observations of H+ absorption lines revealed that the ionization rate of H2 is large in IC 443 (Indriolo et al. 2010, ApJ, 724, 1357). This suggests that a large amount of LECRs are produced. However, H+ observations cannot provide the information on energy density of LECRs. When LECRs collide with the surrounding interstellar material, they ionize the neutral iron in it and emit a fluorescent X-ray at 6.4 keV (Tatischeff et al. 2012, A&A, 546, 24). Since IC 443 interacts with molecular clouds, accelerated particles can collide with them to produce the 6.4 keV line. Analyzing the Suzaku archive data of IC 443, we discovered the

6.4 keV line with a significance level of 3 σ. We measured the spatial intensity distribution of the 6.4 keV line and found that the high-intensity region contains the site where the large ionization rate was observed. The 6.4 keV line would be produced by LECRs with the energy density of 10 – 100 eV/cc for protons and 0.01 – 0.1 eV/cc for electrons.

E1.5-0104-18 A STUDY OF FERMI-LAT GEV GAMMA-RAY EMISSION TOWARD THE MAGNETAR-HARBORING SUPERNOVA REMNANT KESTEVEN 73 AND ITS MOLECULAR ENVIRONMENT

We report our independent GeV γ-ray study of the young shell-type supernova remnant (SNR) Kes 73, which harbors a central magnetar, and CO-line millimeter observations toward the SNR. Using 7.6 years of Fermi-LAT observation data, we detected an extended γ-ray source ("source A") with centroid on the west of the SNR, with a significance of 21 in 0.1-300 GeV and an error circle of 5 4 in angular radius. The γ-ray spectrum cannot be reproduced by a pure leptonic emission or a pure emission from the magnetar, and thus a hadronic emission component is needed. The CO-line observations reveal a molecular cloud (MC) at VLSR 90 km/s, which demonstrates morphological correspondence with the western boundary of the SNR brightened in multiwavelength. The 12CO (J=2-1)/12CO (J=1-0) ratio in the left (blue) wing 85-88 km/s is prominently elevated to 1.1 along the northwestern boundary, providing kinematic evidence of the SNR-MC interaction. This SNR-MC association yields a kinematic distance 9 kpc to Kes 73. The MC is shown to be capable of accounting for the hadronic γ-ray emission component. The γ-ray spectrum can be interpreted with a pure hadronic emission or a magnetar+hadronic hybrid emission. In the case of pure hadronic emission, the spectral index of the protons is 2.4, very similar to that of the radio-emitting electrons, essentially consistent with the diffusive shock acceleration theory. In the case of magnetar+hadronic hybrid emission, a magnetic field decay rate >~ 1036 erg/s is needed to power the magnetar's curvature radiation.

Supernova remnant (SNR) N132D, located in the Large Magellanic Cloud, represents a unique opportunity for the study of gamma-ray emission from shock-accelerated cosmic rays (CRs) in another galaxy since it stands as the first and only extra-galactic SNR detected in gamma-rays. N132D is one of the brightest SNRs in the local Universe in the X-ray, infrared and radio bands, and it has also been detected in TeV energy gamma-rays. N132D's apparent interaction with a giant molecular cloud strongly favors the scenario where the gamma-ray emission results from CR hadrons interacting with dense ambient media. We report on the detection of N132D with the Fermi-LAT, and by characterizing its emission in the MeV-GeV band, as well as constraining the non-thermal contribution to the X-ray spectrum using Chandra observations, we build a very complete picture of the properties of the system and its progenitor, ultimately helping us better understand CR acceleration in SNRs.

E1.5-0106-18 INTERGALACTIC HADRONIC CASCADE MODEL OF BLAZAR EMISSION: BASIC IDEAS, SIGNATURES AND DIFFICULTIES

Timur Dzhatdoev, timur1606@gmail.com

Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russia

Blazars can emit extremely high energy protons and nuclei. If the extragalactic magnetic field in voids of the large scale structure is small enough, gamma-rays from intergalactic electromagnetic cascades initiated by these primary protons or nuclei contribute to observable emission of these sources. Using a novel, fast and precise enough hybrid approach, we discuss in details the observability of these cascade gamma-rays. Assuming a realistic emission model of blazar 1ES 0229+200, we calculate its observable spectrum, accounting for the effect of magnetic fields around the source and in large scale structure between the source and the observer on the spectrum. We show that the observable spectrum shape is mainly determined by the size of the first void. Furthermore, we show that under the above-mentioned assumptions the model of [W. Essey et al., Phys. Rev. Lett., 104, 141102 (2010)] is excluded with statistical significance $Z>7\sigma$. This conclusion is stable with respect to the major astrophysical uncertainties of the model. The details of these calculations are available in our paper [AA, 603, A59 (2017), Sect. 2, Sect. 4 and Sect. 5].

E1.5-0107-18 THE NAKED ORION: A MYSTERIOUS GAMMA-RAY EMISSION MAYBE DUE TO COSMIC RAY ACCELERATION.

Martina Cardillo, martina.cardillo@iaps.inaf.it INAF-IAPS, ROMA, Italy

Nicola Marchili, nicola.marchili@gmail.com IAPS-INAF, ROMA, Italy

Giovanni Piano, giovanni.piano@iaps.inaf.it IAPS-INAF, ROMA, Italy

The Orion region is expected to emit a large amount of diffuse gamma-ray radiation because of the large amount of interstellar medium in its surroundings. We modelled the AGILE data from that region through a template that quantifies the gamma-ray diffuse emission expected from atomic and molecular hydrogen, together with an isotropic contribution. In the excess map, appears an "arc-like" gamma-ray emission with high significance in the high-longitude part of Orion A, confirming previous results from Fermi-LAT. However, we do not think that this emission is correlated with some inaccuracy in the relation between H2 and CO fraction. We think that this emission could be due to Cosmic Ray acceleration in the Termination Shock of k-Orionis wind. Here we present a preliminary spectrum from the excess region and some preliminary attempts of CR acceleration models

Pulsar wind nebulae (PWNe) are magnetised ultra-relativistic particle clouds around neutron stars. They are considered as plausible sources of the primary cosmic-ray positron component observed above 10 GeV. They have also been proposed as candidates instigating a hadronic Galactic cosmic-ray component at energies above the spectral "knee". In this contribution, we aim to shed light on the mechanisms of the transport of accelerated particles from the PWN into the surroundings of the host supernova remnant (SNR) and ultimately into the interstellar medium, by studying in greater detail the morphology of the very-high-energy (VHE) gammaray emission of a PWN.

The composite SNR MSH 15-52 encloses the bright X-ray PWN of PSR B1509-58. In 2005,

H.E.S.S. discovered extended VHE gamma-ray emission coincident with this PWN. We study its gamma-ray morphology with additional H.E.S.S. observations, by modelling the synchrotronemitting particles using an X-ray template and by making assumptions on the magnetic field within. We find a distinct VHE emission component extending beyond the X-ray nebula, and examine the energy dependence of its shape. We discuss the consequences of this morphology for lepton transport from the PWN and explore the possibility and implications of a hadronic gamma-ray emission component, thus probing the validity of PWNe as cosmic ray sources in the Milky Way.

RESEARCH IN ASTROPHYSICS FROM SPACE (E)

SPECTRAL MEETS TIMING: A GLOBAL APPROACH TO ACCRETION ONTO COMPACT OBJECTS (E1.6)

E1.6-0001-18 X-RAY REVERBERATION IN ACCRETING BLACK HOLE SYSTEMS

Barbara De Marco, bdemarco@camk.edu.pl

Nicolaus Copernicus Astronomical Center, Warsaw, Poland

Accreting black hole (BH) systems are characterized by strong, aperiodic variability on a wide range of time scales. The variable primary X-ray radiation interacts with any surrounding matter, including the accretion disc. Short light travel time delays are expected between the primary and the reprocessed emission in the disc. These, so-called "X-ray reverberation lags" can be used to map the geometry of the very inner regions of the accretion flow. I will review recent studies of X-ray reverberation lags in accreting BH systems, discussing the analogies between X-ray reverberation lags in active galactic nuclei (AGN) and in BH X-ray binaries (BHXRB), and showing how the latter give indirect evidence of evolving disc geometry during the outburst.

E1.6-0002-18 MAPPING CORONAL GEOMETRY WITH BROADBAND NOISE CONTINUUM LAGS

Phil Uttley, p.uttley@uva.nl

University of Amsterdam, Amsterdam, Netherlands Julien Malzac, julien.malzac@irap.omp.eu

IRAP, University of Toulouse / CNRS, Toulouse, France

Hard continuum lags have been observed in the broadband noise X-ray variability of accreting black holes since the late 1980s. Since they are seen in the power-law emission which dominates the hard spectral states, they should provide information about the corona or hot flow which produces that continuum. However, previous models for the hard lags either require scattering on very large scales (thousands of gravitational radii) or propagation of mass accretion fluctuations through a hot flow which is substantially radially-extended. Both explanations are inconsistent with the breadth of the iron line and the reverberation lags seen at high Fourier frequencies, which suggest relatively compact coronae (< 20 gravitational radii). We show how this problem can be resolved when the mass-accretion fluctuations propagate through the seed-photon producing disk before reaching (and heating) a compact central corona. The resulting coronal cooling followed by heating predicts the correct frequency and energy-dependent behaviour for the lags, both within the power-law and between the power-law and the disk blackbody emission. The continuum lags model can be combined with reverberation models to provide physically self-consistent explanations of the lags over a large range in time-scale, which can strongly constrain the coronal geometry.

E1.6-0003-18 SPECTRAL-TIMING MODELING OF RELATIVISTIC X-RAY REFLECTION FROM BLACK HOLES

University of Cambridge, Cambridge, United Kingdom

X-ray spectroscopy and timing analysis have been proven to be powerful tools in the study of accreting sources for over three decades; yet, their development and implementation remains largely independent. The synergy between these two techniques offers a potentially transformative new view to the physics of accretion in the strong gravity regime. Here we discuss the theoretical challenges in constructing an unified model for time-dependent relativistic Xray reflection in accreting compact objects. The self-consistently merging the best spectral and timing reflection models allow us to make accurate predictions for observables such as flux-energy, lag-frequency, lag-energy spectra simultaneously. By modeling the response of the accretion disk to an external and variable source of X-rays, we explore the effects of local ionization and ionization gradients in the disk; study impact of geometry and location of the corona; and determine the role of disk's density and vertical extension. We briefly discuss current observational problems that can be addressed by these models in the context of accreting black holes.

E1.6-0004-18 MULTI-TIMESCALE X-RAY REVERBERATION MAPPING OF ACCRETING BLACK HOLES

Guglielmo Mastroserio, g.mastroserio@uva.nl University of Amsterdam, Amsterdam, Netherlands Adam Ingram, adam.ingram@physics.ox.ac.uk University of Oxford, Oxford, United Kingdom Michiel Van Der Klis, michiel@science.uva.nl University of Amsterdam, Amsterdam, Netherlands

Accreting black holes show reflection features in their X-ray spectrum, including an iron Kα line, which result from reprocessing of hard X-ray continuum photons illuminating the accretion disk. Measuring the reverberation lag caused by the differences in path length between direct and reflected emission, and the spectral distortions to the iron line caused by rapid orbital motion and gravitational redshift provides a powerful tool to probe the innermost regions around the black hole. Previous reverberation studies have largely ignored spectral variability of the illuminating continuum. We studied the effect of a pivoting continuum power-law which causes non-linear changes in the shape of the reflection spectrum, and developed an analytic description of the complex cross spectrum as a function of both energy and frequency. I will present our application of this new reverberation model to RXTE data from the black hole X-ray binary Cygnus X-1. We are able to jointly fit the time-averaged X-ray spectrum and the real and imaginary parts of the cross spectrum as a function of energy for a range of Fourier frequencies, thus utilising vastly more information than traditional spectral fitting. I will demonstrate we need to properly account for the continuum variability in order to correctly characterise the parameters of the system such as mass of the central object and inner radius and inclination of the accretion disc.

E1.6-0005-18 X-RAY REVERBERATION MAPPING IN ACTIVE GALACTIC NUCLEI

Erin Kara, ekara@astro.umd.edu

University of Maryland, College Park, College Park, United States

Accreting supermassive black holes can produce more electromagnetic and kinetic luminosities than the combined stellar luminosity of an entire galaxy. Most of the power output from an Active Galactic Nucleus is released close to the black hole, and therefore studying the inner accretion flow–at the intersection of inflow and outflow–is essential for understanding how black holes grow and how they affect their surrounding environments. In this talk, I will present a new results from X-ray reverberation mapping, which allows us to map the gas falling on to black holes and measure the effects of strongly curved spacetime close to the event horizon. I will present the results on several new campaigns aimed at probing the X-ray emitting corona and inner accretion disc in local Seyfert galaxies.

E1.6-0006-18 REVEALING THE STRUCTURE OF BLACK HOLE CORONAE, JETS AND ACCRETION DISCS THROUGH X-RAY REVERBERATION

Dan Wilkins, dan.wilkins@stanford.edu

Stanford University, Stanford, California, United States

From the reflection and reverberation of X-rays from the innermost regions of AGN accretion discs, a three-dimensional picture is starting to emerge of the structure of the disc and the corona producing the intense X-ray emission, as well of how the launching sites of jets may be connected to the corona and inner disc.

Spectral timing analysis of AGN observed by the great X-ray observatories, compared to the predictions of general relativistic ray tracing simulations, reveals not only the mechanisms of variability in the X-ray emission, but enables the structure of the corona and accretion disc to be mapped. We discover how the corona evolves on long and short timescales, giving rise to orders of magnitude variation in luminosity as well as the processes the corona can undergo during transient events, most notably the collimation and ejection of portions of the corona during X-ray flares, reminiscent of the aborted launching of a jet.

The latest X-ray reverberation studies are revealing, for the first time, structure within the corona including a persistent collimated core akin to the base of a jet, even in radio-quiet sources, alongside a second component associated with the accretion disc itself.

This gives us important insight into the small-scale processes close to the event horizon that enable supermassive black holes to power some of the most luminous objects in the Universe, launch vast jets at close to the speed of light and play their important feedback role in the formation of structure in the Universe.

E1.6-0007-18 MODELLING THE X-RAY FRMS VARIABILITY SPECTRUM OF ACTIVE GALACTIC NUCLEI

Labani Mallick, labani@iucaa.in

Inter University Centre for Astronomy and Astrophysics, Pune, India

Active Galactic Nuclei(AGN) are the centre of interest because of their complex broadband electromagnetic spectra and extreme variability ranging from radio, optical/Ultra-Violet (UV) to gamma-ray at the time-scales from a few minutes to hundreds of years depending upon the physical processes they are governed by. In order to understand the complex nature of AGN Xray variability, we developed the fractional root-mean-squared (FRMS) spectral model in ISIS (Interactive Spectral Interpretation System). This technique needs event file as input, derive the observed FRMS spectrum and then it calculates the model FRMS spectrum by varying the specified parameter of a user-defined energy spectral model. We have derived and modelled the FRMS variability spectra of different types of AGN and probed the underlying physical processes responsible for the observed X-ray variability of Seyfert galaxies. In this talk, I would like to present results of the X-ray variability spectral modelling for a number of AGN.

E1.6-0008-18 PROBING THE INNER ACCRETION REGION WITH A 2 MS OBSERVATION ON A NEARBY AND HIGHLY VARIABLE AGN

William Alston, wna@ast.cam.ac.uk

Cambridge University, Cambridge, United Kingdom Andy Fabian, acf@ast.cam.ac.uk

University of Cambridge, Cambridge, United Kingdom Erin Kara, ekara@astro.umd.edu

University of Maryland, College Park, College Park, United States Douglas Buisson, djkb2@cam.ac.uk

University of Cambridge, Cambridge, United Kingdom Michael Parker, mparker@sciops.esa.int

ESAC, Madrid, Spain

The fast timing properties of accreting black hole light curves allow us to probe the direct vicinity of black holes, the region most affected by strong gravity. We present an extensive X-ray variability analysis from a new 1.5 mega-second XMM-Newton VLP observation (plus 500 ks archival = 2Ms) of the highly variable Seyfert 1 galaxy, IRAS 13224-3809. This is the longest observation taken to date on a nearby variable AGN. This long observation has revealed complex underlying variability processes, displaying the first non-linear rms-flux relation in any accreting source. We will show modelling of the coronal and reverberation delays using GR ray tracing models. This allows us to build up the most detailed picture to date of the inner X-ray emitting regions of AGN. We discuss the implication of these results for accreting sources across the mass range.

E1.6-0008-18 BREAKING THE SPECTRAL DEGENERACIES OF BLACK HOLE BINARIES WITH FAST TIMING DATA

Magnus Axelsson, magnusa@astro.su.se Stockholm University, Stockholm, Sweden Chris Done, chris.done@durham.ac.uk Durham University, Durham, United Kingdom

The spectra of black hole binaries in the low/hard state are complex, with evidence for multiple different Comptonisation regions contributing to the hard X-rays, in addition to a cool disc component. However, it is difficult to constrain the shapes of these components uniquely using spectral data alone. Using observations of Cygnus X-1, we show that additional information from fast variability can break this degeneracy. Specifically, we use the observed variability power spectra to reconstruct the energy spectra of the variability on timescales of roughly 10 s, 1 s and 0.1 s. The two longer timescale spectra have similar shapes, but the fastest component is dramatically harder, and has strong curvature indicating that its seed photons are not from the cool disc. We discuss these results in the context of propagating fluctuations through a hot flow, where the outer regions are cooler and optically thick, so that they shield the inner region from the disc.

E1.6-0009-18 TIME DEPENDENT SPECTRUM OF AN X-RAY IRRADIATED ACCRETION DISC WITH STOCHASTIC PERTURBATIONS

Bari Maqbool, barispn1@gmail.com

Indian Institute of Astrophysics, Bengaluru, India Ranjeev Misra, rmisra@iucaa.in

IUCAA, Pune, India

Naseer Iqbal, dni_phtr@kashmiruniversity.ac.in University of Kashmir Srinagar, Srinagar, India

The X-rays emitted by the inner regions of the accretion disk induce structural changes in the outer regions of the disk. We study here how the effective temperature and hence the corresponding spectrum of the disk is altered by stochastic perturbations in the outer regions and thereby try to study the long term variability which has been observed in some X-ray binaries. We use a time dependent global hydrodynamic code to study the variations in the effective temperature of the disk in response to sinusoidal accretion rate perturbations introduced at different radii and with different time periods. To quantify the results, we calculate the root mean square effective temperature at different radii and the root mean square flux at differ- ent frequencies. From our calculations of the time-lags in accretion rate, effective temperature and the different frequencies, we find that the time-lags in presence of X-ray irradiation is significantly smaller than the expected viscous time-scale.

E1.6-0010-18 TOMOGRAPHIC MAPPING OF ACCRETING BLACK HOLES USING X-RAY QUASI-PERIODIC OSCILLATIONS

Adam Ingram, adam.ingram@physics.ox.ac.uk University of Oxford, Oxford, United Kingdom

Accreting stellar-mass black holes often show a quasi-periodic oscillation (QPO) in their X-ray flux with a period that slowly drifts from 10s to 0.05s. The physical origin of the QPO has long been debated, but is often attributed to Lense-Thirring precession, a General Relativistic effect causing the inner accretion flow to precess as the spinning black hole twists up the surrounding space-time. A distinctive prediction of the precession model is that the iron fluorescence line, produced as part of a 'reflection' spectrum by disk irradiation, should rock between redand blue-shifted as the receding and approaching sides of the disk are respectively illuminated by the precessing inner accretion flow. Our recent XMM-Newton and NuSTAR observations in which the centroid energy of the iron line in H 1743-322 varies systematically over the 4 s QPO cycle, confirm this prediction and thus provide strong evidence in favour of the precession model. Here I will focus on the tomographic mapping techniques that this result has enabled. This entails developing a physical model for the QPO phase-dependent reflection spectrum and fitting to the observed QPO phase-resolved spectra. I will present results for our campaign on H 1743-322 and also for NICER observations of the recently discovered source, MAXI J1535-571. I will present results of modelling that additionally takes into account thermal reprocessing, which exploits the very high count rates achieved by NICER in the soft X-ray band.

E1.6-0011-18 NICER SPECTRAL-TIMING STUDIES OF A LOW-FREQUENCY QPO IN THE SOFT-INTERMEDIATE STATE OF MAXI J1535-571

Abigail Stevens, abigailstev@gmail.com

Michigan State University, East Lansing, Michigan, United States Phil Uttley, p.uttley@uva.nl

University of Amsterdam, Amsterdam, Netherlands NICER Science Team

Members of the NICER Observatory Science Working Group

We present the discovery and preliminary spectral-timing analysis of a low-frequency QPO feature in observations of MAXI J1535-571 in the soft-intermediate state, obtained by the Neutron Star Interior Composition Explorer (NICER). The feature is relatively broad and weak, with a weak harmonic and additional low-amplitude broadband noise. These characteristics likely make it a weak Type B QPO, like one previously identified in the soft-intermediate state of the transient black hole X-ray binary XTE J1550-564. The lag-energy spectrum of the QPO shows soft lags of about 50 ms with an inflected spectral shape, flattening above 4 keV. Preliminary QPO-phase-resolved spectral analysis suggests that the inflected lag-energy spectrum is due to the disk blackbody component lagging the Comptonized power-law emission by 27% of a QPO cycle. This large phase shift has similar amplitude but opposite sign to that seen in Rossi X-ray Timing Explorer data for the Type B QPO from the transient black hole X-ray binary GX 339-4. We suggest that the Type B QPOs from these systems may have the same origin, in the form of a precessing jet-like corona illuminating the disk, with the different lag signs depending on the observer inclination angle.

E1.6-0012-18 ADVANCES IN PHASE RESOLVING QUASI-PERIODIC OSCILLATIONS WITH NICER

Jakob Van Den Eijnden, a.j.vandeneijnden@uva.nl University of Amsterdam, Amsterdam, Netherlands Phil Uttley, p.uttley@uva.nl

University of Amsterdam, Amsterdam, Netherlands Adam Ingram, adam.ingram@physics.ox.ac.uk University of Oxford, Oxford, United Kingdom

The X-ray emission of accreting, stellar-mass black holes is variable on a wide range of timescales and often shows quasi-periodic oscillations, or QPOs. Discovered decades ago, the origin of these QPO remains an open question to this day. In the most promising QPO model, the inner accretion flow precesses due to relativistic frame dragging. In addition to X-ray variability, such geometric changes should cause distinct spectral variations with the QPO phase. Phaseresolving the QPO for spectral analysis is therefore an important step towards understanding its physical origin. In this talk, I will discuss how the recently deployed NICER mission, with its CCD-like energy resolution and soft response, has impacted such QPO studies. After introducing different phase-resolving methods, I will compare their results and the improvements brought on by NICER, by presenting a case-study of the QPO in NICER observations the recently discovered accreting black hole MAXI J1535-571.

E1.6-0013-18 THE LENSE-THIRRING PRECESSION MODEL FOR THE LOW-FREQUENCY QPO IN ACCRETING BLACK HOLES

Piotr Zycki, ptz@camk.edu.pl

N. Copernicus Astronomical Center, Warsaw, Poland

The Lense-Thirring precession model is a promising model for the low-frequency QPO in accreting black hole systems. It combines the standard geometry of the accreting two-phase plasma, with a geometrical scenario producing a periodic variability of the X-ray emission.

I am going to present results of Monte Carlo simulations of generation of hard X-ray emission in the scenario of precessing inner hot plasma torus with an outer cold disk. The soft photons from the disk are inverse-Compton upscattered in the hot torus, to produce the hard X-rays. Photon propagation from the system to the observer includes relativistic effects. Changes of the viewing conditions and possibly the plasma temperature during the precession cause the variability of the observed emission.

E1.6-0014-18 A REVIEW ON HIGH-FREQUENCY QUASI-PERIODIC OSCILLATIONS: PAST, PRESENT AND FUTURE

Mariano Mendez, mariano@astro.rug.nl University of Groningen, Groningen, Netherlands

X-ray observations of both Black Holes and Neutron Stars in Low-mass X-ray binaries have shown quasi-periodic oscillations (QPOs) with frequencies as low as Milli-hertz, and as high as 1300 Hz. The highest frequencies we observe are thought to be due to the motion of gas a few gravitational radii from the compact object. In this talk I will review what we know about the so-called kHz QPOs in neutron stars and the high-frequency QPOs in black hole systems, what are the current theoretical models which better describe the data, and how new spectral/timing approaches could help us understand this extreme phenomena.

E1.6-0015-18 BICOHERENCE OF QUASI-PERIODIC OSCILLATIONS FROM GX 339-4

Kavitha Arur, kavitha.arur@ttu.edu

Texas Tech University, Lubbock, Texas, United States Thomas Maccarone, thomas.maccarone@ttu.edu Texas Tech University, Lubbock, Texas, United States

Quasi-periodic oscillations (QPOs) are features that appear as narrow peaks in the power spectrum of X-ray binaries. While QPOs have been observed in many sources, the manner in which they are produced is under debate. The bicoherence, a measure of coupling between the phases of different Fourier frequencies, can be used to differentiate between models that produce very similar features in their power spectra. We analyse several observations of RXTE/PCA archival data of the black hole binary GX 339-4 which show QPOs. We find that these QPOs show different patterns in their bicoherence plots, suggesting that they are produced by different physical processes.

E1.6-0016-18 THE SPECTRAL AND TIMING PROPERTIES OF THE KHZ QPOS IN 4U 1636-53

Evandro, M Ribeiro, evandromartinezribeiro@gmail.com University of Groningen, Groningen, Netherlands Mariano Mendez, mariano@astro.rug.nl

University of Groningen, Groningen, Netherlands Guobao Zhang, zhangguobao@ynao.ac.cn Chinese Academy of Science, Kunming, China

Marcio G B De Avellar, marcio.de.avellar@gmail.com IAG - Universidade de São Paulo, São Paulo, Brazil

Combined spectral-timing techniques are the key to understand the variability, environment and internal composition of neutron-stars in X-ray binary systems. We analyzed all the available RXTE observations of the neutron-star low-mass X-ray binary 4U 1636-53 and studied the rms fractional amplitude of its pair of kilohertz quasi-periodic oscillations (QPOs) as a function of energy and frequency. By combining the observations with the QPOs within chosen frequency ranges we produced frequency-resolved fractional rms amplitude spectra. By selecting lightcurves in different energy bands we created energy-resolved relations of the fractional rms amplitude vs. frequency of the kHz QPOs. We also studied the relation between the frequency of the kHz QPOs and the physical parameters that describe the energy spectrum of 4U 163653. We obtained results that, for the first time, show the connection between the spectral parameters and the dynamical and radiative properties of the kHz QPOs. We discuss the implications of our findings on our understanding of the mechanism that produces the kHz QPOs. Our results demonstrate that a simultaneous description of the time and energy domains is needed to reveal the origin of the kHz QPOs.

E1.6-0017-18 QUASI-PERIODIC OSCILLATIONS FROM POST-SHOCK ACCRETION COLUMN OF STRONGLY MAGNETIZED ACCRETING WHITE DWARFS

Prasanta Bera, pbera.phy@gmail.com IUCAA, Pune, India

Dipankar Bhattacharya, dipankar@iucaa.in

Inter University Centre for Astronomy and Astrophysics, Pune, India

Polars are a set of strongly magnetized accreting white dwarfs which does not form any accretion disk due to its extended magnetosphere. Quasi-periodic oscillations (QPOs) with frequency about a Hz are detected in many optical observations of a few polars. In these binary systems, the high-frequency QPOs are thought to be generated due to the variation in emitted radiation from the post-shock accretion column. Thermal bremsstrahlung is a significant process to generate Xray radiation from this post-shock region. Local thermal instability due to the efficient cooling from the highly dense region is believed as the primary region behind the temporal variability. We study the structure and the dynamical properties of the post-shock accretion column including the effects of bremsstrahlung and cyclotron radiation. We find that the presence of significant cyclotron emission in optical band reduces the overall variability of the post-shock region. These characteristics of the post-shock region are consistent with the observed properties of V834 Cen and in general with Cataclysmic Variable sources that exhibit QPO frequency of about a Hz.

E1.6-0018-18 SOFT BAND SPECTRAL-TIMING OF KHZ QPOS

Peter Bult, p.m.bult@nasa.gov

NASA/GSFC, Greenbelt, Maryland, United States NICER Science Team

Members of the NICER Bursts & Accretion Physics Working Group

The fastest variability signals that may be observed from the accretion process, kilohertz quasiperiodic oscillations (kHz QPOs) have long been recognized as an important probe of the accretion process. A firm theoretical understanding of how these QPOs are generated, however, remains elusive. Measurements of the energy dependent QPO amplitude and time lag may provide some constraints, especially at low photon energies, where proposed models give diverging predictions. In this contribution we present new results from NICER, which, for the first time, observed kHz QPOs down to 1 keV. Extending spectral-timing analysis of these QPOs to the soft band, we discuss our results in the context of QPO emission models.

E1.6-0019-18 NONLINEAR TIMING TECHNIQUES

Thomas Maccarone, thomas.maccarone@ttu.edu Texas Tech University, Lubbock, Texas, United States Kavitha Arur, kavitha.arur@ttu.edu

Texas Tech University, Lubbock, Texas, United States

I will give a review of nonlinear timing techniques, such as the bispectrum and the time skewness. These techniques can be used to break degeneracies between models that produce identical power spectra. In particular, they can determine whether rise times or decay times are faster in light curves, and determine the symmetry of the flux distribution on a variety of timescales.

E1.6-0020-18 (BAYESIAN) INFERENCE FOR X-RAY TIMING

Daniela Huppenkothen, dhuppenk@uw.edu

University of Washington, Seattle, New York, United States

Fourier techniques have been incredibly successful in describing variability of X-ray binaries (XRBs) and Active Galactic Nuclei (AGN). The detection and characterization of both broadband noise components and quasi-periodic oscillations as well as their behavior in the context of spectral changes during XRB outbursts has become an important tool for studying the physical processes of accretion and ejection in these systems. In this talk, I will review state-of-the-art techniques for characterizing variability in compact objects and show how these methods help us understand the causes of the observed variability and how we may use it to probe fundamental physics. Despite numerous successes, however, it has also become clear that many scientific questions cannot be answered with traditional timing methods alone. I will therefore also present recent advances to modeling variability with generative models, some in the time domain like CARMA as well as machine learning approaches like Hidden Markov Models, and discuss where these methods might lead us in the future.

E1.6-0021-18 X-RAY REFLECTION COMPONENTS WITH INTRINSIC ABSORPTION

Andy Fabian, acf@ast.cam.ac.uk

University of Cambridge, Cambridge, United Kingdom Jiachen Jiang, jj447@cam.ac.uk

Institute of Astronomy, University of Cambridge, Cambridge, United Kingdom Michael Parker, mparker@sciops.esa.int

ESAC, Madrid, Spain

Ciro Pinto, ciropinto1982@gmail.com

University of Cambridge, Cambridge, United Kingdom William Alston, wna@ast.cam.ac.uk

Cambridge University, Cambridge, United Kingdom Luigi Gallo, lgallo@ap.smu.ca

Saint Mary's University, Halifax, Canada

X-ray reflection spectra are the result of competition between absorption, scattering and emission. They are usually identified through their emission and scattering properties, although photoelectric absorption edges are clearly present. Absorption lines should also occur, particularly when the reflector is viewed at high inclination. This may be relevant to the detection of blueshifted iron absorption lines in some accreting black hole spectra. The absorption may occur in the outer, possibly more highly ionized, layer of the bright approaching side of the inner accretion disc. Intrinsic disc absorption must be either quantified or eliminated before a genuine outflow can be claimed. For this purpose, we investigate 2 Ms of X-ray data from the highly variable AGN IRAS13224-3809, which shows variable blueshifted absorption lines.

E1.6-0022-18 A NICER LOOK AT X-RAY BINARIES

James Steiner, jsteiner@mit.edu

Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

NICER is the new premier X-ray timing instrument onboard the International Space Station, having been installed in the summer of 2017. NICER offers an order of magnitude better time fidelity than any predecessor X-ray instrument. For spectra, NICER provides CCD-like energy resolution and sensitivity to soft X-rays, low background, and large collecting area, all with negligible pileup for even Crab-bright sources. NICER is poised to make leading contributions to fundamental topics in the X-ray binary field including constraining neutron-star equation of state, measuring black-hole spins, discerning accretion flow structure using quasi-periodic oscillations (QPO), and mapping disk-coronal geometry. I will present some of NICER's first results on black hole microquasar and neutron star systems which showcase the power of NICER for X-ray spectral-timing investigations.

E1.6-0023-18 A NEW ERA FOR SPECTRAL-TIMING AT OPTICAL WAVELENGTHS

Simone Scaringi, simone.scaringi(at)canterbury.ac.nz University of Canterbury, NZ, Christchurch, New Zealand

From supermassive black holes at the centre of galaxies, to young-stellar objects still in the star-forming process, accreting systems on all scales are now known to display very similar phenomenology when comparing their spectral/timing properties. However, it was not until the spectral/timing methods and techniques adopted from accreting stellar-mass black holes and neutron stars were applied to accreting white dwarfs and young-stellar objects that these clear similarities were quantified. Since accreting white dwarfs and young-stellar objects display intrinsically longer accretion-induced timescales and emit most of their accretion-driven radiation at optical/UV wavelengths, applying the well-known spectral/timing methods (bicoherence, fourier-lags, bispectrum) has faced new challenges. In this talk I will discuss these challenges and how they have been overcome to allow us to compare the spectral/timing properties across accreting systems on all mass and size scales. This global spectral/timing analysis approach demonstrated how all accreting systems display the same phenomenological similarities when compared to each other, and more importantly how these remarkably similar properties seem to suggest a common physical mechanism to accretion on all scales.

E1.6-0024-18 STROBE-X: X-RAY TIMING AND SPECTROSCOPY ON DYNAMICAL TIMESCALES FROM MICROSECONDS TO YEARS

Paul Ray, paul.ray@nrl.navy.mil

Naval Research Laboratory, Washington, District of Columbia, United States

We describe a probe-class mission concept that provides an unprecedented view of the X-ray sky, performing timing and 0.2-30 keV spectroscopy over timescales from microseconds to years. The Spectroscopic Time-Resolving Observatory for Broadband Energy X-rays (STROBE-X) comprises three primary instruments. The first uses an array of lightweight optics (3-m focal length) that concentrate incident photons onto solid state detectors with CCD-level (85-130 eV) energy resolution, 100 ns time resolution, and low background rates to cover the 0.2-12 keV band. This technology is scaled up from NICER, with enhanced optics to take advantage of the longer focal length of STROBE-X. The second uses large-area collimated silicon drift detectors, developed for ESA's LOFT, to cover the 2-30 keV band. These two instruments each provide an order of magnitude improvement in effective area compared with its predecessor (NICER and RXTE, respectively). Finally, a sensitive sky monitor triggers pointed observations, provides high duty cycle, high time resolution, high spectral resolution monitoring of the X-ray sky with 20 times the sensitivity of the RXTE ASM, and enables multi-wavelength and multi-messenger studies on a continuous, rather than scanning basis. We describe the mission concept including updated instrument and mission designs resulting from the GSFC IDL and MDL studies.

The STROBE-X concept study is supported by NASA.

E1.6-0025-18 SPECTRAL-TIMING STUDIES OF X-RAY BINARIES AND AGNS WITH ATHENA

Massimo Cappi, cappi@iasfbo.inaf.it INAF - IASF Bologna, Bologna, Italy

I wish to review the expected capabilities of Athena for observing bright (up to Crab) X-ray sources with the onboard calorimeter XIFU, i.e. at an unprecedented high (<10 eV) energy resolution and throughput. I will then present some examples of spectral-timing studies that will allow to probe winds and accretion flows in X-ray binaries and AGN with unprecedented details.

E1.6-0026-18 THE X-RAY / UV / OPTICAL VARIABILITY OF AGN

Ian McHardy, imh@soton.ac.uk

University of Southampton, Southampton, United Kingdom

The origin on the UV and optical variability in AGN has long been unknown. I will discuss the results of recent multiwaveband monitoring campaigns. On long timescales (year) there are optical variations which are not correlated with the X-rays and are probably caused by accretion rate variations in the disc. However on short timescales (hours-weeks) the X-ray variations are correlated with, and lead, the UV/optical variations, implying that reprocessing of X-rays is the origin of the variations. By measuring the lags as a function of wavelength we are able to map out the structure of the surrounding reprocessing material. We find that the accretion disc can account for some of the reprocessed emission but the observed size is larger than expected theoretically. There is also evidence for a second reprocessor at a larger distance, probably the broad line region gas. There is considerable variation between AGN, particularly with regard to the X-ray to UV lag which may be affected by absorption and scattering in an inflated inner disc.

E1.6-0027-18 LINKING TEMPORAL SCALES AND STATE TRANSITIONS OF THE BLACK HOLE BINARY GX 339-4

Eda Sonbas, edasonbas@yahoo.com Adiyaman University, Adiyaman, Turkey Kalvir S. Dhuga, dhuga@gwu.edu

George Washington University, United States Ersin Gogus, ersing@sabanciuniv.edu Sabanci University, Istanbul, Turkey

Low-Mass X-ray Binaries are known to undergo spectral transitions and exhibit a number of distinct spectral states, which are usually depicted as tracks, tracing in an anticlockwise direction, a characteristic q-shape on a hardness intensity diagram (HID). While a number of spectral states and transitions are discussed in the literature, the two most prominent states, of which there is universal agreement, are the Low/Hard (LHS) and the High/Soft states (HSS). The spectral nature of these states is typically understood in terms of changes in the size of the accretion disk. In this work we extract temporal scales and link these to the different state transitions of the source GX 339-4 by constructing a luminosity variability diagram (LVD). This new diagram can be compared directly with a traditional HID.

There are many theoretical and phenomenological models in the literature which try to explain physics of accretion around black holes (BHs). Some of these models assume ad-hoc additional components to explain different timing and spectral aspects of black hole candidates (BHCs) which no necessarily follow from physical equations. Chakrabarti and his collaborators, on the other hand claim in the last two decades that the spectral and timing properties of BHCs must not be treated separately since variation of these properties happens due to variation of matter accretion from two component (Keplerian and sub-Keplerian) of flows, and the Compton cloud parameters only. Recently after the inclusion of two component advective flow (TCAF) solution into HEASARC's spectral analysis software package XSPEC as an additive table model, we found that TCAF is quite capable of describing the underlying accretion flow dynamics around BHs with spectral fitted physical parameters. Properties of different spectral states and their transitions during an outburst of a transient BHC are more clear. A strong correlation between spectral and timing properties could also be seen in Accretion Rate Ratio Intensity Diagram (ARRID), where transitions between different spectral

states are prominent. One can also predict frequencies of the dominating type-C quasi-periodic oscillations (QPOs), which is a temporal phenomena from TCAF model fitted shock parameters. Estimation of the most probable mass ranges of BHCs and X-ray contributions from jets/outflow (if present) could also be done from spectral fits with the TCAF model. This gives us a confidence that we are in the verge of understanding accretion processes most accurately than ever before.

E1.6-0029-18 UNIFIED SPECTRAL AND TIMING MODEL OF SEYFERT 1 GALAXIES OBSERVED WITH NUSTAR AND XMM/SUZAKU

Ken Ebisawa, ebisawa@isas.jaxa.jp ISAS/JAXA, Sagamihara, Japan
Eriko Kusunoki, erik0kus@gmail.com ISAS/JAXA, Sagamihara, Japan

Misaki Mizumoto, mizumoto@astro.isas.jaxa.jp ISAS/JAXA, Sagamihara, Japan

Hiroaki Sameshima, sameshima@cc.kyoto-su.ac.jp Kyoto Sangyo University, Kyoto, Japan

NuSTAR satellite was launched in 2012 and high-quality energy spectra of Seyfert 1 galaxies above 10 keV have been made available for the first time. In this paper, we analyze archival data of the NuSTAR and XMM/Suzaku simultaneous observations of particularly variable Seyfert 1 galaxies, MCG-6-30-15, NGC 4593, NGC 1365, Swift J2127.4+5654 and MCG-5-2316. Our aim is to construct a unified spectral and timing model that explains spectral variations in 0.2-78 keV with minimum free parameters. Consequently, we were successful to explain observed spectral variations of all the five sources at timescales below 1 day with only two independently variable parameters; partial covering fraction and normalization of the power-law component. In this model, the continuum is composed of disk-black body component, cut-off power-law component, and thin-thermal plasma component, if any. The central X-ray source is fully or partially absorbed by ionized absorbers, and the partial covering fraction is significantly variable. Variations of the partial covering fraction and the power-law normalization mostly explain the soft X-ray variation below 10 keV and the hard X-ray variations above 10 keV, respectively. The variable partial absorbers are composed of two layers with different ionization states/column densities. The observed X-ray spectral variations, energy-dependent light curves and RMS spectra are explained only by the two variable parameters.

E1.6-0030-18 THE RELATIVISTIC ACCRETION DISK AND THE ULTRA-FAST OUTFLOW IN IRAS 13224-3809

Jiachen Jiang, jj447@cam.ac.uk

Institute of Astronomy, University of Cambridge, Cambridge, United Kingdom

Narrow-Line Seyfert 1 galaxies (NLS1) are a rare subclass of active galaxies that are usually characterized with a small central black hole mass accreting at rates close to the Eddington limit. We present a detailed time-resolved and flux-resolved spectral analysis of the recent 1.5 Ms XMM-Newton observing campaign on the NLS1 IRAS 13224-3809, taken simultaneously with 500 ks of NuSTAR data. The X-ray lightcurve shows three flux peaks, registering at about 100 times the minimum flux seen during the campaign, and rapid variability with a time scale of kiloseconds. This source is known to exhibit a complex combination of relativistic reflection from the accretion disk and absorption from a mildly relativistic outflow in addition to the primary powerlaw continuum. We will show that the spectral variability is dominated by the powerlaw continuum from the coronal region within a few gravitational radii from the BH and how the relativistic disk and the relativistic outflow components change with the flux level.

E1.6-0031-18 EVOLUTION OF THE ASYMMETRIC MULTI-PHASE DISC ATMOSPHERE IN THE X-RAY BINARY MXB1659-298, DURING ITS 2015-2016 OUTBURST

Equatorial winds and disc atmospheres are fundamental components of accretion onto compact objects and they are typically traced through ionised absorption lines. I will report the analysis of the Chandra HETG, XMM and NuSTAR monitoring campaign of the last outburst of the high-inclination (eclipsing) transient neutron star Low Mass X-ray Binary MXB1659-298. We detected more than 60 absorption lines during the soft state HETG+NuSTAR observation, while only stringent upper limits are observed during the hard state. I will discuss the importance of thermal instabilities for this effect. We also observed, for the first time, a modulation of the intensity of the ionised absorption lines with orbital phase. I will finally discuss how these results shed new light onto our picture of the accretion phenomenon.

We present optical to mid-infrared (mid-IR) spectral–timing observations of the new, bright, black hole candidate transient X-ray binary, MAXI J1535–571. Mid-IR (5–12 micron) observations were acquired with VISIR on the VLT, and optical–near-IR monitoring was taken with the Faulkes, Las Cumbres Observatory (LCO) and Rapid Eye Mount (REM) telescopes. We detect bright (up to 100 mJy), highly variable mid-IR emission in September 2017 as the source made a transition from the hard state towards the soft state. We use X-ray data to track how the optical–IR changes as the source evolves in the hardness–intensity diagram.

The mid-IR 9–12 micron flux density faded dramatically by more than an order of magnitude over one week in September 2017. This is contemporaneous with a near-IR and optical fade of a factor of 10 and 2, respectively. Before the fade, the IR de-reddened spectrum can be described by an optically thin synchrotron power law, with a spectral break at the longer wavelengths to a flatter spectrum. This spectrum, and the wavelength dependence of the fade can be explained by a synchrotron jet which is quenching over the state transition, and a less variable disc component in the optical.

We also present the first (to our knowledge) mid-IR variability study of an X-ray binary on short (minute) timescales. On some dates the mid-IR flux of MAXI J1535–571 varied by a factor of two in less than 15 minutes, and on one date there is a sudden decrease of the flux to undetectable levels. The near-IR flux is also variable on short timescales. The mid-IR fractional rms variability on minute timescales is 15%, which is comparable to the optical fractional rms of GX 339–4 at similar time resolution. We compare these results to the expected fractional rms from the jet internal shock model of Malzac et al., and find that the variability amplitude is consistent with this model.

We also combine our optical–IR spectral energy distributions with radio, mm and X-ray data to build a coherent picture of the evolution of the broadband spectrum. We find that contrary to other sources, the jet does not simply fade over the transition, with the jet spectral break shifting to lower frequencies, but instead there are jet flares and rapid evolution of the jet spectrum that correlate with X-ray hardness deviations. These results represent an excellent case of multiwavelength jet spectral-timing and demonstrate how rich, multiwavelength timeresolved data of X-ray binaries over state transitions can help refine models of the disc-jet connection and jet launching in these systems.

E1.6-0033-18 STUDY OF TIMING EVOLUTION FROM NON-VARIABLE TO STRUCTERED LARGE-AMPLITUDE VARIABILITY TRANSITION IN GRS 1915+105 USING ASTROSAT/LAXPC

Divya Rawat, divyar@iitk.ac.in

Indian Institute of Technology, Kanpur, Ghaziabad, India

In this work we present a sim 90 ks continuous monitoring of the Galactic micro-quasar GRS 1915+105 with AstroSat when the source undergoes a major transition from a non-variable state (similar to chi class) to a structured, large amplitude, periodic flaring state (similar to rho class). We show that such transition takes place via an intermediate state when the large-amplitude, irregular variability of the order of thousands of seconds in the soft X-ray band turned into a 100-150 sec regular, structured, nearly periodic flares, very similar to rho class/heartbeat oscillations. Intererstingly, the properties of a strong low-frequency quasi-periodic oscillation (LF QPO) in the frequency range 3-5 Hz remain stable during all three states. We also study time-lag and rms spectra at the QPO, harmonic and broad noise components and dynamic power spectra. We note few important differences between the flaring state and the rho class and conclude that the flaring state is a precursor of the rho class. Stability of the LF QPO during variability transition implies the disk-corona coupled radiation system which determines the LF QPO properties, mostly uninturrepted by the launch of long, large-amplitude flares, probably from the outer disk. However, the increase in the QPO frequency with the softening of the source is consistent with the significant decrease in the inner accretion disk radius.

E1.6-0034-18 ACCRETION STATES, BLACK HOLE SPIN, AND THE 2017 OUTBURST OF MAXI J1535-571

Members of the NICER Observatory Science Working Group

After two decades of monitoring stellar mass black holes in outburst, there are still lingering questions about the geometry of the accretion disk and its evolution across state transitions. Does the disk extend all the way to the ISCO, or is it truncated at some distance from the black hole? How does this depend on accretion rate, luminosity, and X-ray spectral shape, and how is it connected to timing properties? The recent outburst of MAXI J1535-571, monitored extensively with NuSTAR and NICER, provides a prime opportunity to address these questions. I will present detailed analysis of the spectral evolution of the source over roughly three months, from its rising hard states through its >5 Crab peak, all the way to its soft, disk-dominated state. Applying relativistic reflection models and holding its spin constant across the outburst, I track the evolution of the inner radius of the disk from state to state. With hundreds of millions of counts in dozens of observations, these data offer an incredibly detailed view of the spectral geometry of MAXI J1535-571 for comparison to precision timing results.

E1.6-0035-18 STATE TRANSITIONS IN DWARF NOVAE AND COMPARISONS WITH THE BROADBAND NOISE CHARACTERISTICS

Solen Balman, solen.balman@gmail.com

Middle East Technical University, Ankara, Turkey

Broadband noise in accreting systems have been a diagnostic tool in understanding the structure of accretion disks and state transitions. In this talk I will present broadband noise variations of dwarf novae (DN) in comparison with their energy spectrum changes using the X-ray wavelengths. DN demonstrate band limited noise in the UV and X-ray energy bands, which can be adequately explained in the framework of the model of propagating fluctuations (Balman & Revnivtsev 2012, Balman 2014, 2015). The detected frequency breaks are in the range (1-6) mHz and indicates an optically thick disk truncation in the inner disk of dwarf novae systems indicating existence of hot flows in the inner regions. Analysis of other available data reveal that during the outburst the inner disk radius moves towards the white dwarf and receeds as the outburst declines while changes in the X-ray energy spectrum is also observed. Cross-correlations between the simultaneous Optical, UV and X-ray light curves show time lags consistent with truncated optically thick disk and inner disk hot flows. I will also discuss the hysteresis in these systems and my recent calculation showing a correlation between the break frequency and the temperature of the hot inner thermal flow in the X-ray emitting region.

E1.6-0036-18 DETECTION OF TYPE-1 BURSTS FROM THE GALACTIC CENTER USING ASTROSAT-LAXPC

Gayathri Raman, graman@rri.res.in

Raman Research Institute, Bangalore, India Varun Bahal, varun@rri.res.in

Raman Research Institute, Bangalore, India Nirmal Iyer, nirmal.iyer@gmail.com

KTH, Stockholm, Stockholm, Sweden Biswajit Paul, bpaul@rri.res.in

Raman Research Institute, Bangalore, India

We report the detection of two Type-1 X-ray bursts within a span of a few hours from a crowded region near the Galactic Center (GC) using Astrosat-LAXPC. The detected bursts exhibit a characteristic FRED profile, suggestive of a thermonuclear flash process observed in neutron stars. This region near the GC hosts several potential sources in the LAXPC field of view. The object closest to the LAXPC pointing, 1E 1743.1-2843, is a persistent LMXB, for which, the nature of the compact object is unknown so far. Two other potential candidates, GRS 1741.9- 2853 and SAX J1747.0-2853, are known to be transient low luminosity bursters. Three sources, KS J1741-293, 2E 1742.9-2929 and IGR J17473-272 lie close to the edge of the LAXPC field of view of this observation and for the bursts to be from one of these sources, have to be extremely luminous. We inspect all these sources as possible candidates using pointing information of all three LAXPCs, their relative efficiencies and the observed burst fluences. We also check the pre and post burst luminosity states of these objects. The LMXB object 1E 1743.1-2843 is a strong candidate for being the source of the two bursts. This would establish the presence of a neutron star primary for this binary,resolving the ambiguity associated with the nature of this system. We also examine the energy resolved burst characteristics and burst recurrence times. Results from search for high frequency QPOs will also be presented along with preliminary results obtained from burst spectroscopy.

E1.6-0037-18 PROBING THE NATURE OF THE ACCRETION FLOW IN LOW MASS X-RAY BINARIES USING THE SPECTRAL-TIMING PROPERTIES OF THE KILOHERTZ QUASI-PERIODIC OSCILLATIONS

Konstantinos Karpouzas, karpouzas@astro.rug.nl

Kapteyn Astronomical Institute, University of Groningen, Groningen, Netherlands Evandro, M Ribeiro, evandromartinezribeiro@gmail.com

University of Groningen, Groningen, Netherlands Mariano Mendez, mariano@astro.rug.nl University of Groningen, Groningen, Netherlands Diego Altamirano, d.altamirano@soton.ac.uk

University of Southampton, Southampton, United Kingdom

Over the last two decades several efforts have been made to try and explain the energydependent variability observed in low mass X-ray binary (LMXB) systems. The kilohertz quasi-periodic oscillations (kHz QPOs) represent the fastest variability so far observed from neutron-star (NS) LMXBs. We present a model that reproduces the fractional rms amplitude and time lags of the kHz QPOs as a function of photon energy and QPO frequency. Our model builds upon a previously explored idea, namely that the variability is driven by a coupled oscillation of the temperature of the accretion disc and the heating rate (and hence the electron temperature) of the corona. New here is that we explore the effect of the (expected) coupled oscillation of the electron number density (optical depth and physical size) of the corona and a range of physically motivated feed-back mechanisms between the disc and the corona. We further examined the impact of the seed photon spectra, a corona with a non-uniform optical depth and electron temperature, and the physical size of the corona on the QPO properties. We compared the predictions of our model to simultaneous XMM-Newton and the Rossi X-ray Timing Explorer (RXTE) energy spectra, and RXTE power-density and time-lag spectra of the NS LMXB 4U 1636-53. The ultimate goal is to unravel the underlying mechanisms that drive the variability of these sources.

E1.6-0038-18 TIMING AND SPECTRAL STUDIES OF SXP 15.3 NEAR ITS EDDINGTON LUMINOSITY

SXP 15.3 (RX J0052.1-7319) is a Be X-ray binary pulsar located in the Small Magellanic Cloud. The source was classified as a transient X-ray binary candidate based on ROSAT observations in the 1990's, and pulsations at 15.3 s were subsequently discovered from an outburst in 1996 from the ROSAT data. The source has never been studied in an outburst or a bright state ever since. Following reports of an outburst in November 2017, we triggered a Target of Opportunity observation of SXP 15.3 with AstroSat. We report here the first broadband spectral and timing studies of the source, when the source was accreting near the Eddington limit of 1038erg/s. We discuss the energy dependence of the pulse profiles and the broadband spectrum in context of accr

E1.6-0039-18 THE REFLECTION SPECTRUM OF THE LOW-MASS X-RAY BINARY 4U 1636–53

INAF, Merate, Italy

We present 3–79 keV NuSTAR observations of the neutron star low-mass X-ray binary 4U 1636– 53 in the soft, transitional and hard state. The spectra display a broad emission line at 5–10 keV. We applied several models to fit this line: A gaussian line, a relativistically broadened emission line model, kyrline, and two models including relativistically smeared and ionized reflection off the accretion disc with different coronal heights, relxill and relxilllp. All models fit the spectra well, however, the kyrline and relxill models yield an inclination of the accretion disc of 88o with respect to the line of sight, which is at odds with the fact that this source shows no dips or eclipses. The relxilllp model, on the other hand, gives a reasonable inclination of 56o. We discuss our results for these models in this source and the possible primary source of the hard X-rays.

E1.6-0041-18 X-RAY OBSERVATIONS OF TWO VERY FAINT X-RAY TRANSIENTS (VFXTS) DURING THEIR OUTBURSTS

University of Amsterdam, Amsterdam, Netherlands Rudy Wijnands, r.a.d.wijnands@uva.nl

University of Amsterdam, Amsterdam, Netherlands Matt Middleton, m.j.middleton@soton.ac.uk

University of Southampton, Southampton, United Kingdom

We will present results obtained from a detailed study of two VFXTs, namely; MAXI J1957+032 (J1957) and Swift J1357.2-0933 (J1357). J1957 showed four short outbursts since its discovery in 2015. The nature of the compact object is not clear. We found that the identification depends on the distance to J1957. If the source is <2 kpc, then J1957 might be a black hole system, for distances between 4-8 kpc our results suggest that the source harbors neutron star and if the distances are larger than 8 kpc it is difficult to infer strong constraint on the nature of the accretor. J1357 is the only confirmed black hole VFXT. A toroidal structure in the inner region of the disk has been postulated similar to the obscuring tori seen around AGN. On April 20, 2017, it went into outburst for the second time. Spectral fitting performed using data of Swift-XRT and NuSTAR showed no signatures of cut-off, or any reflection from the disc or the putative torus.

E1.6-0042-18 TIME DEPENDANT SPECTRAL PROPERTIES OF TWO COMPONENT ADVECTIVE FLOW

Arnab Deb, arnabdeb1988@gmail.com

S. N. Bose National Centre for Basic Sciences, Kolkata, India Kinsuk Giri, kinsuk@nitttrkol.ac.in

National Institute of Technical Teachers' Training & Research (NITTTR), Kolkata, Kolkata, India

Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

We study time-dependent spectral properties and effects of Compton cooling using a timedependent viscous hydrodynamic flow coupled with radiative transfer processes. We consider a two-component accretion flow without any reflection symmetry at the equatorial plane in which Keplerian disc is simulated using αviscosity as prescribed in Giri, Chakrabarti 2013. Black body photons originating from Keplerian disc get inverse-Comptonized by hotter electrons present in halo and in the CENBOL region. We run many cases changing the halo accretion rate, critical optical depth (τ) and angular momentum (Λ) and investigate the properties of the spectrum. We also calculate disc accretion rate for different flow parameters and it can be observed that as disc rate increases cooling will also increase thus producing softer spectra.

E1.6-0043-18 BROADBAND RADIO PROPERTIES OF GALACTIC MICRO-QUASARS DURING HARD AND SOFT STATES

Sabyasachi Pal, sabya.pal@gmail.com

Indian Centre for Space Physics, Calcutta, India Dusmanta Patra, dusmanta.phy@gmail.com Indian Centre for Space Physics, Kolkata, India

Micro-quasars are known to show variability of different time-scales in all observable wavelengths. We will report how the broad-band radio properties of micro-quasars change during different spectral states of various micro-quasars. We have used Giant Meterwave Radio Telescope (GMRT) and Jansky Very Large Array (JVLA) and other available radio telescopes for our study. We will study disk-jet behavior of these micro-quasars and will comment on correlation and anti-correlation properties and time lag between X-ray and radio emissions.

E1.6-0044-18 LIMITS ON VISCOSITY PARAMETER IN ACCRETION FLOWS AROUND BLACK HOLES.

Shreeram Nagarkoti, srnagarkoti@gmail.com Indian Centre for Space Physics, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

We study accretion flows around black holes using two component accretion flow paradigm. An accretion flow around black holes have a Keplerian component (with super-critical viscosity parameter) enveloped by sub-Keplerian component (with sub-critical viscosity parameter). We study these component formations theoretically first. We study the flow parameter space which allows us to put a strict uppper limit on viscosity parameter values on the sub-Keplerian component. We use results obtained from observational analysis by other authors to calculate the value of viscosity parameter in Keplerian component and guess the values of critical value of viscosity parameter. We carry out this study for five different outbursting LMXRBs and find that all sub-Keplerian values of viscosity parameter were sub-critical and all Keplerian viscosity parameters were super-critical.

E1.6-0046-18 A CURIOUS CASE OF HMXB 4U 1700-37

Nazma Islam, nislam@camk.edu.pl

Nicolaus Copernicus Astronomical Center, Warsaw, Poland Biswajit Paul, bpaul@rri.res.in

Raman Research Institute, Bangalore, India 4U 1700-37 is an eclipsing High Mass X-ray binary in a short orbital period of 3.412 days. In the absence of detectable pulsations, the orbital evolution is determined from the eclipse timing measurements, both from archival measurements as well as new measurements from long-term light curves obtained with the all sky monitors RXTE-ASM, Swift-BAT and MAXI-GSC. The orbital period decay rate of the system is estimated to be 10−7/yr, smaller compared to its previous estimates. The mid-eclipse times and the eclipse duration measurements obtained from 10 years long X-ray light curve with Swift-BAT are used to separately put constraints on the eccentricity of the binary system and measure any apsidal motion. We carry out a deepest search for pulsations and Cyclotron Resonance Scattering Feature (CRSF) using a 40 kilosec ASTROSAT LAXPC observation. These results will provide some newer insights into the nature of the compact object, which is either a very high mass neutron star or a very low mass black hole.

E1.6-0048-18 NEW FINDINGS IN THE GALACTIC WIND-FED X-RAY BINARY CYGNUS X-3 WITH TWO YEARS OF BROADBAND MONITORING USING ASTROSAT

Mayukh Pahari, m.pahari@soton.ac.uk

University of Southampton, Southampton, United Kingdom AstroSat/CygX3 team

Ranjeev Misra (IUCAA, Pune), Jai Verdhan Chauhan (TIFR, Mumbai), Sudip Bhattacharyya (TIFR, Mumbai), Biswajit Paul (RRI, Bangalore), J S Yadav (TIFR, Mumbai), P C Agrawal (CBS, Mumbai), R K Manchanda (University of Mumbai), Sunil Chandra (NW University, South Africa), Varsha Chitnis (TIFR, Mumbai), Pankaj Jain (IIT, Kanpur)

Possibly harboring a black hole at its center, the puzzling wind-fed Galactic X-ray binary Cygnus X-3 shows most powerful radio jets (sim20 Jy) among all Galactic sources. Using long-term monitoring program (sim2 years) with AstroSat, we explore the broadband X-ray spectroscopic evolution, its connection with the radio emission and timing properties of Cygnus X-3 at regular intervals and investigate the origin of spectra/timing correlated behavior and major radio jets in this source. We observe all spectral states previously reported but and found a new intermediate state where a flat hard X-ray spectrum is caused by the synchrotron radiation from the radio jet base. Using all available AstroSat observations, we also attempt to compute the hardness-intensity diagram ('q' diagram) of the source and compare with earlier results.

Using 0.3-80.0 keV broadband spectral modeling, we are able to constrain the nature of absorption and its variation at different parts of the binary orbital phase. We also notice that the size and the temperature of a large scattering medium around the accretion disk changes in different spectral states and we find evidence that such phenomena are closely connected with the radio jet intensity. Owing to the broadband spectroscopic capabilities and high efficiency at hard X-rays, we successfully carry out the most extensive investigation of the complex accretion geometry around Cygnus X-3 so far and present the results here.

E1.6-0049-18 THE LONG-TERM X-RAY VARIABILITY OF THE BLACK HOLE BINARY GRS 1915+105

Yutaro Tachibana, tachibana@hp.phys.titech.ac.jp Tokyo Tech, Tokyo, Japan

Nobuyuki Kawai, nkawai@phys.titech.ac.jp Tokyo Institute of Technology, Tokyo, Japan Satoshi Sugita, sugita@phys.aoyama.ac.jp Aoyama Gakuin University, Sagamihara, Japan Kazuki Shiraishi, shiraishi@hp.phys.titech.ac.jp Tokyo Institute of Technology, Tokyo, Japan

Since the discovering in 1992 August by GRANAT/WATCH, the violent X-ray activity in GRS 1915+105, one of the brightest objects in the X-ray sky even now, have been observed seamlessly over 25 years by multiple X-ray observation instruments.

Thanks to its brightness and various observations with the high timing resolution, it has been revealed that the celestial object exhibits 12 characteristic X-ray fluctuations in the time-scale of sub-second to an hour (Belloni et al. 2000), but few studies about the transition/relationship between the 12 states, or in the other words, the X-ray behavior in much longer time-scale (a month to years), are performed so far.

To reveal the comprehensive and global picture of the system, especially the accretion physics under the nearor super-Eddington accretion rate, we performed spectral and timing analysis for the X-ray light curve covering over 20 years obtained by RXTE/ASM and MAXI/GSC. Although the variation in the timescale of sub-second to an hour cannot be fully captured by the all-sky X-ray monitoring instruments, we found that the long-term X-ray variation is possible to be classified to three states based on the hardness-intensity relation, the shape of the spectrum, and the variance in flux, similar to the result shown in Belloni et al. 2000.

In this presentation, we show the newly discovered property in the long-term X-ray variation including the classification and then discuss the global dynamics of GRS 1915+105 based on the results.

E1.6-0050-18 RADIO VLBI AND X-RAY SPECTROSCOPY OF THE SS 433 JETS

Herman Marshall, hermanm@space.mit.edu

Massachusetts Institute of Technology, Cambridge, Massachusetts, United States David Roberts, roberts@brandeis.edu

Brandeis University, Waltham, Massachusetts, United States

In the binary system SS 433, oppositely directed, precessing jets emit line emission from highly ionized plasma moving at 0.26c from the compact object. In a 2005 Chandra High Energy Transmission Grating Spectrometer (HETGS) observations of SS 433, we found a large Doppler shift change on a time scale of 20 ks, a time much shorter than the known dynamical times. The rapid change could be related to the formation and ejection of a jet knot, as observed in VLBI observations, perhaps as a leptonic jet impinges on a disk wind and shock heats it. More recent data were obtained to test this model in a long continuous HETGS observation. The VLBA and Chandra HETGS data were obtained but while no radio ejections were observed during the Chandra observation, there were interesting aspects to the observations. First, although the jet emission lines were expected to vary with the usual precession period (162 days) or with the period of the nodding motion (6.6 days), we did not detect the expected Doppler shifts in over 120 ks of exposure. Furthermore, there is new evidence for jet curvature that has not been previously reported. We will show how XARM can provide new constraints on the physical parameters at the jet origin.

Support for this work was provided in part by the National Aeronautics and Space Administration (NASA) through the Smithsonian Astrophysical Observatory (SAO) contract SV3-73016 to MIT for support of the Chandra X-Ray Center (CXC), which is operated by SAO for and on behalf of NASA under contract NAS8-03060. Support was also provided by NASA under grant GO4-15040A to MIT.

E1.6-0051-18 SPECTRAL-TIMING OF AQUILA X-1

Peter Bult, p.m.bult@nasa.gov

NASA/GSFC, Greenbelt, Maryland, United States NICER Science Team

Members of the NICER Bursts & Accretion Physics Working Group

In this contribution we report on the spectral-timing analysis of Aquila X-1 observations taken with the Neutron Star Interior Composition Explorer (NICER). Leveraging NICER's excellent spectral and timing capabilities we extend, for the first time, the spectral-timing analysis of the accreting neutron star hard state to soft photon energies. We find that the slow X-ray variability shows a dramatic increase in amplitude towards its lowest photon energies. We discuss the implications of our results on the structure of the accretion flow around neutron stars, and highlight the similarities and differences with respect to hard state black hole systems.

E1.6-0053-18 SPECTRAL SIGNATURE OF TRANSITION BETWEEN BURST-ON AND BURSTOFF STATES OF VARIABLE SOURCES

Anuvab Banerjee, anuvab.banerjee@bose.res.in

S. N. Bose National Centre for Basic Sciences, Kolkata, India Ayan Bhattacharjee, ayan12@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

The class variable source GRS 1915+105 is different from the transient sources in the sense that it exhibits peculiar time variabilities in the range of a few seconds to days. Depending on cts/s in different energy bands and the color-color diagram, the variability was first grouped into seventeen classes. The variability arises because of the Comptonization of outflow and its subsequent fall-back, increasing the local disk accretion. Systematic evolution of this feature would be transparent if the evolution of accretion rates are studied. Chakrabarti et al. (2002) determined the inner disk temperature and spectral slope on soft and hard state and three intermediate states of GRS 1915+105 using diskbb+power-law model, and found that the slope gradually gets steeper as one moves from hard to soft state. We do the spectral fitting using TCAF+Cutoff power-law model, and the variation of the accretion rates agree with the previous findings. The burst-off states of the intermediate phase could be fitted with same TCAF normalization for the hard states, and in the burst on state, there is significant change in the disk rate. That gives a legitimate picture of the transition between hard to soft state vis-a-vis the accretion rate.

E1.6-0054-18 NEW GALACTIC BLACK HOLE CANDIDATE MAXI J1535-571: ANALYSIS WITH THE TCAF MODEL

S.N. Bose National Centre for Basic Sciences, Kolkata, India

Recently discovered X-ray transient Galactic black hole candidate MAXI J1535-571 has been studied during its very first outburst after discovery using archival data of Swift XRT BAT instruments. Maximum X-ray flux in 0.3-10 keV band is observed to rise by a factor of 25 times as in the quiescent state, which was 4 Crab. Using the combined Swift XRT BAT observations, accretion flow properties during the 2017 outburst are studied from spectral fits with the Two-Component Advective Flow (TCAF) model fits file in XSPEC. We observed significant double Iron emission lines at around 6.5 keV in the spectra. Sharp type-C QPOs are also detected both in the raising as well as declining phases of the outburst. The monotonic evolution of the frequency of the dominating QPOs are studied with the propagating oscillatory shock (POS) model, to have estimation of the instantaneous locations, strength, velocity etc. of the propagating shock wave. The POS model fitted shock parameters are found to be consistent with the TCAF model fitted spectral (shock) parameters. We also estimate mass of the black hole to be 10 solar masses from our TCAF model fitted spectral analysis.

E1.6-0057-18 COMPLEX UV/OPTICAL EMISSION VARIABILITY IN 1H 0419-577

Sachindra Naik, snaik@prl.res.in

Physical Research Laboratory, Ahmedabad, India

We present a detailed study on the UV/optical variability and its connection to the X-ray emission using six XMM-Newton observations of a Seyfert 1 galaxy 1H 0419 - 577. All six observations consist of simultaneous coverage in the X-ray as well as in the UV/optical bands. The variable emission observed in all the bands appears correlated to each other. The UV/optical variations seem to follow the variations of X-ray band on time-scale of about three months, though, the estimation of such lag is not possible due to sparse data. The model-independent way using and indices also support the X-ray reprocessing when we compared with Grupe et al. 2010. Time-scale of variations is comparable to the size of broad line region. The broadband X-ray to UV/optical spectral modeling supports the X-ray reprocessing scenario due to the observed excess in the UV/optical bands over the best-fit model of X-ray plus disk model. Moreover, the spectral modeling in the X-ray band also favors the changes in the geometry of corona. Furthermore, optical emission seems delayed to the UV emission before the peak and in declining part, the optical emission appears more variable compared to the UV emission. Such variations also support the changes in the geometry of disk/corona.

E1.6-0058-18 CORRELATING TIME SERIES WITH SPECTRAL RESULTS OF RXTE DATA: OBSERVATIONAL EVIDENCES FOR FOUR DIFFERENT ACCRETION CLASSES

Banibrata Mukhopadhyay, bm@iisc.ac.in Indian Institute of Science, Bangalore, India

Oluwashina Adegoke, adegoke.olushina@gmail.com Indian Institute of Science, Bangalore, India Prasun Dhang, prasundhang@gmail.com

Indian Institute of Science, Bangalore, India

We analyze RXTE/PCA data of black hole and neutron star sources. By analyzing independently the underlying time series (which helps in understanding their nonlinear variabilities) and spectral states, we try to correlate them. Depending on the variation in temporal classes, compact sources exhibit different nonlinear features. Sometimes they show low correlation/fractal dimension, but in other classes or intervals of time they exhibit stochastic nature. This is expected as the accretion flow is a nonlinear system involving magnetohydrodynamics. However, the more conventional way of addressing a compact source is the analysis of its spectral state. What is the connection of nonlinearity to the underlying spectral properties of the flow when the nonlinear properties are related to the associated transport mechanisms describing the geometry of the flow? The talk aims at addressing this question. Based on the connection between observed spectral and nonlinear (time series) properties of two X-ray binaries: GRS 1915+105 and Sco X-1, we attempt to diagnose the underlying accretion modes of the sources in terms of known accretion classes, namely, Keplerian disk, slim disk, advection dominated accretion flow (ADAF) and general advective accretion flow (GAAF). We explore the possible transition of the sources from one accretion mode to others with time. We further confirm that the accretion rate must play an important role in transition between these modes.

E1.6-0059-18 PROBING SUPERORBITAL VARIATIONS IN SMC X-1 WITH SUZAKU THROUGH SIMULTANEOUS TIMING AND SPECTRAL ANALYSIS

Pragati Pradhan, pragati2707@gmail.com

Raman Research Institute, Bangalore, India Biswajit Paul, bpaul@rri.res.in

Raman Research Institute, Bangalore, India Harsha Raichur, harsha.raichur.astro@gmail.com Nordita, Stockholm, Sweden

SMC X-1 was observed with Suzaku ten times during different intensity states of the superorbital variation in 2011. We present a broadband (0.3-70 keV)spectral analysis and a detailed joint comparison of the spectra in these intensity states for the first time and interpret the results to map accretion geometry/mechanisms. The spectrum in all the states can be described by an absorbed powerlaw with a smoothened high energy cutoff. Additional black-body component and Fe K emission line is detected, apart from few other low energy emission lines. The spectral shape is also dependent on flux with the hard X-ray spectrum steepening with increasing flux. Through spectral analysis, we probe the nature of the absorber in the precessing warp of SMC X-1 that cause the superorbital modulation. We have carried out orbital corrections for Doppler shift in the HXD lightcurves and report detection of pulsations in hard X-rays in all but one observation. Detection of the X-ray pulses in the low state help us limit the contribution of the scattering/reprocessed component of the X-ray emission in the low state.

E1.6-0060-18 CLUMPY X-RAY OBSCURATION AND ECLIPSES: A NEW MODEL FOR AGN

Pontificia Universidad Catolica de Chile, Santiago, Chile Robert Nikutta, rnikutta@astro.puc.cl

Pontificia Universidad Catolica de Chile, Santiago, Chile

Most active galactic nuclei are seen through thick circum-nuclear gas and dust. Also, these column densities vary on time scales of days to years, indicating that the obscurer is made from clumps. We present the first clumpy obscurer model that reproduces eclipse events and column density distributions, and is also compliant with the CLUMPY optical/infrared model. We developed a new, open-source Monte Carlo code, XARS, to X-ray illuminate arbitrary geometries and present high S/N X-ray spectra for XSPEC. Preliminary fits show good agreement with NuSTAR spectral observations of some nearby Compton-thick AGN. However, an additional, Compton-thick inner wall is necessary. Physical interpretations of this new component, and its infrared counterpart, will be discussed.

E1.6-0061-18 INVESTIGATING STATE TRANSITION LUMINOSITIES OF BH X-RAY BINARIES IN THE OUTBURST DECAY

Armin Vahdat Motlagh, arminvahdat@sabanciuniv.edu Istanbul Technical University, Istanbul, Turkey

Emrah Kalemci, ekalemci@sabanciuniv.edu Sabanci University, Istanbul, Turkey

Thomas Maccarone, thomas.maccarone@ttu.edu Texas Tech University, Lubbock, Texas, United States

We have performed a comprehensive spectral and timing analyses of black hole (BH) X-ray transients during outburst decay in order to obtain the distribution of state transition luminosities. Using the archival data of the Rossi X-ray Timing Explorer (RXTE), we have calculated the state transition luminosities for 12 BH sources in 19 different outbursts and for disk and power-law luminosities separately. Our results show a tight clustering in bolometric power-law luminosity around 1.85 ± 0.43 % Eddington (EDD) during transition to the hard state as well as disk black body luminosity around 4.92 ± 2.19 % EDD during a transition to hard-intermediate state. We also report a third clustering during index transition for power-law with a value and error of 2.85 ± 0.81 % EDD. We discuss the reasons for clustering and possible explanations for sources that show a transition luminosity below or above the general trend.

E1.6-0062-18 SPECTRAL VARIATIONS IN HERCULES X-1 AND RELATION TO STRUCTURE OF THE ACCRETION FLOW

Denis Leahy, leahy@ucalgary.ca University of Calgary, Calgary, Canada

Spectra from Hercules X-1 (Her X-1) were extracted from Rossi X-ray Timing Explorer (RXTE) PCA observations taken over the lifetime of RXTE. This is the most extensive database of spectra for Her X-1, and the properties of this data set are described in Leahy and Igna (2011, ApJ, 736, 74). More recently this dataset was used to measure the X-ray corona in the binary system (Leahy, 2015, ApJ, 800, 32) and to detect atmospheric reflection of HZ Her in the low and short high states (Abdallah and Leahy, 2015, MNRAS, 453, 4222). The current work considers X-ray spectral variations in Her X-1. The variations are demonstrated to be consistent with the predicted changes in the reflected component from the inner disk edge in the model of Leahy (2002, MNRAS, 334, 847).

E1.6-0063-18 ACCRETION FLOW PROPERTIES OF MAXI J1543-564 DURING ITS INITIAL PHASE OF THE 2011 OUTBURST

Debjit Chatterjee, debjitchatterjee92@gmail.com Indian Centre for Space Physics, Kolkata, India Dipak Debnath, dipakcsp@gmail.com

Indian Centre for Space Physics, Kolkata, India Santanu Mondal, astrophy.sm@gmail.com Universidad de Valparaiso, Valparaiso, Chile

We study the initial phase of the 2011 outburst of the Galactic transient black hole candidate (BHC) MAXI J1543-564 using archival data of RXTE/PCA instruments. 2.5-25 keV PCA data are used to infer the spectral and temporal properties of this transient source during its very first outburst after discovery. We use additive table model fits file of the Two Component Advective Flow (TCAF) solution to study the accretion dynamics of the source during the initial phase of the outburst. Observed low frequency quasi-periodic oscillations (QPOs) showed monotonically increasing trend in frequency. We find that this evolution of the QPO frequencies fits well with the propagating oscillatory shock (POS) model to find instantaneous shock parameters. We see that POS model fitted extracted shock parameters, such as shock location, compression ratio, etc. roughly match with those from TCAF model. We estimate most accurately mass of the black hole from spectral fits with the TCAF solution and from QPO evolution fitted with the POS model.

E1.6-0064-18 ACCRETION - EJECTION MECHANISM OF SWIFT J1753.5-0127 WITH THE TCAF SOLUTION

Arghajit Jana, argha0004@gmail.com

Indian Centre for Space Physics, Kolkata, India Dipak Debnath, dipakcsp@gmail.com

Indian Centre for Space Physics, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India Debjit Chatterjee, debjitchatterjee92@gmail.com

Indian Centre for Space Physics, Kolkata, India Santanu Mondal, astrophy.sm@gmail.com Universidad de Valparaiso, Valparaiso, Chile

Galactic black hole Swift J1753.5-0127 was discovered 2005 June 30 by Swift/BAT. We studied 3-25 keV RXTE/PCA data for our spectral and timing analysis. The spectral analysis has been done with two components advective flow (TCAF) model fits file in XSPEC to extract physical accretion flow parameters such as, mass of the black hole, two types of accretion rates, and shock parameters, etc. From the nature of the evolution of spectral fitted parameters, we classified entire 2005 outburst of the source into two types of harder spectral states: hard (HS) and hard-intermediate (HIMS). According to TCAF solution unlike other models, TCAF model normalization must be constant for any particular source, since it is function of intrinsic source parameters: mass, distance and inclination angle. But during 2005 outburst of Swift J1753.5-0127, TCAF model normalization constant for all observations. Higher values of TCAF normalizations are required to fit 5 observed data in HIMS, which may be due to the jet activity, since jet also contributes in the X-rays. After introduction of a new method, we estimated jet contributions in X-rays. The jet is found to contribute maximum upto 32%. The correlation between radio and jet X-ray fluxes are studied to have knowledge of the jet properties. A weaker correlation between radio and jet X-ray fluxes during HIMS, indicates nature of jet may not be fully compact, but partially blobby, while during HS, it is fully compact. We have also estimated mass of the black hole $\sim 5.3 \pm 0.6$ M0.

E1.6-0065-18 CAN NEUTRON STAR SPECTRUM ALSO BE EXPLAINED BY THE TCAF PARADIGM?

Ayan Bhattacharjee, ayan12@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

Two-component advective flow (TCAF) solution provides a thorough understanding of spectral properties in terms of flow parameters for black hole candidates (BHCs), but a similar study about its suitability is yet to be done for neutron stars. From purely theoretical point of view, an accretion onto a neutron star is dissimilar only when the flow reaches very close to the compact objects. For a black hole, matter is advected in and for a neutron star flow has to stop at the surface and the energy must be released at the very spot. The shock at the surface of neutron star thus produces the normal boundary layer (NBOL) emitting a blackbody radiation. It is, therefore, no wonder that up to a great extent, the spectral properties of matter accreting on a neutron star, in the soft/hard X-ray band, are similar to those of stellar mass black holes. We propose that the TCAF solution should be applicable here if the NBOL component is added. We study spectral properties of TCAF around a neutron star. We compute the effects of thermal Comptonization of soft photons emitted from a Keplerian disc and the NBOL by the post-shock region of a sub-Keplerian flow, formed due to strong centrifugal barrier around the star. The shock location Xs is the inner edge of the Keplerian disc. We compute a series of realistic spectra assuming a set of temperature of the post-shock region TCE, the temperature of NBOL TNS and the shock location Xs. We find that the resultant spectrum becomes harder when the halo accretion rate ($\dot{m}$ h) and angle of observation is increased. The spectrum is controlled strongly by TNS due to its proximity to the Comptonizing cloud since photons emitted from the NBOL cool down the post-shock region very effectively. Finally, we compare our results with a few observed cases. We found that when the absorption of photons below 10 keV due to interstellar media is included, the spectra become realistic. Many of the weakly-magnetic accreting neutron stars, viz., Sco X-1, 4U 1705-44, 4U 1728-34, 4U 1820-30, GX 3+1, GX 340+0, 4U 1700-37,

have been observed and are being observed by numerous X-ray missions. These objects differ from each other in terms of the mass of the companion (LMXB/HMXB), the class they belong in (Z/atoll) and the frequency of their spectral activity (persistent/transient) and thus, can serve as a broad pool for the verification of our theoretical model. We plan on analyzing the spectral data from different satellites, especially in the hard X-rays beyond 50 keV, of such sources with our solution.

E1.6-0066-18 DOES THE GEOMETRY OF KEPERIAN DISK VARY DURING THE OUTBURSTS OF A TRANSIENT LMXB?

Arindam Ghosh, arindam.ghosh@bose.res.in

Satyendra Nath Bose National Centre for Basic Sciences, KOLKATA, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

The central object in a low-mass X-ray binary (LMXB) accretes matter from its companion star mainly via Roche lobe overflow; the Keplerian disk, having high angular momentum and high viscosity becomes instrumental in overall accretion. In the same transient LMXB, the accumulation radius, from where matter rushes towards the black hole due to thermal-viscous instability, may be different in different outbursts. Using RXTE/ASM long-term data and employing a simple timing analysis, we examine more than a dozen outbursts in transient LMXBs, exhibiting either multiple outbursts (GX 339-4 and H 1743-322) or sporadic outbursts (e.g. 4U 1543-47, etc.). It is found that the Keplerian disk indeed varies in its size from an outburst to another; this, in turn, dictates the brightness of outbursts. Both canonical and anomalous/failed outbursts can be distinguished from our results. Outbursts, in general, are shown to fall into two types, based on four features observed by us.

E1.6-0067-18 EVIDENCE OF TWO COMPONENTS IN ACCRETION FLOW FROM TIME LAG PROPERTIES: LONG-TERM RXTE/ASM DATA ANALYSIS OF SEVERAL COMPACT OBJECTS

Arindam Ghosh, arindam.ghosh@bose.res.in

Satyendra Nath Bose National Centre for Basic Sciences, KOLKATA, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

Long-term RXTE/ASM X-ray data of several Galactic black holes (persistent, class-variable, and transient) are analyzed. The results of this analysis show the existence of two components in accretion flow in both low-mass and high-mass X-ray binaries (LMXBs HMXBs). Large disks with long viscous timescales in the accreting matter with high angular momentum are prevalent in LMXBs due to processes like Roche lobe overflow, while small disks with little viscous delays are observed in HMXBs primarily because of wind accretion. Because of two viscous time scales in the two components, there would be significant lag between the timesof-arrival of these two components. A large Keplerian disk in LMXB should cause a larger time lag as compared to that in HMXB. To detect such a lag using the ASM data having limited energy resolution, we introduce an index (Θ), which is a proxy of the usual (i) hardness ratio (HR), (ii) photon index, (iii) spectral index (α), and (iv) Comptonization efficiency (CE) defined to be the ratio of the number of hard photons to the number of soft photons injected into the Compton cloud at each instant of time. Temporal variation of Θ also reveals spectral state transitions. Classic method of cross-correlation between the two photon fluxes may not necessarily reveal the aforesaid lag. But when Θ, being susceptible to changes in the hard flux, is considered as a reference, a significant time lag is observed between the two fluxes in LMXBs. However, this lag is negligible in HMXBs. We therefore establish that there are indeed two components in the accretion onto a black hole.

E1.6-0068-18 LONG TERM X-RAY/RADIO MONITORING OF GALACTIC MICRO-QUASAR CYGNUS X-1

Dusmanta Patra, dusmanta.phy@gmail.com Indian Centre for Space Physics, Kolkata, India Sabyasachi Pal, sabya.pal@gmail.com

Indian Centre for Space Physics, Calcutta, India

The Galactic micro-quasar Cygnus X-1 is known to show variability of different time-scale. We are reporting long-term monitoring of the source, covering more than twenty years of time-span, using The Rossi X-ray Timing Explorer (RXTE) and Jansky Very Large Array (JVLA). We will discuss jet-disk relation of the system and will comment on possible correlation/anti-correlation between X-ray and radio emission.

E1.6-0069-18 EVOLUTION OF ACCRETION DISC GEOMETRY IN GRS 1915+105 DURING CHI STATE

Sun Yat-sen University, Zhuhai, China

Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

The evolution of the low frequency quasi-periodic oscillations (LFQPOs) and associated time lag in out-bursting black hole sources as function of time can be explained by variation of the Compton cloud size. We attempted a similar study of a persistently variable source, GRS 1915+105 during its two different χ state. We study the evolution of LFQPOs, time lag and Comptonizing efficiency (CE) with propagatory oscillating shock (POS) solution. We find a systematic drifting of Comptonizing region with a constant velocity for the both χ state observations. These propagation is similar to what we observe in XTE J1550-564 during 1998 outburst. The time lag varies in a similar way as the size of the Compton cloud. Most interestingly, in both the cases, the lag switches sign (hard lag to the soft lag) at a QPO frequency of 2.3 - 2.5 Hz irrespective of the energy of photons. We also find, at very low frequencies > 1 Hz, the Comptonizing efficiency (CE) increases with frequency and at higher frequency the tend is opposite and the time lag is always positive at all energies when CE is larger than 0.85% for both the sources. We explain the accretion dynamics with possible accretion geometry.

E1.6-0070-18 DO JETS INDUCE SOFT LAGS OF GALACTIC BLACK HOLE CANDIDATES AND AGNS?

Dusmanta Patra, dusmanta.phy@gmail.com Indian Centre for Space Physics, Kolkata, India Arka Chatterjee, arka019icsp@gmail.com Indian Centre for Space Physics, Kolkata, India

Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India Broja Gopal Dutta, brojadutta@gmail.com

Department of Physics, RBC College & Indian Centre for Space Physics, Kolkata, India

Time and phase lags of Galactic black hole candidates and AGNs are becoming more and more important in the last few years. Many of the intriguing features of time lag properties are discovered in recent years. However, a true nature of lag variation remains complicated mostly because of the nonlinear physical mechanisms that are originating the lag of the photons which are coming from the accretion disks. The hard lag contribution is found to be originated from the inverse Comptonization and disk reflection mechanism. But, the exact reason for soft lags are yet to be unveiled. We draw correlations between the radio intensities of outbursting cases where soft lags are found. Finally, we correspond this result with the measured linear polarization variation in radio band of such candidates in precise time domain of hard to soft lag inversion.

E1.6-0071-18 MULTI-FREQUENCY OBSERVATION OF HIGH MASS X-RAY BINARY CYGNUS X-3 DURING FLARES

Sabyasachi Pal, sabya.pal@gmail.com

Indian Centre for Space Physics, Calcutta, India

We studied the multi-frequency properties of the Galactic high mass X-ray binary Cygnus X-3 during various flaring activities using The Rossi X-ray Timing Explorer (RXTE), the Giant Metrewave Radio Telescope (GMRT), Jansky Very Large Array (JVLA) etc. The flare of 2006 May-June was one of the largest flare in the history of the source which is thoroughly discussed. We also observed few large flares of this source between 2007 and 2009. We commented on correlation and lag between X-ray and radio emissions during flares. We construct the radio spectrum of the source in the rising and fading phase of flares using GMRT, JVLA and published results using RATAN. We clearly see that the turn-over frequency is shifting towards lower frequencies as the flares evolve gradually. The two point spectral index between 614 MHz and 235 MHz varies from positive (optically thick) and negative (optically thin) values which is consistent with the synchrotron self absorption model. We calculated some physical parameters of the source such as the size of emitting region using the synchrotron self absorption model. The size of the emitting region expands with the flare. We estimate the velocity of the expansion of the blob in the non-relativistic range from the expansion of the size of emitting region.

E1.6-0072-18 HIGHER ORDER STABILITY ANALYSIS FOR ASTROPHYSICAL ACCRETION PROCESSES

Kinsuk Giri, kinsuk@nitttrkol.ac.in

National Institute of Technical Teachers' Training & Research (NITTTR), Kolkata, Kolkata, India

Sayan Kundu, sayan.astronomy@gmail.com India

We have done nth order perturbation analysis of the Navier-Stokes equation. Green's function is used to solve the n-th order velocity perturbation equation for accretion disc to deduct a stability criteria. Considering a thin disc, Shaker-Sunyeeb turbulent viscosity prescription is used for viscous terms. A local velocity stability criterion is proposed for a thin disc using Lynden and Bell's coordinate transformation method. Also, we used global boundary condition for accretion disc for finding boundary instabilities.

E1.6-0073-18 ROLE OF VISCOSITY AND COOLING ON THE ORIGIN OF SPECTRAL AND TIMING PROPERTIES: OBSERVATIONAL EVIDENCES

Max Planck Institute for Astrophysics, Garching, Germany Dipak Debnath, dipakcsp@gmail.com

Indian Centre for Space Physics, Kolkata, India

Low angular momentum (sub-Keplerian) and low viscosity flow produce a standing shock (boundary of the Compton cloud) during the outburst of a transient black hole candidate. As the day progresses, cooling increases and the average shock location moves closer to the black hole to satisfy the Rankine-Hugoniot condition during the rising phase. Because of resonance between cooling time scale and infall time scale, the shock oscillates, producing low frequency Quasi Periodic Oscillations (QPOs) of monotonically increasing frequency. Exactly opposite situation prevails during the declining phase. The geometry of the Compton cloud also dictates the spectral states. Thus the QPOs, the spectral states, and the formation of the shock itself are linked to viscosity of the sub-Keplerian flow. We analyze a few transient sources and calculate their Keplerian (αK) and sub-Keplerian (αSK) component viscosity parameters during the rising and the declining phases of the outburst. We see that the viscosity parameter changes monotonically in a similar way for all the outbursting candidates during its evolution. We estimate the range of viscosity parameter which is required to trigger different spectral states. This is important, since some sources do not reach the soft or even the soft intermediate states. We shed light on this very important correlation. From our study, we infer that the typical range of αSK parameter of the sub-Keplerian flow is within 0.1 for the transient sources. Most importantly our calculated αK of these sources is well above αSK, which makes the analysis more consistent.

E1.6-0074-18 VARIABILITY PROPERTIES OF TWO SEYFERT 1 ACTIVE GALACTIC NUCLEI MRK 493 AND ZW 229.015

Oluwashina Adegoke, adegoke.olushina@gmail.com Indian Institute of Science, Bangalore, India Gulab Chand Dewangan, gulabd@iucaa.in IUCAA, Pune, India

Banibrata Mukhopadhyay, bm@iisc.ac.in Indian Institute of Science, Bangalore, India Pramod Pawar, pawar.pk123@gmail.com

Swami Ramanand Teerth Marathwada University, Nanded, India 431 606, Nanded, India

From the simultaneous X-ray and UV observations of the narrow-line Seyfert 1 AGNs Mrk 493 and Zw 229.015, we study their variability properties in appreciable depth. The UV/X-ray data of Mrk 493 show remarkable correlation between the variability in both bands. Crosscorrlation analysis reveal that variations in the UV emissionn lead the X-ray emission and the measured time lag is consistent with the Comptonizastion scenario where disc UV seed photons are Compton-upscattered in the corona into the observed X-rays. Although the longterm Swift UV/X-ray emission of Zw 229.015 does not show a clear lead/lag, the source appear to be brighter in the UV when softer in X-rays. Both sources additionally show soft X-ray excess in their energy spectra which are well fitted by both the thermal comptonization and reflection models. Moreso, our spectro-temporal analyses supports the existence of a compact corona with radius r~ 20Rg in AGNs

E1.6-0075-18 A COMPARISON STUDY OF LFQPOS IN NEUTRON-STAR AND BLACKHOLE LOW-MASS X-RAY BINARIES

Qingcui Bu, buqc@mail.bnu.edu.cn Beijing Normal University, Beijing, China

We studied comparatively the properties of low-frequency quasi-periodic oscillations in a sample of fourteen black-hole and four neutron-star low mass X-ray binaries observed by the Rossi X-ray Timing Explorer satellite. We examined the similarities between these two classes of systems in terms of the FWHM - frequency correlation of QPO fundamentals and harmonics. We find that the fundamentals and the harmonics of black holes are consistent with a frequency modulation, while the harmonics of neutron star systems suggests amplitude modulation. We also studied all the sources from our sample in the aperiodic variability amplitude - frequency diagrams. We find that systems with lower source luminosity are likely to have a higher total variability amplitude.

NOVE ERUPTIONS, CATACLYMMIC VARIABLES AND RELATED SYSTEMS: OBSERVATIONAL VS. THEORETICAL CHALLENGES IN THE 2020 ERA (E1.7)

E1.7-0001-18 THE DISK-WIND-JET CONNECTION IN ACCRETING WHITE DWARFS AND RELATED OBJECTS

Christian Knigge, c.knigge@soton.ac.uk

University of Southampton, Southampton, United Kingdom

I will review our current understanding of disk winds and radio jets in accreting white dwarfs. I will focus particularly on the phenomenology of these outflows compared to those observed in neutron star and black hole X-ray binaries. However, I will also discuss the physical mechanisms that may drive these different forms of mass loss. Finally, I will explore the impact of such outflows on the underlying accreting system itself, on our observations of it, and on its environment.

E1.7-0002-18 THE DISK INSTABILITY MODEL FOR CATACLYSMIC VARIABLES AND XRAY BINARIES

Guillaume Dubus, guillaume.dubus@univ-grenoble-alpes.fr

Institut de Planétologie et d'Astrophysique de Grenoble, Grenoble, France Jean Pierre Lasota, lasota@iap.fr

Institut d'Astrophysique de Paris, Paris, France Magdalena Otulakowska-Hypka, magdaot@amu.edu.pl Adam Mickiewicz University, Poznan, Poland

The outbursts of dwarf novae cataclysmic variables (CVs) and low-mass X-ray binaries (XRBs) are thought to be due to a thermal-viscous instability of the accretion disk. The instability arises when hydrogen ionisation causes drastic changes in the opacity and thermodynamical properties of the disk. A fundamental prediction of this model is that, for a given masstransfer rate, systems are stable or unstable according to the size of the disk, mostly set by the orbital period. I will review how this compares with the observational data, focusing on our recent analysis of a large sample of CVs. I will conclude on the prospects for theoretical and observational progress in understanding the outbursts of CVs and XRBs through the disk instability model.

E1.7-0003-18 TURBULENT TRANSPORT OF ANGULAR MOMENTUM IN MAGNETIZED DISKS OF DWARF NOVAE

Nicolas Scepi, nicolas.scepi@univ-grenoble-alpes.fr

Institut de Planétologie et d'Astrophysique de Grenoble (IPAG), Saint Martin D'Hères, France Guillaume Dubus, guillaume.dubus@univ-grenoble-alpes.fr

Institut de Planétologie et d'Astrophysique de Grenoble, Grenoble, France Geoffroy Lesur, geoffroy.lesur@univ-grenoble-alpes.fr

Institut de Planétologie et Astrophysique de Grenoble, Saint Martin D'Hères, France

The eruptive cycles of dwarf novae (DNe) are thought to be due to a thermal-viscous instability in the accretion disk surrounding the white dwarf. This model has long been known to imply enhanced angular momentum transport in the accretion disk during outburst. This is measured by the stress to pressure ratio α, with α 0.1 required in outburst compared to α 0.01 in quiescence. Such an enhancement in α has been observed in simulations of turbulent transport driven by the magneto-rotational instability (MRI) when convection is present, without requiring a net magnetic flux (Hirose et al. 2014). We will compare these results to our simulations of vertically stratified, radiative, shearing boxes with the thermodynamics and opacities appropriate to dwarf novae (Scepi et al. 2018). We will discuss the impact of Ohmic dissipation on transport in the quiescent state of DNe, which is poorly ionized and likely to be MRI-stable. Finally, we will present our recent work on the impact of a large scale magnetic field on the enhancement of α and the resistive quenching of the MRI. Ultimately, these results will help us build a disk instability model (DIM) taking into account the effects of magnetic fields.

E1.7-0004-18 SUPERHUMPS LINKED TO X-RAY EMISSION. THE SUPEROUTBURSTS OF WZ SGE-TYPE STARS.

Vitaly Neustroev, vitaly@neustroev.net University of Oulu, Oulu, Finland

Only a handful of WZ Sge-type dwarf novae have been observed in X-rays, and until recently GW Lib was the only binary of this type with complete coverage of an X-ray light curve throughout a superoutburst. Here, we present extensive Swift X-ray observations of two other such systems to understand the extent to which the unexpected properties of GW Lib are common to the WZ Sge class. We analysed more than 4 years of Swift X-ray observations of the 2013 superoutburst, subsequent decline and quiescence of SSS J122221.7-311525, and Swift X-ray observations of the 2015 superoutburst of ASASSN-15po. We analysed the X-ray light curves and compared them with the behaviour of superhumps which were detected in the optical light curves. The results were compared with the properties of GW Lib. We found that in contrast to most of ordinary dwarf novae, SSS J122221.7-311525 and other WZ Sge-type stars showed an increase of their X-ray luminosity during an outburst and a very extended postoutburst decline lasting at least several hundred days. We have showed for the first time that the X-ray flux from SSS J122221.7-311525, GW Lib, ASASSN-15po, and possibly other WZ Sge-type systems is linked to their simultaneous superhump behaviour, thus linking the inner disc properties to those of the outer (possible whole) disc. This result suggests that models for accretion discs in high mass ratio accreting binaries are currently incomplete. The very long decline to X-ray quiescence is also in strong contrast to the expectation of low viscosity in the disc after outburst. We propose that the disc precession is a cause of an enhanced viscosity and an increased temperature of the inner disc, stimulating thus a matter drift through the disc during the decline stage of superoutbursts.

E1.7-0005-18 INSIGHTS FROM MULTI-WAVELENGTH OBSERVATIONS DURING HIGH AND LOW ACCRETION STATES OF NON-MAGNETIC CVS

Paula Szkody, szkody@astro.washington.edu

University of Washington, Seattle, Washington, United States

Close binaries containing a white dwarf accreting from a disk that receives material from a late stellar companion show an interesting variety of behavior that depends on their accretion rate and the changes in this rate. The highest accretion rates are evident during the bright states of novalikes, as well as the superoutbursts of the shortest period dwarf novae, followed by normal outbursts and the standstills of Z Cam systems. While the normal outbursts and superoutbursts of dwarf novae can be understood from the standpoint of disk and tidal instabilities, the changes in rates in novalikes when they enter low brightness states and the cause of extremely high rates for the systems between 3-4 hrs (SW Sex) remain elusive. The differences found from X-ray, UV and optical observations between these high and low states will be summarized as well as the prospects for increased understanding from the anticipated long term extensive coverage that will be provided by LSST and its resulting followup.

E1.7-0006-18 ACCRETION-INDUCED VARIABILITY ACROSS ALL SCALES

Simone Scaringi, simone.scaringi(at)canterbury.ac.nz University of Canterbury, NZ, Christchurch, New Zealand

Accreting objects are intrinsically variable on a wide range of timescales and wavelengths. This variability is mostly attributed to the accretion disks themselves, which transport material inwards through complex viscous processes. I will give a brief review of aperiodic variability (flickering) in accreting compact objects, with special emphasis on observations of accreting white dwarfs over the last decade, and present new observational results linking accreting systems across a wide range of scales, masses, and magnetic field strengths.

E1.7-0007-18 GW LIBRAE: A UNIQUE LABORATORY FOR PULSATIONS IN AN ACCRETING WHITE DWARF

Universidad de Valparaiso, 60102, Chile

Non-radial pulsations in accreting white dwarf offer insight into the excitation of pulsation modes in atmospheres with mixed compositions of hydrogen, helium, and metals, and the response of these modes to changes in the white dwarf temperature due to accretion outbursts.

The dwarf nova, GW Librae stands out by having a well-established observational record of three independent pulsation modes present in the optical and ultraviolet which disappeared when the white dwarf temperature rose dramatically following its 2007 superoutburst. Our analysis of Hubble Space Telescope (HST) ultraviolet spectroscopy taken in 2002, 2010, and 2011, showed that pulsations produce variations in the white dwarf effective temperature as predicted by theory. However, in our 2013 May HST/Cosmic Origin Spectrograph (COS) ultraviolet observations, GW Lib, besides showing variability at 275 s, which is close to the post-outburst pulsations detected with HST in 2010 and 2011, the white dwarf exhibited a large-amplitude variability on an 4.4 h time-scale (Toloza et al. 2016, MNRAS, 459, 3929T). This long-term variability is intermittent and had been detected previously in the optical. The first observations of this phenomenon in the ultraviolet allowed us to demonstrated that it is caused by an increase of the temperature of a region covering up to 30 percent of the visible white dwarf surface. However our study could not unambiguously identify the nature that causes this variability. Two viable hypotheses are a short-lived accretion episode or non-radial pulsations on a rapidly rotating star.

To further investigate the complex behaviour of the white dwarf in GW Lib, we organised in 2017 an intensive simultaneous multi-wavelength campaign using Kepler/K2, HST /COS, and Swift. K2 observed GW Lib during Campaign 15 in short-cadence mode (60sec) for 80 consecutive days, and the data is soon to be released. The K2 observations were complemented on August and September 2017 with multiple Swift X-ray and with HST /COS. Our

preliminary analysis of the COS ultraviolet light curve shows again the presence of the long period modulation, superimposed by the short period pulsations.

Here, in addition to the published work, we will present the analysis of this new multiwavelength data set, which will provide the most detailed insight into the pulsations of the accreting white dwarf in GW Lib ever obtained.

E1.7-0008-18 V341 ARA – THE NOVA-LIKE VARIABLE THAT HAS IT ALL

Noel Castro Segura, n.castro-segura@soton.ac.uk

University of Southampton, Southampton, United Kingdom
Christian Knigge, c.knigge@soton.ac.uk

University of Southampton, Southampton, United Kingdom

Non-magnetic nova-likes are cataclysmic variables with mass-transfer rates high enough to keep the accretion disk in a permanent high state. These systems are therefore great test beds for our understanding of steady-state accretion disks.

V341 Arae is an 11th magnitude blue object embedded in a large (8′ x 10′) emission line nebula. [O III] images suggest a parabolic bow-shock shape for the nebula, with V341 near the apex. The ionized mass of the nebula is very low compared to the canonical PN, though is inline with the spected form an old nova shell. The source was long misclassified as a Cepheid variable and first revealed as a nova-like CV by Samus, Pastukhova Durlevich (2007) and Frew (2008) independently. Even since then, it has remained surprisingly unnoticed by the CV community. The binary nature of the source is suggested by several strands of evidence: its blue optical colours, its X-ray luminosity and hardness, the presence of short time-scale flickering, and its optical spectrum (which contains broad absorption lines with emission cores). Remarkably, even though V341 Ara is one of the brightest novalikes known, even its orbital period has not yet been determined.

Here, we present results from a spectroscopic campaign we have been carrying out with the SAAO 1.9m telescope, in order to constrain the orbital period of the system. This is supplemented by archival data obtained with the CTIO 1.5m and new observations gather with SALT. We also present the results from long-term photometric light curves obtained by the ASAS-SN and KELT surveys, which reveal long-term (10 day) super-orbital (quasi-) periodicities.

E1.7-0009-18 ACCRETION IN MAGNETIC CVS FROM AN OBSERVATIONAL PERSPECTIVE

Axel Schwope, aschwope@aip.de

Leibniz Institute for Astrophysics Potsdam, Potsdam, Germany Hauke Worpel, hworpel@aip.de

Leibniz-Institut für Astrophysik Potsdam (AIP), Potsdam, Germany Iris Traulsen, itraulsen@aip.de

Leibniz-Institut für Astrophysik Potsdam (AIP), Potsdam, Germany

The census of XMM-Newton observations of polars will be presented. The spectral evolution through high and low states, the physical structure of the accretion region, and the spectral energy distribution of the accretion process will be discussed based on the large body of archival data and detailed multi-wavelength campaigns of key objects. Gaia parallaxes will be used to derive luminosities, the first time for a large subset of MCVs and update the X-ray luminosity function.

An outlook is given on the expected results from eROSITA all-sky surveys beginning 2019 and detailed X-ray spectroscopic observations with ATHENA.

Magnetic cataclysmic variables (mCVs) present a host of opportunities for time-resolved studies of accretion dominated by magnetic fields. Since their initial discovery by virtue of X-ray emission, they have been subject to multi-wavelength studies which have continued to reveal new insights. Here we review the role of high time resolution optical observations of mCVs and discuss how these have impacted on our understanding of the accretion processes at work. Recent work by us has included the search for observations of QPOs, which would appear to be rarer than initially thought. Polarimetry has always been a crucial tool to unlock the nature of the accreting magnetic white dwarfs in these systems and recent results in this area will also be presented.

E1.7-0011-18 MEASURING THE MASSES OF INTERMEDIATE POLARS WITH NUSTAR

Aarran Shaw, aarran@ualberta.ca University of Alberta, Edmonton, Canada Craig Heinke, heinke@ualberta.ca University of Alberta, Edmonton, Canada Koji Mukai, koji.mukai@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States Gregory Sivakoff, sivakoff@ualberta.ca

University of Alberta, Edmonton, Canada John Tomsick, jtomsick@ssl.berkeley.edu

Raman Research Institute, Bengaluru, India Poshak Gandhi, p.gandhi@soton.ac.uk

University of Southampton, Southampton, United Kingdom

The X-ray spectra of intermediate polars can be modelled to give a direct measurement of white dwarf mass. However, as the characteristic temperature of the standing shock located above the surface of the white dwarf is typically > 10 keV, we require telescopes capable of detecting hard X-rays. I will first discuss the fitting of accretion models to NuSTAR spectra of three intermediate polars; V709 Cas, NY Lup and V1223 Sgr in order to determine their masses. From fits to their 3–78 keV spectra, we find masses of 0.88+0.05, 1.16+0.04 and 0.75 ± 0.02 M0 for V709

Cas, NY Lup and V1223 Sgr, respectively. Our measurements are generally in agreement with those determined by previous surveys of intermediate polars, but with typically a factor 2 smaller uncertainties. This work has paved the way for an approved NuSTAR Legacy Survey of white dwarf masses in magnetic CVs, utilizing 1Ms of time to observe 25 magnetic CVs. The survey aims to constrain the mass distribution of magnetic white dwarfs in our Galaxy, which has important implications for binary evolution models and the production of type Ia supernovae. Finally, I will present the first results from the survey, which began observations in November 2017.

E1.7-0012-18 WHITE DWARF MASSES IN INTERMEDIATE POLARS

Valery Suleimanov, suleimanov@astro.uni-tuebingen.de University of Tuebingen, Tuebingen, Germany

Victor Doroshenko, doroshv@astro.uni-tuebingen.de Universitaet Tuebingen, Tuebingen, Germany Klaus Werner, werner@astro.uni-tuebingen.de Eberhard Karls University, Tübingen, Germany

We present results of white dwarf (WD) mass measurements in a sample of intermediate polars (IPs) observed by Suzaku and NuSTAR. A novel two-parameter grid of accretion-column spectra accounting for the finite magnetosphere size was used for this aim. The grid parameters are the WD mass, ranging between 0.3 - 1.4 solar masses, and the normalized magnetospheric radius Rrmm/RrmW D ranging between 1.5 - 1000. The fit to the hard X-ray spectrum of some IPs gives a strip on the WD mass - Rrmm plane, and a lower limit of the WD mass could be found assuming that the magnetospheric radius equals the radius of corotation. Assuming additionally that the break frequency in the power spectra of IPs corresponds to the Keplerian frequency at the magnetosphere allows then to estimate the WD mass and the magnetospheric radius simultaneously. This new method was tested using EX Hya, and allowed to obtain the WD mass in GK Per. We also showed that the magnetospheric radius in that IP increased from 2.8pm0.2 to sim4.3 RrmW D when its luminosity decreased from the maximum to quiescence during the outburst. This method was used for all available IPs observed by Suzaku and NuSTAR. Obtained WD masses are compared with masses published by other authors including those obtained with optical methods.

E1.7-0013-18 PROPERTIES OF HARD X-RAY BRIGHT POLARS

Koji Mukai, koji.mukai@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States

Polars are a subclass of magnetic cataclysmic variables (CVs) in which a strongly magnetic white dwarf accretes matter from a late-type, Roche-lobe filling mass donor. They are usually soft X-ray bright and hard X-ray dim, due to either buried shocks or strong cyclotron cooling, depending on system parameters. Indeed, the majority of the 100 currently-known polars were detected in the ROSAT all-sky survey. However, a small subset of polars have been detected as bright hard X-ray sources in INTEGRAL and Swift BAT surveys, and they make up a small, but increasingly non-negligible, fraction of INTEGRAL and BAT-detected CVs. I will present the current sample of polars detected in the BAT 105-month survey, as well as results of pointed X-ray observations of a subset of them. I will then summarize the current status towards understanding why a subset of polars are hard X-ray bright.

E1.7-0014-18 X-RAY PROPERTIES OF MAGNETIC CATACLYSMIC VARIABLES

Domitilla De Martino, demartino@oacn.inaf.it

INAF - Osservatorio Astronomico di Capodimonte, NAPLES, Italy Federico Bernardini, bernardini@nyu.edu

New York University Abu Dhabi, Abu Dhabi, United Arab Emirates Koji Mukai, koji.mukai@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States Maurizio Falanga, mfalanga@issibern.ch

International Space Science Institute, Bern, Switzerland Nicola Masetti, masetti@iasfbo.inaf.it

INAF - IASF Bologna, Bologna, Italy

Among hard X-ray galactic sources detected by the SWIFT and INTEGRAL surveys, those discovered as accreting white dwarf binaries have surprisingly boosted in number, representing 20% of the galactic sample. The majority are identified as magnetic Cataclysmic Variables (mCVs) of the Intermediate Polar type suggesting this subclass as an important costituent of galactic population of X-ray sources. We will discuss the X-ray emission properties as observed with our-ongoing XMM-Newton programme of newly discovered sources that enlarged sample almost by a factor of two, identifying commonalities and outliers.

E1.7-0015-18 RADIO OBSERVATIONS OF MAGNETIC CATACLYSMIC VARIABLES

Paul Barrett, pebarrett@gmail.com

US Naval Observatory/NVI, Washington, District of Columbia, United States

The Jansky Very Large Array was used to observe 121 magnetic cataclysmic variables (MCVs). We report radio detections of 18 stars. Thirteen are new radio sources, increasing the number of MCVs that are radio sources by more than twofold, from 8 to 21. Most detections are at 8.7 GHz (X-band) with a lesser number at 5.4 and 21.1 GHz (Cand K-bands). With the exception of AE Aqr whose flux density is typically > 5 mJy, the flux densities are in the range of 24-780 uJy. Thirteen of the detections show highly circularly polarized emission, which is characteristic of electron-cyclotron maser emission. The maser emission most likely occurs as a result of magnetic reconnection events near the surface of the red dwarf. Kbanddetections of such emission imply localized surfacemagnetic fields of >4 kG. The data suggest that MCVscould possibly be divided intotwo classes of radio emitters: those dominated by weakly polarizedgyrosynchrotron emission and those byhighly polarizedelectron-cyclotron maser emission.

E1.7-0016-18 MHD SIMULATION OF ACCRETION CURTAINS IN MAGNETIC CVS

Dmitry Bisikalo, bisikalo@inasan.ru

Institute of Astronomy of the RAS, Moscow, Russia Andrey Zhilkin, zhilkin@inasan.ru

Russia

Polina Isakova, isakovapb@inasan.ru

Institute of Astronomy of the RAS, Moscow, Russia

A three-dimensional numerical model for accretion in the magnetosphere of a white dwarf in a magnetic cataclysmic variable is developed. The model is based on the equations of modified MHD, where a strong external magnetic field acts as an efficient fluid with which the plasma interacts. The suitability of the model is confirmed by modeling the accretion in a typical intermediate polar EX Hya. Results of simulations show that the accretion in EX Hya proceeds via accretion columns, which are not closed and have curtain-like shapes. These columns are very thin and the hot spots cover a small fraction of the accretor surface. The numerical results are confirmed by comparison with available EX Hya system observations.

E1.7-0017-18 GROND OBSERVATIONS OF MAGNETIC CVS

Vadim Burwitz, burwitz@mpe.mpg.de

Max-Planck-Institut fur extraterrestrische Physik, Garching, Germany Dicle Zengin Camurdan, dzcamurdan@gmail.com

Ege University, İzmir, Turkey

We present the first results from a large project to obtain simultaneous optical and IR data of magnetic cataclysmic variables (mCVs) in preparation of observations that will be obtained with current and future X-ray observatories. The main goal is to characterize the IR light curves of a large sample of magnetic CVs homogeneously to determine system parameters as well as improve the ephemerides for these objects. With these measurements we would like to improve our knowledge of the space density of magnetic cataclysmic variables (mCVs). Until now it has been difficult bring the results from theoretical predictions and measurements together due selection effects (the main difficulty being flux limitation). To extend our sample to include fainter mCVs we are currently obtaining g'r'i'z'JHK measurements using the GROND 7 channel imaging instrument mounted on the 2.2m telescope at La Silla, Chile. From the light curves obtained with GROND we can determine the distance to objects by using the relationship between the distance and K-band surface brightness of the secondary star.

E1.7-0018-18 NEW RADIAL VELOCITY OBSERVATIONS OF V630 CAS: A 2.5 DAY ORBITAL PERIOD CATACLYSMIC VARIABLE

Juan Echevarria, jer@astro.unam.mx

Instituto de Astronomia, UNAM, Mexico City, Mexico

We present new radial velocity observations of this difficult-to-observe object due to its long period and to its alias-day synchronization. New semi amplitude of both components are derived as well as an an estimation of the mass ratio and the most probable inclination angle. Since the secondary is highly visible, we discuss its evolutionary state.

E1.7-0019-18 A WHITE DWARF DISPLAYING MAGNETICALLY GATED ACCRETION BURSTS

Simone Scaringi, simone.scaringi(at)canterbury.ac.nz University of Canterbury, NZ, Christchurch, New Zealand Thomas Maccarone, thomas.maccarone@ttu.edu

Texas Tech University, Lubbock, Texas, United States Caroline D'Angelo, dangelo@strw.leidenuniv.nl Netherlands

Christian Knigge, c.knigge@soton.ac.uk

University of Southampton, Southampton, United Kingdom Paul Groot, p.groot@astro.ru.nl

Radboud Universiteit Nijmegen, Netherlands

The accreting white dwarf MV Lyrae spends most of its time in an optically bright luminosity state but occasionally drops by more than a factor of 250 for short durations (weeks to months), sometimes fading to V 18. Here we present Kepler observations of MV Lyrae during a lowstate, displaying quasi-regular bursts of about 30minutes duration roughly every 2hours. The timescale and amplitude of these bursts indicate the presence of an unstable, magnetically regulated accretion mode, which in turn implies the existence of magnetically gated accretion. We are able to infer both the white dwarf magnetic field strength as well as the inner disk truncation radius throughout the magnetically accretion bursts. Additionally, to confirming a new accretion mode for white dwarfs, our results extend the connections between accretion onto white dwarfs, young stellar objects and neutron stars, for which similar magnetically gated accretion cycles have been identified.

E1.7-0020-18 PHASE-RESOLVED SPECTROSCOPY AND PHOTOMETRY OF THE ECLIPSING POLAR, UZ FORNACIS

Zwidofhelangani Ndamulelo Khangale, khangalezn@saao.ac.za South African Astronomical Observatory, 7708, South Africa Stephen Potter, sbp@saao.ac.za

SAAO, Cape Town, South Africa Patrick Woudt, pwoudt@ast.uct.ac.za

University of Cape Town, Cape Town, South Africa

We present phase-resolved spectroscopy and high-speed photometry of the eclipsing polar, UZ Fornacis. The blue continuum of UZ For is dominated by singleand/or double-peaked emission from the HeII, HeI and the Balmer lines. The red spectrum shows weak emission and absorption from NaI doublet at 8183 Å and 8194 Å and strong emission from CaII lines at 8498 Å and 8542 Å. Doppler tomography, using the inside-out technique based on the fast maximum entropy, of the strongest features reveal the presence of emission from the threading region, the ballistic and magnetic confined accretion stream as well as the irradiated face of the secondary star. We have obtained 31 new mid-eclipse times of UZ For to test the two-planet model proposed to explain the variations in its eclipse times. The new data agree with the predicted model but requires the outer planet to be highly eccentric. The orbital periods for the inner and outer planets are 5.17(2) and 14.76(3) years, respectively.

E1.7-0021-18 DISCUSSION I: CV OUTFLOWS, ACCRETION PHYSICS, DISK STRUCTURE, AND OBSERVATIONAL TOOLS

E1.7-0023-18 HYDRODYNAMIC SIMULATIONS OF CLASSICAL NOVAE OUTBURSTS AND THEIR EVOLUTION TO SUPERNOVA IA EXPLOSIONS

Sumner Starrfield, sumner.starrfield@asu.edu

Arizona State University, Tempe, Arizona, United States

We have continued our studies of accretion onto white dwarfs by following the evolution of thermonuclear runaways on Carbon Oxygen (CO) white dwarfs. We have varied the mass of the white dwarf and the composition of the accreted material but chosen to keep the mass accretion rate at 2 10–10M0 yr–1 to obtain the largest amount of accreted material possible with rates near to those observed. We assume either 25% core material or 50% core material has been mixed into the accreting material prior to the explosion. We use our 1D, Lagrangian, hydrodynamic code: NOVA. We will report on the results of these simulations and compare the ejecta abundances to those measured in pre-solar grains that are thought to arise from classical nova explosions. We find that in all cases and for all white dwarf masses that less mass is ejected than accreted and, therefore, the white dwarf is growing in mass as a result of the accretion and resulting explosion. We also find that these simulations are producing a significant amount of 7Li and, in addition, the best agreement with both nova explosions and pre-solar grains are with those simulations that assume 25% core material is mixed into the accreting material. This work was supported in part by NASA under the Astrophysics Theory Program grant 14- ATP14-0007 and the U.S. DOE under Contract No. DE-FG02- 97ER41041. SS acknowledges partial support from NASA, NSF, and HST grants to ASU. WRH is supported by the U.S. Department of Energy, Office of Nuclear Physics. Our results benefitted from collaborations and/or information exchange within NASA's Nexus for Exoplanet System Science (NExSS) research coordination network sponsored by NASA's Science Mission Directorate.

E1.7-0024-18 AT THE FOREFRONT OF MULTI-OUTBURST MODELING OF NOVA EXPLOSIONS

Yael Hillman, yhillman@amnh.org

American Museum of Natural History, New York, New York, United States Michael Shara, mshara@amnh.org

American Museum of Natural History, New York, New York, United States Dina Prialnik, dina@planet.tau.ac.il

Tel Aviv University, Tel Aviv, Israel Attay Kovetz, attay@etoile.tau.ac.il Tel Aviv University, Tel Aviv, Israel

Most nova evolution simulations consider several consecutive outbursts for a white dwarf (WD) of given mass and temperature and for a constant accretion rate. The results show that the nova characteristics depend strongly both on the WD mass and on the accretion rate. Although these calculations have been successful in reproducing the wide ranges of observed nova properties, there remain open questions that can only be answered by long term multi-cycle calculations that account for the evolution of the WD as well as the evolution of the binary system, which determines the rate of mass transfer.

We have followed the evolution of WDs of various initial masses through long series (thousands to tens of thousands) of nova cycles and we will show the gradual changes in mass and in internal structure that occur, as well as the resulting changes in the nature of nova outbursts. We consider both hydrogen and helium accretion and address the consequences of helium flashes. We show the circumstances under which WDs can grow up to the Chandrasekhar mass, to become progenitors of type Ia Supernovae (SN). We also consider the evolution of the companion and the change in separation of the binary system, which leads to a variable mass transfer rate. We account for the various mechanisms that affect the binary separation, including the illumination of the companion by eruptions (in parametrized form). These results may serve to characterize observed nova systems, predict future eruptions and detect potential progenitors of type Ia SN.

E1.7-0025-18 NOVA OUTBURSTS AND THE MESA MODELS

William Wolf, wmwolf@asu.edu

School of Earth and Space Exploration, Arizona State University, Tempe, Arizona, United States

For over 45 years, 1D stellar models have been used to simulate classical nova outbursts. These models continue to be useful, but the tools to model them have evolved and multiplied. This has given rise to a rich variety of predictions full of emergent consensus and intriguing discrepancies. A newcomer to the field is the open source Modules for Experiments in Stellar Astrophysics, or MESA. The star module in MESA is a general purpose stellar evolution code for evolving spherically-symmetric objects from planets to core collapse supernovae to accreting neutron stars. In this talk I present MESA models of accreting white dwarfs from accumulation through the thermonuclear runaway, outburst, and the post-outburst supersoft phase. I'll call special attention to points of uncertainty arising from different physical assumptions and areas of deficiency in the models' abilities to reproduce observations. I'll conclude with a broad outline of what is needed to enhance 1D models to extend their utility into the 2020 era where highquality multi-wavelength data will become the norm for nova observations.

E1.7-0026-18 MULTI-WAVELENGTH STUDIES OF NOVAE: THERMAL EMISSION

Kim Page, klp5@le.ac.uk

University of Leicester, Leicester, United Kingdom

The rapid response capabilities of the Swift satellite, together with the daily planning of its observing schedule, make it an ideal mission for following novae in the X-ray and UV bands, particularly during their early phases of rapid evolution and throughout the super-soft source interval. A number of both classical and recurrent novae have been extensively monitored by Swift throughout their super-soft phase and later decline. We report results from these observations, including the high-amplitude flux variation often see at the start of the super-soft emission, the differing relationships between the X-ray and UV variability, and the spectral evolution seen in the X-ray band.

E1.7-0027-18 SWIFT-XRT OBSERVATIONS OF SHORT PERIOD OSCILLATIONS SEEN IN THE SUPER SOFT SOURCE EMISSION FROM CLASSICAL AND RECURRENT NOVAE

Andrew Beardmore, ab271@le.ac.uk

University of Leicester, Leicester, United Kingdom

We report short timescale, soft X-ray flux modulations seen by the Neil Gehrels Swift Observatory X-ray Telescope (XRT) during the super soft source (SSS) emission phase from novae. A periodogram analysis revealed oscillations were visible in the 0.3 10.0 keV XRT light curves obtained from RS Oph (period, P=35.0 s), KT Eri (P=34.9 s), V339 Del (P=54.0 s), and V5668 Sgr (P=69.7 s), with fractional rms variabilities ranging from 1 – 8 per cent.

During day 32 59 of the RS Oph outburst, the oscillation central frequency appeared quite variable, ranging from 26.2 31.1 mHz, caused by a lower coherence at this time. However, after day 50 the oscillation became more coherent, with a frequency that slowly increased from 28.3 28.9 mHz over 9 days, before the trend reversed. The oscillation frequency was less variable in KT Eri and V339 Del. No other correlations, such as between the oscillation frequency or amplitude with source intensity, were apparent.

A wavelet analysis of the variability seen in RS Oph, KT Eri and V339 Del revealed the oscillations were sometimes visible for entire XRT snapshots lasting 1.0 1.5 ks, yet on other occasions, they were detected for only 120 s (i.e. 2 4 cycles). The modulation fractional amplitude was variable, occasionally reaching values of 15 20 per cent for a few cycles. During times when the coherence was low, the oscillation phase was seen to jump by 0.4 0.6 cycles in RS Oph, then remain stable for 10 cycles. KT Eri showed smaller phase jumps of 0.2 cycles.

We detect a significant spectral variation through the 35 s oscillation seen in RS Oph, with the spectrum becoming harder at the time of the modulation maximum. Fits to the oscillation maximum and minima spectra suggest the increased flux between 0.6 0.75 keV in the former is caused by a 25 per cent reduction in the oxygen column density at this phase.

We discuss the possible origins behind the oscillations.

E1.7-0028-18 THE COMPLICATIONS OF LEARNING FROM SUPER SOFT SOURCE XRAY SPECTRA

Jan-Uwe Ness, juness@sciops.esa.int

European Space Astronomy Centre, Villanueva De La Canada, Spain

Super-Soft-Sources (SSS) are emitted by hot white dwarfs hosting nuclear burning on their surface. Observations of SSS promise to reveal information about the central nuclear burning engine that keeps the whole system alive. Important parameters are the effective temperature, chemical composition of material before it is ejected, and mass of the underlying white dwarf. CCD spectra of SSS can in many cases already be reproduced by a blackbody model yielding an effective temperature and radius. However, without physically realistic assumptions the values are not reliable. Atmosphere models can also reproduce CCD spectra (no wonder with more parameters), but their parameters cannot be constrained from observations and are thus not more reliable than blackbody parameters. High-resolution X-ray grating spectra do allow atmosphere models to give us more information, because they resolve absorption lines and their profiles. However, we have not found any atmosphere model yet that reproduces the observed spectra well enough to provide parameters that can be trusted. I will present examples of SSS spectra, illustrating the complexity of them discussing the challenges we are facing during interpretation.

E1.7-0029-18 MODELLING OF COMPLEX ABSORPTION ON HIGH-RESOLUTION X-RAY SPECTRA OF NOVAE: THE CASE OF V4743 SGR

Cigdem Gamsizkan, cigdem.gamsizkan@gmail.com Middle East Technical University, Ankara, Turkey Solen Balman, solen.balman@gmail.com

Middle East Technical University, Ankara, Turkey

Nova V4743 Sgr was discovered in outburst on September 2002 and was observed by XMMNewton RGS (Reflection Grating Spectrometer) on April 2003. The RGS spectra of V4743 Sgr show complex absorption features and the previous studies indicate a blueshift in the spectra, hence we considered there exist a collisionally ionised hot absorber and/or a photoionized warm absorber component originating from wind and/or ejecta. We utilise SRON software SPEX

3.03.00 for our analysis and use its absorption models. The light curve showed oscillations in the count rate during the observation. The spectral analysis of the entire spectrum indicates that the models are inadequate. Taken into account the oscillations in the spectrum we considered to work on several resolved spectra on QPO time-scale. One of the best fit for a chosen RGS spectrum yields a blackbody for the continuum with temperature range 41-45 eV. We assumed two warm and one hot absorption components yielding blue shifts 1200-3500 km/s, along with an interstellar absorption and a dust absorption components. The resulting two warm absorption models have NH1 3.5-4 1021 cm−2 and NH2 9-7.5 1020 cm−2 with ionization parameter Log(ξ1) 3.7 erg cm s−1 and Log(ξ2) 1.3 erg cm s−1. The hot component has

NH 0.4-0.7 1024 cm−2 and temperature deviating between 1.5-3.2 keV. The best fits for the other spectra can also be obtained with the same composite model. The χ2 values differs from region to region and ranges between 2.3-7.2.

E1.7-0030-18 TRANSIENT SUPERSOFT X-RAY BINARIES IN THE MAGELLANIC CLOUDS OBSERVED WITH SALT AND ASTROSAT

Philip Charles, p.a.charles@soton.ac.uk

University of Southampton, Southampton, United Kingdom David Buckley, dibnob@saao.ac.za

University of the Free State, Bloemfontein, South Africa Gulab Chand Dewangan, gulabd@iucaa.in

IUCAA, Pune, India

We have exploited the ToO capability of SALT, and its blue-sensitive spectrograph RSS, together with ASTROSAT to observe X-ray binary transients in the Magellanic Clouds, including new and known supersoft systems (SSS). These are generally accepted to be examples of steady thermonuclear burning on the surfaces of white dwarfs accreting at or above the Eddington rate. To achieve such rates requires an inverted mass ratio (i.e. the donor is heavier than the white dwarf), but this paradigm has never been confirmed as no accurate mass measurements have ever been possible, due to the extreme brightness of the continuously hot accretion disc. Through the SALT Transients Large Program we have studied highly variable SSS with the aim of searching for evidence of the nature of the donor stars in SSS, and to study their behaviour as a function of X-ray flux level.

E1.7-0031-18 WHAT WE HAVE LEARNED FROM THE BRIGHTEST NOVAE IN THE XRAY BAND IN THE MAGELLANIC CLOUDS

Marina Orio, marina.orio@oapd.inaf.it

INAF-Padova (Italy) and Dept. of Astronomy, University of Wisconsin (USA), Padova, Italy

Classical and recurrent novae in the Magellanic Clouds offer the advantage of following nova eruptions at known distance. In the soft X-rays, the lack of conspicuous interstellar absorption towards the Clouds compensates for their distance, on average 10 times larger than known Galactic novae, so high resolution X-ray spectra of good quality can be obtained. In this talk I will review the results of two works done with two different teams of coauthors, on Nova LMC 2009a and on Nova SMC 2016a, respectively. N LMC 2009a was a luminous recurrent nova and had a relatively slow X-ray development, with spectra in which the absorption features are less deep than in most novae. The second nova, N SMC 2016a, was unusually luminous at all wavelengths, and may be the prototype of a rare class of "hyperluminous" novae. Its spectra shows very deep, blue-shifted absorption features, which evolved quite rapidly. The peak effective temperatures we derived for the white dwarfs of both novae imply massive objects, most likely exceeding 1.2 solar masses. I will show what we learned about the chemistry and physics of these novae that exploded in lower metallicity environment than the Galactic ones. I will also discuss what we expect to be able to learn with Athena.

E1.7-0032-18 MULTIWAVELENGTH OBSERVATIONS OF THE TWO REMARKABLE NOVAE SMCN 2016-10A AND V407 LUP

Elias Aydi, eaydi@saao.ac.za SAAO, Cape Town, South Africa

In this presentation I will elaborate on multiwavelength observations of the very fast and extremely bright nova SMCN 2016-10a. This observational set is one of the most comprehensive for any nova in the Small Magellanic Cloud. The progenitor system contains a bright disk and a main sequence or a sub-giant secondary. The nova is very fast with t2 4.0 1.0 d in the V - band. If the nova is in the SMC, at a distance of 61 10 kpc, we derive MV,max 10.5 0.5, making it the brightest nova ever discovered in the SMC and one of the brightest on record. In the talk, I will also highlight very interesting results on the remarkable nova V407 Lup, which is an intermediate-polar candidate.

E1.7-0033-18 ALMA OBSERVATIONS OF THE SHELL AROUND NOVA V5668 SGR

IAG - Universidade de São Paulo, São Paulo, Brazil

Nova Sgr 2015b is a peculiar dust forming nova (Banerjee et al. 2015) that has been extensively observed in multiple wavelengths from radio (Linford et al. 2015) to gamma-rays (Cheung et al. 2015). A broad ionization range (Kuin et al. 2015) indicates a clumpy ejecta early after outburst. The formation of the unstable 7Be isotope has been confirmed in this nova (Tajitsu et al. 2016) as well as a slowly anisotropic expanding shell. We present ALMA long baseline (C40-9) observations of this recent shell with 0.029" resolution, both in the continuum at 230 GHz and in the H30α NLTE boosted recombination line. We have detected a 0.45" shell from the 2015 outburst. The presence of a highly structured ejecta 2.5 years after outburst is discussed in comparison with older resolved shells.

E1.7-0034-18 THE OUTBURST OF THE SLOW CLASSICAL NOVA V612 SCT 2017.

Drahomír Chochol, chochol@ta3.sk

Ľubomír Hambálek, lhambalek@ta3.sk

Astronomical Institute, Slovak Academy of Sciences, Tatranská Lomnica, Slovak Republic

We present the results of multicolor photometry and optical spectroscopy of the slow classical nova V612 Sct. Our UBVRI CCD photometry was obtained with 0.18 and 0.6m telescopes and optical echelle spectra (spectral resolution 12000 and 24000) with 0.6 and 1.3m telescopes of the Astronomical Institute of the Slovak Academy of Sciences at the Stará Lesná and Skalnaté Pleso observatories. Our data were completed by the AAVSO International Database and the Astronomical Ring for Access to Spectroscopy (ARAS) data. The nova V612 Sct underwent its outburst in June 2017 and reached the brightness maximum on July 30, 2017. We used the maximum magnitude - rate of decline relations to find the absolute magnitude of the nova at maximum. We estimated the value of colour excess and calculated the distance to the nova. The Hα and Hβ line profiles allowed us to study the structure of the nova V612 Sct expanding envelope. We identified principal and diffuse enhanced P-Cygni absorptions, which originate in two separate expanding shells. We investigated the evolution of radial velocities of both shells and expansion velocities found from the Hα and Hβ emission lines.

E1.7-0035-18 POPULATIONS AND PROPERTIES OF CLASSICAL AND RECURRENT NOVAE IN M31

Martin Henze, mhenze@sdsu.edu

San Diego State University, San Diego, California, United States
Matt Darnley, m.j.darnley@ljmu.ac.uk

Liverpool John Moores University, Liverpool, United Kingdom

The first nova in the Andromeda galaxy (M31) was discovered over a century ago and today we know of more than one thousand such objects. This unparalleled sample permits study of the physical properties and distributions of various sub-classes of novae, such as spectral classes, donor stars, or stellar environments, together with their rates. In this talk we present recent results from multi-wavelength observations of M31 novae and discuss their relevance and connection to new theoretical nova models. Particular focus will be given to recurrent novae, their population properties, rates, and importance for the single-degenerate channel of type-Ia supernova progenitors.

This talk will be given in tandem with Dr. Matt Darnley (LJMU).

E1.7-0037-18 NOVAE AS GAMMA-RAY SOURCES FROM RADIOACTIVITIES AND PARTICLE ACCELERATION

Margarita Hernanz, hernanz@ieec.uab.es

Institute of Space Sciences ICE (CSIC) and IEEC, Bellaterra (Barcelona), Spain

Nova explosions synthesise radioactive nuclei, which are emitters of γ-rays in the MeV range. Lines at 478 and 1275 keV correspond to 7Be and 22Na decays. In addition, positron-electron annihilation also produces γ-ray emission, with the 511 keV line and a continuum below it. γ-ray spectra and light curves are unique tools to trace the corresponding isotopes and to give insights on the properties of the expanding envelope. Photons in the MeV energy range from nova explosions have not been detected yet, because past and current instruments (e.g., CGRO/Comptel and INTEGRAL/SPI) are not sensitive enough, and only novae closer than about 1 kpc are expected to be detected; there have not been candidates so far. More optimistic perspectives will be offered by the ESA (M5) proposed mission e-ASTROGAM.

Another type of γ-ray emission from novae originates in particle acceleration in strong shocks related to mass ejection. Shocks can be either external - between the nova ejecta and the dense wind of the red giant companion in symbiotic recurrent novae - or internal - within the nova ejecta of classical novae. Collisions between accelerated protons produce neutral pions which decay emitting photons with energies larger than 100 MeV (hadronic process); relativistic electrons are responsible for Inverse Compton emission, also at high energies (leptonic process). Fermi/LAT has detected high-energy γ-rays in several novae, of both types, since its launch in 2008.

A review and update of both topics will be presented, together with the implications for the understanding of nova nucleosynthesis (MeV γ-rays) and shocks during mass ejection (GeV γ-rays).

E1.7-0038-18 GAMMA-RAY NOVAE: FERMI-LAT OBSERVATIONS AND THEORETICAL PROSPECTS

Fermi-LAT collaboration Fermi-LAT collaboration

Novae are now firmly established as a high-energy (>0.1 GeV) gamma-ray source class by the Fermi Large Area Telescope (LAT). In symbiotic-like binary systems such as V407 Cyg 2010, there is a clear theoretical framework for the production of accelerated particles in the nova ejecta from passage of the shock through the dense wind of the red giant companion as was previously proposed for RS Oph 2006. The high-energy gamma-ray emission detected in classical novae, sited in compact binary systems with less evolved stellar companions, cannot be explained in the same way. It could, instead, be produced by internal shocks within the ejecta. We summarize the Fermi-LAT gamma-ray observations of novae, highlighting the main properties that will guide further studies particularly in the MeV energy range.

E1.7-0039-18 HIGH ENERGY EMISSION FROM THE RECURRENT NOVAE RS OPH & V745 SCO

Laura Delgado Pardo, lauradelgadopardo@gmail.com

Institut de Ciències de l'Espai (IEEC-CSIC), Northridge, Los Angeles, California, United States Margarita Hernanz, hernanz@ieec.uab.es

Institute of Space Sciences ICE (CSIC) and IEEC, Bellaterra (Barcelona), Spain

In recent years, eleven nova explosions have been detected by the Fermi /LAT satellite, ten classical novae and two symbiotic recurrent novae. The very high-energy γ-ray emission in novae is produced by π0 decay and/or Inverse Compton, which is a consequence of particle, p and e−, acceleration. The strong shock between matter ejected by the white dwarf and the circumstellar medium is responsible for this process. RS Ophiuchi was the first nova for which particle acceleration was predicted, during its 2006 outburst. Our aim is to understand the acceleration process through the analysis of contemporaneous X-ray emission.

We present the shock wave evolution of the recurrent novae V745 Sco and RS Oph based on the analysis of early X-ray observations. We analyse X-ray observations of V745 Sco by Swift /XRT simultaneous to particle acceleration and thus Fermi /LAT detection. Then, we study the XMM-Newton's observations of RS Oph early after its 2006 outburst both with RGS spectrograph and EPIC-MOS camera. Finally, we compare the observations of these two novae with other X-ray satellite data and with the IR and radio emission contemporaneous of early hard X-ray emission. This study allows us to globally describe the evolution of the nova remnant the first days after nova outburst and its relationship with particle acceleration.

E1.7-0040-18 NOVA OUTFLOWS, MODELLING TNRS AND THE OUTBURST VERSUS MULTI-WAVELENGTH OBSERVATIONS AND LINKS TO SN TYPE IA-CONTINUED

E1.7-0042-18 MODELLING OF THE MAGNETIC FIELD DISTRIBUTION IN THE MAGNETIC CATACLYSMIC VARIABLES

Lilia Ferrario, lilia.ferrario@anu.edu.au

Australian National University, Canberra, Australia Gordon Briggs, gbriggs@bigpond.com

Australian National University, ACT 2601, Australia

We have proposed that high field magnetic white dwarfs are the result of close binary interaction and merging during common envelope evolution. We now synthesise a population of binary systems to investigate the hypothesis that the magnetic fields in the accreting magnetic white dwarf in cataclysmic variables also originate during stellar interaction in the common envelope phase. We have found that those systems that emerge from common envelope more tightly bound form the cataclysmic variables with the strongest magnetic fields. We vary the common envelope efficiency parameter alpha and compare the results of our population syntheses with observations of magnetic cataclysmic variables. We find that common envelope interaction can indeed well explain the observed characteristics of these binaries at low values of alpha.

E1.7-0043-18 THE SYMBIOTIC BINARY POPULATION CHARACTERISTICS, MODELS AND EVOLUTION

Joanna Mikolajewska, mikolaj@camk.edu.pl

Nicolaus Copernicus Astronomical Center, Warsaw, Poland

Symbiotic stars are long-period strongly interacting binaries in which the first-formed white dwarf accretes material from a red giant companion. Their study is essential to understand the evolution and interaction of detached and semi-detached binaries involving RGB and AGB stars. I will discuss progress in deriving physical properties of these binaries as well as challenges they continually pose to the binary evolution theory. Among these are the issues regarding stability of mass transfer and synchronization in systems with tidally distorted giants, distribution of the orbital parameters of S-type systems, and their chemical peculiarities.

E1.7-0044-18 AM CVN STARS: THEIR POPULATION CHARACTERISTICS AND EVOLUTION

Tom Marsh, t.r.marsh@warwick.ac.uk

Department of Physics, University of Warwick, Conventry, United Kingdom

First recognised 51 years ago, AM CVn stars are compact close binaries in which white dwarfs accrete from hydrogen-deficient companion stars. We know of about 50 AM CVn stars, half of them discovered within the past 8 years. Their orbital periods range from 5 to 65 minutes, which makes them strong emitters of gravitational radiation at frequencies accessible to space-based detection. Gravitational radiation is the determining factor in the evolution of AM CVn stars, and leads to a very strong stratification of their properties with orbital period. I will review the properties of the known population of AM CVn stars and discuss their evolution. I will show that we currently face a conundrum in understanding the origin of these stars because all identified pathways to their formation face problems when confronted with observations. Understanding this is key for a quantitative prediction of their significance as supernova hosts and for the Galactic spectrum of gravitational waves below periods of 15 minutes.

E1.7-0045-18 SECULAR EVOLUTION OF CVS AND ASSOCIATED SPACE DENSITIES

Juan Venancio Hernandez Santisteban, j.v.hernandez@uva.nl University of Amsterdam, Amsterdam, Netherlands

The standard model of evolution of cataclysmic variables has been around for over 3 decades. Within this time, both theoretical and observational progress has deliver a robust description of the overall population properties of CVs. However, several discrepancies between predictions and properties of the observed CV population remain. In the last few years, efforts have concentrated in forming an observational picture from the youngest systems (post-common envelope systems) to the oldest (period bouncers). This has allowed to probe the evolution of CVs in a wider time-scale and directly test our assumptions implemented in the theory. In parallel, the advent of new stellar evolution codes and binary population synthesis codes have allowed to trace the different outcomes and shortcomings of the standard model, such as common envelope physics and influence of nova eruptions, and its impact in the present-day CV population. In this review talk, I will provide the current state of our knowledge of CV evolution and present the recent theoretical and observational breakthroughs of the past years. In particular, I will focus on the impact of these results on the space densities of the present CV population. The next decade will deliver a deeper and rich multi-wavelength all-sky dataset which will enable us to probe both ends of the evolution (as well as everything in between) and will provide firmer limits to the true space density of the CV population.

E1.7-0046-18 A SYSTEMATIC STUDY OF THE SPECTRAL ENERGY DISTRIBUTION OF WZ SGE-STARS REVEALS NEW SOLID CANDIDATES FOR PERIOD-BOUNCERS.

Vitaly Neustroev, vitaly@neustroev.net University of Oulu, Oulu, Finland Christian Knigge, c.knigge@soton.ac.uk

University of Southampton, Southampton, United Kingdom Sergey Zharikov, zhar@astrosen.unam.mx

Instituto de Astronomia, UNAM, Ensenada, Mexico

According to standard evolutionary theory, cataclysmic variables (CV) evolve from longer to shorter orbital periods until a minimum period P min is reached. The period bouncers are such CVs that have passed beyond P min and are evolving back toward longer periods, with the donor star now extremely dim. This has long been predicted to be the "graveyard" and current state of 70% of all CVs, though only about a dozen of more or less robust candidates for such period bouncer systems have been identified until now, out of a thousand of known CVs. CVs of the WZ Sge-type have been long considered as potential period-bouncer candidates. However, only very few of recently discovered WZ Sge-type stars were observed spectroscopically in quiescence due to their faintness (19-22 mag). Thus, the lack of information on many WZ Sge-type stars does not allow us to put restrictions on their system parameters and to confirm or deny their period bounce nature. The determination of system parameters requires many hours of observations with very large telescopes. This explains why direct (spectral) evidence for brown-dwarf donors exists only for a couple of CVs. We recently took a novel, simpler yet equally valuable approach based on multicolour broadband photometry, without the recourse to spectroscopy, to reveal the best candidates for the period bouncers. By adopting such an approach, we have already studied 30 WZ Sge-type stars (the observations are still in progress) and have found solid evidence for very low-mass donor stars of very low luminosity in several of them. In this presentation, we will discuss the various methods by which post period-minimum CVs can be recognized, and will highlight recent progress in this field.

E1.7-0047-18 CV EVOLUTION AND THE WHITE DWARF MASS PROBLEM

Monica Zorotovic, mzorotovic@dfa.uv.cl Universidad de Valparaiso, Valparaiso, Chile Mathias R. Schreiber, matthias.schreiber@uv.cl Universidad de Valparaiso, 60102, Chile

Although the theory of CV evolution is able to explain several observational aspects, strong discrepancies have existed for decades between observations and theoretical predictions of the orbital period distribution, the location of the minimum period, and the space density of CVs. Moreover, in 2011 we showed that the average white dwarf (WD) mass observed in CVs is significantly higher than the average mass in single WDs or in detached close WD+MS binaries that are going to become CVs (Zorotovic, Schreiber & Gaensicke 2011). We also confirmed the absence of helium-core WDs (with masses below 0.5 Msun) in CVs, which is not observed in their immediate detached progenitors. These results are in strong disagreement with theoretical models, because nova eruptions are supposed to prevent the WD to increase in mass during the CV phase. This highly motivated us to revise the theory of CV formation and evolution. We developed a new empirical model for angular momentum loss in CVs that allows us to explain the high average WD mass observed in CVs and the absence of CVs with helium-core WDs (Schreiber, Zorotovic & Wijnen 2016). This model seems to solve not only the WD mass problem but also several other previously mentioned disagreements between theory and observations. Moreover, it also provides us with a very likely explanation for the existence of low-mass WDs without a companion (Zorotovic & Schreiber 2017).

Cataclysmic Variables (CVs) are one of the best classes to test our understanding of the evolution of compact, interacting binaries: they are numerous, relatively bright, and both stellar components are structurally simple. Nonetheless, our recent results from a large HST program (Pala et al. 2017) have highlighted a number of discrepancies between current population models and observations. Only once these discrepancies are resolved we can trust the theoretical models to be sensibly applied to more complex systems, such as black hole binaries, X-ray transients or SN Ia progenitors.

In particular, one of the most striking disagreements is the lack of period bouncers, i.e. old CVs in which the companions have been eroded down to brown dwarf masses. These systems are predicted to make up for 70% of the observed CV population, yet very few have been identified so far, suggesting that the physical mechanisms driving CV evolution (such as the mechanisms of angular momentum loss, the common envelope phase and/or the response of the companions to the mass loss) are still not completely understood. For this reason we have started a high cadence photometric survey using JAST/T80Cam aimed to find these elusive systems and we present here the preliminary results from this observing program.

E1.7-0049-18 THE HIBERNATION THEORY OF CVS REVISITED: CLUES FROM NEW MODELS AND THE M87 HST SURVEY

Michael Shara, mshara@amnh.org

American Museum of Natural History, New York, New York, United States

Is the mass transfer rate Mdot from red dwarfs to white dwarfs a constant during the millenia between nova eruptions? The original hibernation scenario of cataclysmic binary evolution (Shara et al 1986) posited that Mdot varies by orders of magnitude, driving old novae to eventually look like dwarf novae, and perhaps detached systems. I will review observational and theoretical evidence for and against hibernation that has accumulated over the past 30 years. I will also present the results of the longest-ever HST survey of M87, seeking the stillelusive Rapidly recurring Novae which are the best canddate CV SNIa progenitors.

E1.7-0050-18 THE ORIGIN OF MAGNETIC WHITE DWARFS AND MAGNETIC CATACLYSMIC VARIABLES

Lilia Ferrario, lilia.ferrario@anu.edu.au

Australian National University, Canberra, Australia

The first detection of a magnetic field in a star other than our own Sun, 78 Vir, was obtained in 1947 and the first magnetic white dwarf, Grw+70o8247, was discovery in 1970. However, the origin of magnetic field in stars, from pre-main sequence to the compact star stage, is still one of the main unanswered questions in astrophysics. It is also quite curious that there is not a single magnetic white dwarf paired with a non-degenerate companion star in a non-interacting binary. In order to explain this peculiar finding, we cannot employ a process that impedes the formation of a strong magnetic field in a proto-white dwarf when it has a companion, because such a process would also prevent the formation of magnetic cataclysmic variables (MCVs) which are binary systems consisting of a magnetic white dwarf accreting mass from a red dwarf companion. This curious puzzle points to the absurd conclusion that MCVs have no progenitors! This is the reason why it has been proposed that fields in certain classes of magnetic stars are generated through an $\alpha\,\Omega$ dynamo within the common envelope of a binary system where a weak seed poloidal field is twisted up by differential rotation to create a strong toroidal field. However toroidal and poloidal fields are unstable on their own, so once the toroidal field reaches its maximum strength and differential rotation subsides, the decay of toroidal field leads to the generation of a poloidal field with the two components stabilising each other and limiting field growth until they reach a final stable configuration. According to this scenario, the closer the cores of the two stars are drawn before the envelope is ejected, the stronger the final field of the star emerging from common envelope will be. The strongest fields occur when the two stars merge and form an isolated magnetic white dwarf. If the two stars do not merge but come out of common envelope just before mass transfer starts, they become the progenitors of the MCVs. The most strongly magnetic binaries would appear as pre-polars where the magnetic white dwarf accretes matter from the wind emanated from its companion.

In this solicited talk I will present very recent results on the generation of fields in isolated and binary magnetic white dwarfs showing that binary interaction and stellar merging can indeed explain the strong fields observed in these exotic objects.

E1.7-0051-18 POSSIBLE EVOLUTION OF MAGNETIZED WHITE DWARFS BY ACCRETION LEADING TO HIGHLY MAGNETIZED SUPER-CHANDRASEKHAR WHITE DWARFS

Banibrata Mukhopadhyay, bm@iisc.ac.in Indian Institute of Science, Bangalore, India

A.R. Rao, arrao@tifr.res.in

Tata Institute of Fundamental Research, Mumbai, India Upasana Das, upasana.das@gmail.com

University of Colorado, Boulder, Boulder, Colorado, United States

We sketch a possible evolutionary scenario by which a highly magnetized super-Chandrasekhar white dwarf could be formed by accretion on to a commonly observed magnetized white dwarf. This is an exploratory study, when the physics/astrophysics in CVs is very rich and complex. Our current exploration is however simplistic and based on the phenomenon of flux freezing. Nevertheless, our proposal and initial choice of evolution has observational support, like, the recent discovery of a large number of magnetized white dwarfs by SDSS. Based on this, we also explore the possibility that the white dwarf pulsar AR Sco acquired its high spin and magnetic field due to repeated episodes of accretion and spin-down. An accreting white dwarf can lead to a larger mass and consequently a smaller radius thus causing an enhanced rotation period and magnetic field. This spinning magnetic white dwarf temporarily can inhibit accretion, spin down, and, eventually, the accretion can start again due to the shrinking of the binary period by gravitational radiation. The repetition of this cycle can eventually lead to a highly magnetized white dwarf (B-WD), recently postulated to be the reason for over-luminous type Ia supernovae. This evolution leading to a spinning B-WD could also be an ideal source for soft gamma-ray repeaters (SGRs) and anomalous X-ray pulsars (AXPs). SGRs/AXPs are generally believed to be highly magnetized, but observationally not confirmed yet, neutron stars. Invoking B-WDs to explain them does not require the magnetic field to be as high as for neutron star based model, however reproducing other observed properties intact.

E1.7-0052-18 EVOLUTION OF MAGNETIC CVS BETWEEN POLARS AND INTERMEDIATE POLARS

Arti Joshi, arti@aries.res.in ARIES, Nainital, India

From the X-ray, UV, and optical (photometric/spectroscopic / polarimetric) observations, the temporal and spectral features have been investigated for few magnetic CVs. Various attempts were made with these observed features which allow to probe the exact geometry, structure and the properties of magnetic CVs which further helps us to classified these systems either as polars or an intermediate polars. The selected MCVs also serve as an important tool to improve our understanding regarding the various classes of magnetic CVs from intermediate polars to polars. The observed spectra of most of the magnetic CVs probed through the various theoretical models to explain well about these systems. Shock parameters like shock temperature and shock height have also estimated using the hard X-ray spectrum of the system which is further used to determined the mass of the white dwarf. The nature and origin of the strong fluorescent Fe Kα emission line at 6.4 keV in magnetic CVs is also investigated with their detailed study. The phase-resolved X-ray spectroscopy also have a great potential and provide us the dependence of spectral parameters on the binary and rotational phases.

E1.7-0053-18 POPULATION STUDIES OF SINGLE AND BINARY WHITE DWARFS

Boris Gaensicke, boris.gaensicke@warwick.ac.uk University of Warwick, Coventry, United Kingdom

The vast majority of stars will end their lives as white dwarfs, Earth-sized electron-degenerate stars. As part of close binaries, white dwarfs give rise to a wide range of spectacular phenomena, including accretion disc instabilities, explosive shell burning, and their total annihilation in Type Ia supernovae. Due to their small radii, white dwarfs are intrinsically faint objects, and until recently, much of our knowledge regarding these stellar remnants has been based on serendipitous discoveries.

I will review how large-area surveys providing colour information, time-domain photometry, and spectroscopy enable us to move from individual object studies to the analysis of large and homogeneous samples, and I will discuss the observational results in the context of population synthesis models. I will in particular focus on the impact that the Sloan Digital Sky Survey and the Catalina Real Time Transient Survey had, and highlight the enormous potential of the Gaia mission for the study of white dwarfs, both single and in binaries. Finally, I will conclude with an outlook on a number of forthcoming spectroscopic and photometric surveys, including WEAVE, DESI, SDSS-V, 4MOST, and LSST.

E1.7-0054-18 ULTRAVIOLET VARIABLE STARS IN THE SWIFT GALACTIC BULGE SURVEY

Liliana E. Rivera Sandoval, liliana.rivera@ttu.edu Texas Tech University, Lubbock, Texas, United States

X-ray transients with peak X-ray luminosities below 1E36 erg/s are called very faint X-ray transients (VFXTs). These systems seem to have little or no accretion, and occasionally they leave their quiescent state to enter in outburst. At large distances these systems are usually very difficult to detect by all-sky monitors given their faint luminosities. The Swift Galactic Bulge survey (SBS) is an imaging survey of 16 square degrees of the Galactic Bulge in X-rays and Ultraviolet using the detectors XRT and UVOT on board the Neil Gehrels Swift Observatory. The SBS has helped to detect a handful of new VFXTs, as well as several variable stars. I will present results of the analysis of the SBS UV images. I will mostly focus on the discussion of the UV behavior of several variable sources, which likely include cataclysmic variables. I will describe the spacial distribution and optical properties of these SBS UV variables. I will also mention results about the UV counterparts of the newly detected VFXTs.

E1.7-0055-18 AN X-RAY VIEW ON CATACLYSMIC VARIABLES IN SOLAR NEIGHBORHOOD AND IN THE GALAXY BULGE

Xiaojie Xu, xuxj@nju.edu.cn Nanjing University, Nanjing, China

Q. Daniel Wang, wqd@astro.umass.edu

University of Massachusetts, Amherst, Massachusetts, United States Xiangdong Li, lixd@nju.edu.cn

Department of Astronomy, Nanjing University, Nanjing, China

We have carried out a systematic investigation on the population of Cataclysmic Variables (CVs) in solar neighborhood and in the Galaxy bulge (GB). The Fe emission lines, the shock temperature and the white dwarf masses were compared and correlations were drawn for a sample of Suzaku observed local CVs. Based on the Fe line ratio, we conclude that the Galactic Bulge X-ray Emission (GBXE) is dominated by non-magnetic CVs, or dwarf novae (DNe). From the Fe line ratio - WD mass - shock temperature correlation, the mean WD mass of CVs in the GBXE was determined to be 0.8 solar mass, which is consistent with the value of WDs in local CVs.

E1.7-0056-18 THE WHITE DWARF BINARY PATHWAY PROJECT

Mathias R. Schreiber, matthias.schreiber@uv.cl Universidad de Valparaiso, 60102, Chile

Type Ia Supernovae (SN Ia) represent a very, perhaps even the most, important step on the extra-galactic distance ladder, and they have led to ground-breaking discoveries such as dark energy. Despite their outstanding importance, we still struggle to understand the details of the evolutionary pathways that produce SN Ia. The two main progenitor channels that have been proposed are the single degenerate channel in which the white dwarf accretes from a nondegenerate companion and the double degenerate channel which explains SN Ia explosions as the merger of two white dwarfs. However, whether nature has a strong preference for one of these channels, or whether a combination of several evolutionary channels contributes to the observed SN Ia rate remains an open question. This is partly because the direct progenitor systems for both channels are difficult to characterise observationally and partly because binary population models are uncertain and contain several unconstrained parameters. We run a large program on detached white dwarf + AFGK main sequence star binaries because this evolutionary stage is part of both main pathways towards SN Ia. By characterizing a large sample of these binaries we aim at providing the much needed observational constraints for calibrating binary population models which will significantly contribute towards solving the SN Ia progenitor puzzle.

E1.7-0057-18 EVOLUTIONARY LINKS BETWEEN POST-ABG/POST-RGB BINARIES AND ACCRETING WHITE DWARFS

Devika Kamath, devika.kamath@mq.edu.au Macquarie University, 2109, Australia

For lowto intermediate-mass stars, their AGB phase of evolution is terminated either by a powerful dust-driven wind or via a binary interaction. It is well established that binary interactions can alter the intrinsic properties of stars (such as: pulsation, mass-loss, photospheric chemistry, dust-formation, circumstellar envelope morphology etc.) and plays a dominant role in determining its ultimate fate. While past studies have shown that binarity can end the life of a star on the AGB, our recent studies have revealed that, in specific cases, binarity can also pre-maturely terminate the RGB evolution of a stars's life. A characteristic feature of these evolved binaries is the presence of a Keplerian circumbinary disk of gas and dust. These discs are an integral component of many post-AGB/ post-RGB binaries, driving the loss of angular momentum and playing a lead role in the evolution of these systems. Additionally, some of these systems also show a high-velocity outflow, originating from the circum-companion disc. In this talk I will review our advances in the research landscape of post-AGB and post-RGB binary stars, focussing on their observational properties, spectral energy distribution, photospheric chemistry, the characterisation and evolution of their stable circumbinary discs, and the evolutionary connection between the enigmatic post-AGB and post-RGB binaries, and other systems whose primary component is a White Dwarf.

E1.7-0058-18 BOTTLE ACCRETION IN A DETACHED MAGNETIC BINARY: A DETAILED PICTURE.

In close detached post-common-envelope binaries, both components may have sufficient magnetic fields to become coupled and synchronized, thereby channelling the entire stellar wind from the late pre-main sequence star to the white dwarf. In binaries with K and earlier types, the accretion rate can be significant. We studied one such system, V1082 Sgr by means of fast, continuous long-term photometry using the K2 satellite and high-resolution spectroscopy. The data allowed us to reconstruct a detailed picture of the binary system and obtain several precise parameters.

E1.7-0059-18 DISCUSSION III: ACCRETING WD BINARIES, THEIR EVOLUTION AND LINKS TO XRBS AND AGB BINARIES

E1.7-0061-18 WIDE-FIELD ULTRAVIOLET IMAGER FOR ASTRONOMICAL TRANSIENT STUDIES

Joice Mathew, joice@iiap.res.in

Indian Institute of Astrophysics, Bengaluru, India

Ultraviolet (UV) domain plays a vital role in the studies of astronomical transient events but the UV time domain sky is largely unexplored. We have designed and build a wide-field UV imager for UV transient studies which can be flown on a range of available platforms, including highaltitude balloons, CubeSats, and other small satellite space missions. The major scientific goals are to study the variability of astronomical sources, detection of transients such as supernovae, novae, tidal disruption events and AGN variability. The instrument has a 70 mm aperture with a circular field of view of 10.8 degrees and the observation window is 280 - 390 nm. The detector for the instrument is a Micro Channel Plate (MCP) based detector with photon counting capability. A FPGA based detector readout mechanism and real-time data processing have been implemented. The imager is designed in such a way that its lightweight and compact nature is well fitted for a CubeSat dimension. Here we present the scientific potential of the proposed wide-field UV transient imager and the instrumentation (optomechanical design and interface, detector readout, electronics module etc.) involved. Our sophisticated design provides a low-cost implementation of the proposed payload. The transient survey with the proposed imager will have an overlap in time with other ongoing and planned astronomical facilities for transient studies, such as LIGO, SKA, LSST etc.

E1.7-0062-18 EVIDENCE FOR SPIRAL SHOCKS IN THE ACCRETION DISC OF SDSS1238

Anna Francesca Pala, annafpala@gmail.com University of Warwick, Coventry, United Kingdom Boris Gaensicke, boris.gaensicke@warwick.ac.uk University of Warwick, Coventry, United Kingdom Tom Marsh, t.r.marsh@warwick.ac.uk

Department of Physics, University of Warwick, Conventry, United Kingdom

Spiral shocks and magnetorotational instability (MRI) are thought to drive angular momentum transport in the accretion discs of cataclysmic variables (CVs). It has been suggested that spiral shocks dominate during quiescence, when the gas in the disc is mostly neutral and the efficiency of MRI results greatly reduced. In contrast, during outbursts the disc material is almost fully ionised, and angular momentum transport should be driven by both MRI and spiral shocks. Although spiral shocks have been observed in the accretion discs of novalike CVs and dwarf novae during outbursts, at present, there are only few clues (derived from the analysis of Doppler maps) on their presence in the accretion discs of quiescent CVs.

We present here high-time-resolution photometry and phase-resolved spectroscopy of the shortperiod (80.52 min) CV SDSS J123813.73−033933.0 (SDSS1238), observed with HST, the Kepler/K2 mission and the VLT. The light curve of SDSS1238 shows a double hump quasisinusoidal photometric modulation at half the orbital period. This phenomenon has been observed to be stable on time scales of years and the HST data unambiguously demonstrate that it arises from two heated regions on the white dwarf that become alternatingly visible to the observer every half orbital period. We suggest that the double-hump modulation is related to spiral shocks in the accretion disc resulting in an enhanced accretion rate heating two localised regions on the white dwarf, with the structure of the shocks fixed in the binary frame explaining the period of the double humps. This represents the first direct evidence that strong spiral shocks can steadily develop in the quiescent accretion disc of CVs and that, by reaching the inner part of the disc, they can drive accretion onto the white dwarf.

E1.7-0063-18 MULTICOLOR MONITORING OF WZ SGE - TYPE STAR TCP J18154219 + 3515598 IN VARIOUS STAGES OF OUTBURST ACTIVITY.

Institute of Astronomy, Russian Academy of Sciences, Moscow, Russia Alla Zharova, allazharova55@gmail.com

Sternberg Astronomical Institute, Moscow State University, Moscow, Russia

We present U BV RI monitoring of the new dwarf nova object during its main outburst in June 2017, a post-super-outburst phase, series of rebrightenings and a quiescence stage. We found the period of superhumps (Psh) close to 0.063 days. The period variations are analyzed by the (O-C) method during different stages of outburst activity.

We constructed and interpreted the multicolor and color indices light curves as well as the tracks of the object in various two-color diagrams. We estimated changes of the color temperature during the outburst and brightness decline, the luminosity, the value of dP/dT, the superhumps excess (Psh/Porb − 1), the mass ratio, the distance to the system and other physical parameters.

The time intervals between rebrightenings of our object are compared with other similar objects. After the series of rebrightenings our object returned to a quiescence stage, when only irregular brightness fluctuations were observed.

E1.7-0064-18 TV COL: A CASE STUDY OF REFLECTION AND COMPLEX ABSORPTION OF X-RAYS IN INTERMEDIATE POLAR SYSTEMS

Raimundo Lopes De Oliveira, raimundo.lopesdeoliveirafilho@nasa.gov NASA Goddard Space Flight Center, Greenbelt, Maryland, United States Koji Mukai, koji.mukai@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States

Once produced by accretion onto a white-dwarf, X-ray photons of intermediate polar systems interact with a rich medium surrounding the degenerated star. It comprises (i) the stellar surface itself, (ii) the accretion disk that arises when material from the low-mass companion star overflow the Roche lobe and orbit the white dwarf, and (iii) the accretion column over the star from material of the inner part of the accretion disk which is swept and tapered by magnetic lines of the compact object. While a fraction of the X-rays suffers from photoelectric absorption inducing a deficit in the observed flux, more pronounced in soft X-rays, another part is reflected and results in a surplus of hard X-rays around 10-50 keV. Thus, the investigation of both “deficit” and “surplus” allows constraining the geometry of the system. Here we present a case study of reflection and complex absorption in intermediate polar systems by exploring the case of TV Col. It is among the hard X-ray brightest IPs and therefore suitable for a detailed study. First, we discuss quantitatively the need to have a broad spectral coverage in X-rays to carry out that study in intermediate polar systems, dissociating the contribution of absorption and reflection. Second, we describe the spectral properties of TV Col and how it constrains the white dwarf mass.

E1.7-0065-18 AN ENGINE OF GAS-DYNAMICAL ORIGIN OF FLARES ACTIVITY IN BINARY STAR SYSTEMS WITH WHITE DWARFS

Daniela Boneva, danvasan@space.bas.bg

Space Research and Technology Institute - Bulgarian Academy of Sciences, Sofia, Bulgaria

In the population of binary stars, stellar flares appeared as periodic or non-periodic variations in the luminosity, which manifest in their light curves. They are characterized by small magnitude and rather long timescales. The transition from a quiescent to an active state requires an engine, by which to increase the accretion rate in a level high enough that outflow development is able to be produced. It has been recently studied the relation between the flow structure transformation and the brightness variability in some binary stars, appeared in an events like bursts, flickerings or flares. We suggest that the vortices and vortical-like wave structures, which are formed in the accretion flow, could be a productive source and an efficient engine for flares activity. The investigations in this paper are made for SS Cyg, V592 Cas and MV Lyr.

E1.7-0067-18 A STUDY ON THE INTRINSIC ABSORPTION MODEL AND THE WHITE DWARF MASSES OF INTERMEDIATE POLARS

Xiaojie Xu, xuxj@nju.edu.cn Nanjing University, Nanjing, China
Zhuoli Yu, yuzl00@126.com Nanjing University, Nanjing, China

X-ray spectroscopy can be used to constrain shock temperatures and white dwarf (WD) masses in magnetic cataclysmic variables (mCVs), especially intermediate polars (IPs). However, the previously inferred WD masses based on Suzaku observations are not fully consistent with the optical measured values, which could be due to the flaws when describing the intrinsic absorption of IPs. In this work, we introduce a new log-normal distributed absorption model to characterize the intrinsic absorption of IPs, and perform X-ray spectroscopy on archival Suzaku observations of IPs. Our results show satisfying chi2 values. More importantly, our inferred WD masses agree well with the optically determined values. We futher show the different treatment of intrinsic absorption could greatly affect the inferred WD masses in IPs.

E1.7-0068-18 EXPLORING ON-BOARD X-RAY TRANSIENT DETECTION WITH ATHENA - WIDE FIELD IMAGER

Pragati Pradhan, pragati2707@gmail.com

Penn State Astronomy and Astrophysics, State College, Pennsylvania, United States Jamie Kennea, kennea@astro.psu.edu

Pennsylvania State University, University Park, Pennsylvania, United States Abraham Falcone, afalcone@astro.psu.edu

Pennsylvania State University, United States David Burrows, dxb15@psu.edu

Pennsylvania State University, State College, Pennsylvania, United States

X-ray transients, like novae, GRBs, compact objects, for example, are among the most enigmatic objects in the cosmic sky. The unpredictability of their transient behaviour has been a study of much interest in the recent years. While significant progress has been made in this direction, a more complete understanding of such events is often hampered by the delay in the rapid follow-up of any transient event. An efficient way to mitigate this constraint would be to devise a way for on-board detection of such transient phenomenon so that multi-wavelength follow-up observations can be carried out near simultaneously. The Wide Field Imager (WFI), which is a part of the upcoming X-ray mission Athena, with its 40′ X 40′ field of view can add some valuable contribution to this. In this work, we discuss an algorithm for the on-board detection of such X-ray transients with WFI. We will also present a few test cases for the feasibility test of that algorithm on Swift-XRT data. Finally, we discuss the type of X-ray transients best suited for on-board detection from WFI, their probability of detections and the useful science that can follow.

E1.7-0069-18 MAGNETARS AS HIGHLY MAGNETIZED LOWLY LUMINOUS WHITE DWARFS

Banibrata Mukhopadhyay, bm@iisc.ac.in Indian Institute of Science, Bangalore, India

A.R. Rao, arrao@tifr.res.in

Tata Institute of Fundamental Research, Mumbai, India Mukul Bhattacharya, mukul.b@utexas.edu

University of Texas at Austin, TX, Texas, United States

Soft gamma-ray repeaters (SGRs) and anomalous X-ray pulsars (AXPs) are generally believed to be the sources of highly magnetized neutron stars, namely magnetar model. However, such a high field invoked in this model, of the order of Peta Gauss, has not been observationally confirmed yet. In this talk, we plan to reopen the possibility of explaining magnetars by magnetized white dwarfs, originally proposed by Paczynski and Usov independently in 90s. However, we now explore them based on our recently proposed highly magnetized white dwarfs (B-WDs), which are also lowly luminous, hence do not suffer from any UV constraint. Interesting, invoking B-WDs to explain SGRs/AXPs does not require the magnetic field to be as high as that required for neutron star based model, however reproducing other observed properties intact. The plan is to show how different mass-radius relation for spinning B-WDs (different compared to neutron stars and white dwarfs following Chandrasekhar's theory) is adequate to explain several properties of SGRs/AXPs.

E1.7-0070-18 STRONGLY MAGNETIZED WHITE DWARFS AND THEIR STABILITY

Prasanta Bera, pbera.phy@gmail.com IUCAA, Pune, India

The mass of a non-magnetic, non-rotating white dwarf is bounded by a maximum value, known as Chandrasekhar mass-limit (1.4 M0). The characteristic light curve of type-Ia supernovae is attributed to the direct consequence of crossing this maximum mass-limit in an accreting binary system. We study the strongly magnetized white dwarf configurations in a self-consistent manner as a progenitor of the over-luminous type-Ia supernovae. We compute static axisymmetric equilibria of white dwarf stars containing a strong magnetic field and present the modification of white dwarf mass-radius relation caused by the magnetic field. From a static equilibrium study, we find that a maximum white dwarf mass of about 1.9 M0 may be supported if the interior poloidal field is as strong as approximately 1010 T. On the other hand, if the field is purely toroidal the maximum mass can be more than 5 M0. From the perturbation study we find that these strongly magnetised axisymmetric configurations are sensitive to magnetic instabilities where the perturbations grow at the corresponding Alfvén time scales. Hence, we conclude that the presence of long-lived magnetically supported massive magnetic white dwarfs is unlikely.

E1.7-0071-18 THE X-RAY PROPERTIES OF INTERMEDIATE POLAR XY ARI

Dicle Zengin Camurdan, dzcamurdan@gmail.com Ege University, İzmir, Turkey

Presenting author: Solen Balman, solen.balman@gmail.com Middle East Technical University, Ankara, Turkey

Vadim Burwitz, burwitz@mpe.mpg.de

Max-Planck-Institut fur extraterrestrische Physik, Garching, Germany

XY Ari is one of the few known eclipsing intermediate Polar. We present results of total spectrum and spin phase-resolved X-ray spectroscopy of XY Ari. We utilize archival data of XMM-Newton EPIC-pn and MOS in a quiescent state of the source. The X-ray orbital modulation and spin pulse variations are investigated in 0.2-10 keV energy band and also in different energy bands. Our results confirmed the broad orbital modulation observed with various observations at hard X-ray (>1.6 keV). The pulse profile showed a double peak profile as expected from two pole accretion and it is found to be energy dependent. The adopted model is composed of CEVMKL and a Gaussian line at 6.43 eV to account for the continuum which is partially absorbed. The maximum plasma temperature is found 28 keV with an iron abundance 0.37. We find two intrinsic partial covering absorption columns of 6.2 x1022 cm−2

and 105.3 x1022 cm−2 with covering fraction of 0.53, 0.41 respectively. The X-ray luminosity of the source is 4.2 x1032 erg s−1 in the 0.2-10 keV energy band assuming a 270 pc distance.

The spin-phase resolved spectral analysis of XY Ari confirm the variation of the absorption column parameters. The energy dependent nature of the X-ray spin pulse and the presence of absorption in its spectrum are seen generally in IPs indicating an accretion column absorbing structure.

E1.7-0072-18 A NEW CATALOGUE OF GALACTIC NOVAE

Ergün Ege, ergun.ege@ogr.iu.edu.tr

Istanbul University, Institute of Science, Istanbul, Turkey Aykut Ozdonmez, aykut.ozdonmez@ogr.iu.edu.tr Istanbul University, Institute of Science, Istanbul, Turkey Tolga Guver, tolga.guver@istanbul.edu.tr

Istanbul University, Faculty of Science, Istanbul, Turkey Tansel Ak, tanselak@istanbul.edu.tr

Istanbul University, Faculty of Science, Istanbul, Turkey

We compiled a new Galactic novae catalogue by collecting important parameters of these sources such as their light curve parameters, classifications, FWHM of Hα, distances and interstellar reddening estimates. The catalogue is also published on a website with a search option via a SQL query and an online tool to re-calculate the distance/reddening of a nova from the reddening-distance relations derived using the same methodology in Ozdonmez et al. (2016). In this poster, I will present the catalogue itself and the website of the catalogue covering results obtained from the compilation of this catalogue such as spatial distribution, Galactic model parameters.

E1.7-0073-18 INCLINATION DEPENDENT VARIABILITY PROPERTIES OF COMPACT BINARY SOURCES

Broja Gopal Dutta, brojadutta@gmail.com

Department of Physics, RBC College & Indian Centre for Space Physics, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

In X-ray binaries, fast variability in X-ray emission on time-scales of milli-seconds to seconds is a common and very complex phenomenon. Studies of energy dependent temporal properties in different variability time scales can thus diagnose dynamics of accretion geometry. We study the energy dependent temporal properties in different variability time scale for the edge on (high inclination) and face on (low inclination) compact binary sources. We find different variability signatures for the high and low inclination objects. We discussed all possible mechanisms, specifically reflection and focusing effect due the gravitational bending of photons, which could be controlling the property of the variability. We explain the variability properties within the framework of a single two component advective flow model.

E1.7-0074-18 THE XMM-NEWTON OBSERVATION OF THE DWARF NOVA EY CYG AND THE SECONDARY STAR

Armin Nabizadeh, armin.nabizade@gmail.com University of Turku, Turku, Finland

Solen Balman, solen.balman@gmail.com

Middle East Technical University, Ankara, Turkey

We present the X-ray spectral and temporal analysis of dwarf nova EY Cyg (45 ksec) using the XMMNewton Observatory archival data obtained in quiescence. We find orbital modulations in the X-rays. We simultaneously fitted EPIC pn, MOS1 and MOS2 data using a model for interstellar absorption (tbabs) and a multi-temperature plasma emission model (CEVMKL) which yields a maximum temperature kTmax of 15.0 keV with an unabsorbed X-ray flux and luminosity in the 0.1 to 50.0 keV energy band of 2.0x10−12ergcm−2s−1 and 2x1031ergs−1,

respectively. The fit shows an excess in the soft energies which can onlt be modeled using a MEKAL model at 3sigma significance with a temperature of 0.1 keV with an unabsorbed X-ray luminosity of 1.5x1030ergs−1. This confirms that the secondary is a K-type star as was suggested.

E1.8-0001-18 INTRODUCTION AND OVERVIEW OF THE SPACE VLBI MISSION RADIOASTRON

Yuri Kovalev, yyk@asc.rssi.ru

Lebedev Physical Institute of Russian Academy of Sciences, Moscow, Russia

The RadioAstron Space VLBI mission utilizes the 10-m radio telescope on board the dedicated Spektr-R spacecraft to observe cosmic radio sources with an unprecedented angular resolution at 92, 18, 6 and 1.3 cm in total and polarized light. The longest baseline of the space-ground interferometer is about 350 000 km. It successfully operates since 2011 together with up to 40 largest ground radio telescopes. Proposals for its observations are invited annually with deadlines at the end of January. Formal resolution as high as 8 and 11 microarcsec has been achieved for mega-masers and quasars observed at 22 GHz, respectively. Successful results have been obtained in all areas of its science program including active galactic nuclei, pulsars and scattering, galactic and extragalactic masers, gravitational redshift measurements.

E1.8-0002-18 THE TANAMI PROGRAM FOR VLBI MONITORING OF SOUTHERN AGN

Philip Edwards, philip.edwards@csiro.au CSIRO, Epping, Australia
the TANAMI team the TANAMI team

VLBI monitoring observations are the backbone of the TANAMI multi-wavelength program monitoring gamma-ray detected AGN. TANAMI is the only source of parsec scale information on extragalactic jets in the southern third of the sky, encompassing many sources of interest. The detection of extraterrestrial neutrinos by IceCube makes a comprehensive astronomical multi-wavelength program to observe AGN jets indispensable for astroparticle physics.

With new high-energy neutrino events and gamma-ray sources to be discovered as well as substantially improved data on current sources, long term VLBI monitoring remains a crucial part of the study of AGN, as it is the only method for measuring parsec scale jet kinematics and structural changes. This is essential information for both the RadioAstron AGN Survey and for studying the broad-band spectral energy distribution in order to understand AGN high-energy emission mechanisms.

The TANAMI project and recent results will be described in this talk.

E1.8-0003-18 RADIOASTRON POLARIZATION KSP: PROBING THE INNERMOST REGIONS OF BLAZAR JETS AT TENS OF MICROARCSECONDS RESOLUTION

Jose L. Gomez, jlgomez@iaa.es

Instituto de Astrofisica de Andalucia, Granada, Spain Evgeniya Kravchenko, evgenia.v.kravchenko@gmail.com

Lebedev Physical Institute of Russian Academy of Sciences, Moscow, Russia

RadioAstron provides the first true full-polarization capabilities for space VLBI observations on baselines longer than the Earth diameter. We present the results of our “Polarization” Key Science Program aimed to study the innermost regions of AGN jets and their magnetic fields at the highest angular resolutions achieved to date. Among our earlier results, we have successfully imaged the jet in BL Lac at an angular resolution of 21 microarcseconds, revealing a large scale helical magnetic field in the vicinity of the central black hole. Our quasi-simultaneous RadioAstron, Event Horizon Telescope (EHT), and GMVA observations of OJ287 reveal a highly twisted jet at an unprecedented angular resolution of 10 microarcseconds (26 Schwarzschild radii); these are analyzed in combination with our multiwavelength monitoring to test jet formation models and the supermassive binary black hole scenario proposed for this source.

E1.8-0004-18 RADIOASTRON IMAGING OF NEARBY RADIO GALAXIES

Tuomas Savolainen, tuomas.k.savolainen@aalto.fi Aalto University, Espoo, Finland

RadioAstron Nearby AGN Key Science Program uses ultra high angular resolution radio observations provided by the space-VLBI mission RadioAstron to study the structure of the radio jets in nearby active galactic nuclei close to their launching site. Our space-VLBI images of radio galaxies 3C84 and M87 well resolve both jets in transverse direction, revealing structures that are not seen in the ground-based VLBI data. In 3C84, we are able to reliably resolve the limb-brightened jet just 30 microarcseconds from the core in our 22GHz image, which allows us to measure the jet collimation profile from 102 to 104 gravitational radii from the black hole. We find a very broad, almost cylindrical structure extending all the way to the core. The bright outer layer has a transverse radius of 250 gravitational radii at only 350 gravitational radii (deprojected) from the core, which raises the possibility that the jet sheath originates in the accretion-disk. Our 5GHz RadioAstron image of 3C84 discovers a previously unseen lowintensity emission from a cocoon-like structure around the recently restarted, one parsec long, jet. The cocoon pressure provides a natural explanation for the cylindrical jet profile seen in the 22GHz image. In the case of M87, we have obtained a high dynamic range 1.6GHz image with space baselines up to 5 Earth diameters. The image shows a striking internal structure in the M87 jet starting from the core and extending up to 450 mas. The image reveals a structure of helical filaments inside the jet. This is the first time such a pattern is clearly seen in the acceleration and collimation zone. The implications of this will be discussed.

E1.8-0005-18 INNERMOST REGION OF THE BLAZAR S5 0716+714 FROM RADIOASTRON POLARIMETRIC OBSERVATIONS AT 22 GHZ

Evgeniya Kravchenko, evgenia.v.kravchenko@gmail.com

Lebedev Physical Institute of Russian Academy of Sciences, Moscow, Russia Yuri Kovalev, yyk@asc.rssi.ru

Lebedev Physical Institute of Russian Academy of Sciences, Moscow, Russia Jose L. Gomez, jlgomez@iaa.es

Instituto de Astrofisica de Andalucia CSIC, Granada, Spain

We present results of μas radio polarimetric imaging of one of the most studied BL Lac object S5 0716+714, observed with the RadioAstron space-VLBI mission. The source is well known because of its extreme and rapid variability through the whole electromagnetic spectrum. S5 0716+714 gamma-ray activity is strongly related to the inner jet morphology, which together with the short-scale variations at radio and optical bands makes the blazar the best candidate for an intrinsic origin of its intra-day variability (IDV).

Our observations of the source was made with the 10-m space radio antenna and eleven ground stations on 2015 January 3-4 at 22 GHz. The projected baselines reached 4-6 Earth's diameters in length, resulted in angular resolution of 24 μas, the highest for the studied source to-date. The S5 0716+714 image revealed elongation of the apparent base of jet within innermost 0.2 mas in direction, almost perpendicular to the larger-scale flow. This is consistent with the temporal variations of the inner jet direction with the amplitude of about 60 degrees, resulted from our analysis of multi-epoch observations of the blazar within the VLBA-BU-BLAZAR monitoring program at 43 GHz. We suggest, that this fine-scale region of the S5 0716+714 jet may be responsible for the IDV and flaring activity of the source.

The source exhibits large-scale magnetic field, perpendicular to the jet flow, which is consistent with its helical geometry. We detect compact linearly polarized component in the innermost 0.2 mas of the jet, which coincides well with the position of a stationary feature, seen in other studies, and points on possible association with the recollimation shock.

E1.8-0006-18 RESULTS FROM THE RADIOASTRON AGN POLARIZATION KSP: OBSERVATIONS OF 3C273 AT MINIMUM ACTIVITY

Gabriele Bruni, gabriele.bruni@iaps.inaf.it INAF-IAPS, Rome, Italy

Jose L. Gomez, jlgomez@iaa.es

Instituto de Astrofisica de Andalucia CSIC, Granada, Spain

The RadioAstron active galactic nuclei (AGN) polarization Key Science Project (KSP) aims at exploiting the unprecedented angular resolution provided by RadioAstron to study jet launching/collimation and magnetic-field configuration in AGN jets. The targets of our KSP are some of the most powerful blazars in the sky. We present observations at 22 GHz of 3C273, performed in 2014, designed to reach a maximum baseline of approximately nine Earth diameters. Reaching an angular resolution of 0.3 mas, we study a particularly low-activity state of the source, and estimate the nuclear region brightness temperature, comparing with the extreme one detected one year before during the RadioAstron early science period. We also make use of the VLBA-BU-BLAZAR survey data, at 43 GHz, to study the kinematics of the jet in a

~1.5-yr time window.

We find that the nuclear brightness temperature is two orders of magnitude lower than the exceptionally high value detected in 2013 with RadioAstron at the same frequency (1.4 1013 K, source-frame), and even one order of magnitude lower than the equipartition value. The kinematics analysis at 43 GHz shows that a new component was ejected 2 months after the 2013 epoch, visible also in our 22 GHz map presented here. Consequently this was located upstream of the core during the brightness temperature peak. Fermi-LAT observations for the period 2010-2014 do not show any γ-ray flare in conjunction with the passage of the new component by the core at 43 GHz. Conclusions. These observations confirm that the previously detected extreme brightness temperature in 3C 273, exceeding the inverse Compton limit, is a short-lived phenomenon caused by a temporary departure from equipartition. Thus, the availability of interferometric baselines capable of providing μas angular resolution does not systematically imply measured brightness temperatures over the known physical limits for astrophysical sources.

E1.8-0007-18 CORES OF ACTIVE GALACTIC NUCLEI STUDIED AT UNPRECEDENTED RESOLUTION

Yuri Kovalev, yyk@asc.rssi.ru

Lebedev Physical Institute of Russian Academy of Sciences, Moscow, Russia RadioAstron AGN survey team

RadioAstron AGN survey team

The Space Very Long Baseline Interferometer RadioAstron has performed a survey of 248 radio-loud AGNs at 18, 6, and 1.3 cm at projected spacings up to 350,000 km. Significant detections at space-ground baselines were found for 164 AGNs. Formal resolution as high as 11 microarcsec has been achieved. Apparent brightness temperature up to about or higher than 1014 K was found in cores of observed AGNs. These measurements challenge our understanding of the non-thermal continuum emission in the vicinity of supermassive black holes. Physical implications of these findings will be discussed. While the survey was dedicated to total intensity measurements, we have also discovered that fractional linearly polarized correlated flux density increases with long SVLBI projected spacings. This suggests the presence of ultra-compact regions with ordered magnetic field, most probably within the core of those quasars.

E1.8-0008-18 INTER-STELLAR SCINTILLATION, ISS, AND INTRINSIC VARIABILITY OF RADIO AGN

David Jauncey, david.jauncey@csiro.au CSIRO, Weston, Australia

A comparison of the ISS observations from our VLA 5 GHz MASIV survey and the published OVRO 15 GHz intrinsic variability observations reveals a significant relationship between these two parameters. This relationship can be attributed to the mutual dependence of intrinsic variability and ISS on radio core compactness at 50 - 100 micro-arcsecond scales. For the full MASIV sample we find that the Fermi-detected gamma-ray loud sources exhibit significantly higher 5 GHz ISS than the gamma-ray quiet sources.

E1.8-0009-18 IMPLICATIONS OF REFRACTIVE SCINTILLATION FOR OBSERVATIONS OF ACTIVE GALACTIC NUCLEI WITH RADIOASTRON

Michael Johnson, mjohnson@cfa.harvard.edu

Harvard-Smithsonian Center for Astrophysics, Cambridge, Massachusetts, United States Yuri Kovalev, yyk@asc.rssi.ru

Lebedev Physical Institute of Russian Academy of Sciences, Moscow, Russia Carl Gwinn, cgwinn@physics.ucsb.edu

University of California Santa Barbara, Santa Barbara, California, United States Leonid Gurvits, lgurvits@jive.eu

Joint Institute for VLBI ERIC and TU Delft, Dwingeloo, Netherlands

Interstellar scattering imposes a fundamental limitation on the angular resolution of radio observations. With the combination of extremely high brightness temperatures in active galactic nuclei (AGN) and the unprecedented resolution afforded by Earth-space baselines with RadioAstron, we are now confronting this limit directly. In particular, the scattering introduces refractive substructure, which produces interferometric signatures that can mimic those of ultra-compact intrinsic structure. Nevertheless, the scattering also enables new measurements of intrinsic structure, including precise estimates of brightness temperature and core shift with sparse data. We will discuss the effects of refractive interstellar scintillation on microarcsecond imaging of AGN with RadioAstron, new techniques to mitigate the scintillation, and new measurements enabled by the scintillation.

E1.8-0010-18 IMAGING STRONG BLAZARS WITH SPACE VLBI

Anton Zensus, azensus@mpifr-bonn.mpg.de

Max Planck Institute fur Radioastronomie, Bonn, Germany Andrei Lobanov, alobanov@mpifr.de

Max Planck Institute fur Radioastronomie, Bonn, Germany Eduardo Ros, ros@mpifr-bonn.mpg.de

Max Planck Institute fur Radioastronomie, Bonn, Germany

Imaging observations performed with RadioAstron as part of a key science program on studies of powerful extragalactic jets have provided a series of detailed multi-frequency images of a number of the strongest blazars of the radio sky. The observations were made at the wavelentghs of 18, 6, and 1.3 cm, targeting prominent radio sources such as 0836+710, 3C 345, 3C 273, and 1642+690, with ground-space baselines reaching up to about 10 Earth diameters. The resulting improved angular resolution enables resolving the internal structure of the outflows and detecting regions with extremely high brightness temperatures exceeding 1013K. These images have enabled multifaceted studies of physical conditions in the relativistic jets to be perf o resolution mm V LBI imaging at 3.5 mm with the Global Millimeter V LBI Array, and in some cases, even with the Even Horizon Telescope at Λ 1.3 mm. We present here some highlights of the RadioAstron observations of prominent radio sources and discuss ample potentials for their synergy with mm-VLBI observations. This synergy should address some of the still unanswered questions on the physical nature of relativistic jets and nuclear regions in active galaxies.

Pulsars are pointlike at the highest attainable angular resolution, and present excellent targets for studies of the effects of interstellar scattering at meter to decimeter wavelengths. Studies of the scattering of pulsars enable understanding of the interstellar medium, and provide essential insights into observations of compact radio sources at the highest attainable angular resolutions. Conversely, scattering acts as an enormous optical system that provides insight into the electrodynamics of pulsars.

Using the uniquely long interferometer baselines offered by the Radioastron mission, we have detected and characterized “cosmic prisms,” large-scale plasma gradients that deflect source images and geometrically disperse pulses from pulsars. We have detected at least two varieties of substructure within the scattered images of pulsars, and extended their study to active galactic nuclei. We have observed the spatial decorrelation of giant pulses from the Crab pulsar on Earth-space baselines. We have detected and

analyzed the orderly "scintillation arcs" that mark the scattering of nearby strong pulsars. We discuss these results, and their interpretation.

One of the scientific research fields of RadioAstron project is probing the interstellar plasma by radio pulsars. Pulsars are point radio sources and not resolved even by space-ground interferometer. Nevertheless, RadioAstron interferometer provides great advantages in the study of scattering effects since it makes it possible to measure directly the angular size of the scattering disks that are usually enclosed in the interval from 0.01 to 0.001 arcseconds at decimeter wavelengths. For ground interferometers such scattering disks are usually unresolved. During the execution of RadioAstron pulsar scientific program a number of major results were obtained:

As a result of the analysis of observations of several pulsars, conducted with RadioAstron, scattered screens were localized in the direction toward these pulsars. We emphasize that the uniform model of scattering plasma distribution on the line of sight does not fit any pulsar.

Non-isotropic structures of inhomogeneities in the interstellar plasma were revealed. Such structures may be connected with the influence of the magnetic field.

Detection of the "cosmic prism" at distances as small as a few parsecs. Such effective scattering layers of plasma in the local interstellar medium were postulated before to explain the rapid variability of compact extragalactic sources.

Substructure in pulsar scattering disks was discovered. The presence of such structure requires the update of radio waves scattering physics.

Studying giant pulses from the Crab pulsar revealed the decisive role of the plasma located in the vicinity of the nebula itself on the observed scattering effects.

In this report we present above mentioned results in some details

E1.8-0013-18 STUDIES OF MASERS IN STAR FORMING REGIONS OF OUR GALAXY AND MEGAMASERS IN EXTERNAL GALAXIES

James Moran, jmoran@cfa.harvard.edu

Ural Federal University, Ekaterinburg, Russia

Observations of the masers in the RadioAstron (RA) mission yielded detections of fringes for a number of sources in both H2O and OH maser transitions. Several sources display numerous ultra-compact details. This proves that implementation of the space VLBI technique for maser studies is possible technically and is not always prevented by the interstellar scattering, maser beaming and other effects related to formation, transfer and detection of the cosmic maser emission. RA observations provided absolute record of the angular resolution in astronomy. Fringes from the NGC 4258 megamaser were detected on baseline 26.7 Earth Diameters (340,000 km). This corresponds to the angular resolution 8 as sufficient to measure parallax of the maser source in the nearby galaxy LMC. The sharpest "direct" linear resolution <4.e11 cm was achieved in observations of the maser in Orion. RA also detected the smallest structures ever observed in a Galactic maser. Analysis of the data on Cep A water maser indicates that the source contains features with the sizes about the diameter of the Sun. The space-Earth cross power spectrum shows two unresolved components smaller than 15 as (1.6e11 cm) separated by 160±35 as which differ in velocity by 0.5 km/s. The brightness temperatures are >2.e14 K, and the line widths are 0.5 km/s. Most of the flux density (90 per cent) is contained in a halo of diameter 1 mas. We discuss possible interpretations for the compact structure.

E1.8-0014-18 RADIOASTRON REVEALS SUPER-COMPACT STRUCTURES IN THE FLARING WATER MASER SOURCE G25.65+1.05

Stan Kurtz, skurtz@mailaps.org UNAM, Morelia, Mexico

G25-maser

Stan Kurtz,Olga Bayandina, Alexey Alakoz, Ross Burns, Evgeny Lekht, Georgij Rudnitskij, Nadezhda Shakhvorostova, Irina Val'tts, Alexandr Volvach, Larisa Volvach

In recent years the water maser source in the massive star-forming region G25.65+1.05 (IRAS 18316-0602, Mol 62, RAFGL 7009S) has undergone several powerful flares. During regular monitoring of the source with the 22-m radio telescope in Pushchino (Moscow Region) a strong burst was detected with the peak flux density of the strongest maser line increasing from 70 Jy (on 16.06.2016) to 50,000 Jy (on 12.12.2016), i.e., a more than 500-fold increase. A second super-burst was observed with the RT-22 in Simeiz (Crimea), detecting a flux density of 20,500 Jy. The maximum flux density of 65 kJy was detected on 16.09.2017. The maser source was observed several times with the space-ground interferometer RadioAstron (RA) and also with the VLBA and the EVN ground-based interferometers. Strong fringes were obtained during the 29.09.2017 session on the space-ground baselines RA-Torun and RA-HartRAO, with baseline lengths from 8.6 to 9.3 Earth Diameters. The angular resolution of 24 μas corresponds to a linear size for the emitting region of about 0.05 AU (assuming a source distance of 2.08 kpc). This is the first time that such compact structures have been detected in water masers. The extraordinarily high intensity of the observed flare provides a large dynamic range for the analysis of the compact components found in this source. The differing responses on the space-ground and ground-ground baselines indicates that a range of size scales are present. Using the precise spatial distribution of individual maser components, it is possible to identify hierarchical structures within the masers. These observations serve to clarify the nature of the masing source, which in turn offers additional insights into the high mass star formation process.

E1.8-0015-18 TOWARD A SENSITIVE TEST OF THE EINSTEIN EQUIVALENCE PRINCIPLE BY MEASURING THE GRAVITATIONAL REDSHIFT WITH RADIOASTRON

Joint Institute for VLBI ERIC and TU Delft, Dwingeloo, Netherlands

The incompatibility of general relativity and quantum theory is a fundamental problem in our understanding of the physical world. The Einstein equivalence principle (EEP) is a cornerstone of general relativity, and the gravitational redshift is a consequence of the local position invariance aspect of it. An accurate measurement of the gravitational redshift and a comparison with prediction is therefore of prime importance. Here we report on such a measurement. The Spektr-R spacecraft of the RadioAstron mission was launched in 2011 into a highly elliptical orbit around Earth. Since early on the spacecraft has been used for astrophysical observations of compact radio sources with the technique of space VLBI (very long baseline interferometry). The spacecraft has a hydrogen maser frequency standard on board that operated till 2017. For several years the downlink signals at 8.4 and 15 GHz, locked to the frequency of the hydrogen maser, were recorded at ground stations, which are also equipped with hydrogen masers. About 2900 sessions each with 100,000 frequency recordings at each of the two frequencies were obtained. During the 9-day elliptical orbits the spacecraft traveled through the varying gravitational potential of Earth, which according to the EEP should cause an oscillating gravi tational redshift of the downlink signals. The predicted relative frequency shift varied between

6.8 10−10 and 4 10−10. The data from the RadioAstron mission are being largely independently analyzed by more than one group to provide for a better reliability of our anticipated final results. We report on our analysis of data recorded at the ground stations in

Pushchino, Russia, and Green Bank, USA, and discuss the possibility of testing the EEP with a higher sensitivity than that obtained from the Gravity Probe A mission.

E1.8-0016-18 ON THE PROSPECTS OF IMAGING THE EVENT HORIZON OF SAGITTARIUS A* FROM SPACE

Heino Falcke, h.falcke@astro.ru.nl

Radboud Universiteit Nijmegen, Nijmegen, Netherlands Freek Roelofs, f.roelofs@astro.ru.nl

Radboud Universiteit Nijmegen, Nijmegen, Netherlands

Very Long Baseline Interferometry (VLBI) at sub-millimeter waves has the potential to image the shadow of the black hole in the Galactic Center, Sagittarius A* (Sgr A*), and thereby test basic predictions of the theory of general relativity. In our work, the imaging prospects of a new Space VLBI mission concept have been investigated. An initial design study of the concept has been performed for the purpose of the Event Horizon Imager (EHI) experiment. The concept may be suitable for imaging Sgr A* at frequencies up to 690 GHz, which has significant advantages over performing Earth-based VLBI at 230 GHz. The investigated setup consists of two satellites in polar or equatorial circular Medium-Earth Orbits with slightly different radii. This setup will result in a dense spiral-shaped uv-coverage with long baselines, allowing for extremely high-resolution and high-fidelity imaging of radio sources. We simulate observations of a general relativistic magnetohydrodynamics (GRMHD) model of the accretion flow around Sgr A* for the proposed configuration and noise calculated from model system parameters. After gridding the uv-plane and averaging visibilities accumulated over multiple months of integration, images of Sgr A* with a resolution of up to 4 uas (about 8% of the shadow diameter) could be reconstructed. The black hole shadow could be measured much more precisely than with ground-based VLBI, allowing for stronger tests of General Relativity and accretion models.

Earth-based aperture synthesis is limited in resolution by the Earth diameter and suffers from a sparse spatial frequency sampling. Its observing frequency is restricted by the atmospheric propagation effects. This work considers a space-borne interferometer concept, which is free of the above-mentioned constraints. The concept assumes two identical satellites in polar or equatorial orbit of Medium Earth Orbit altitude that is suitable to image the shadow of the event horizon of the Sagittarius A* (Sgr A*) with the angular resolution of circa 5 micro arc-seconds at the frequency above 600 GHz. This work provides the requirements to (i) the knowledge of positions of phase centers of space-borne antennas, (ii) the accuracies of the altitude and orbit control systems, and the visibility of navigation satellites, (iii) the frequency plan for the interferometer and its inter-satellite links. The work presents the current progress in the intersatellite links for velocity (and distance) measurements, and data exchange including but not limited to link budgets, critical components, and performance quality factors. Sensitivity details of the interferometer are presented. Two sub-mm-class radio astronomy antennas are installed on separate identical satellites. The selected orbits provide well-sampled spatial frequency coverage, and allow us to operate outside the radiation belts of the Earth magnetosphere and consider a centimeter-level on-the-fly accuracy of the relative orbit determination using the global navigation satellite system (GNSS). To compress the downlink signal bandwidth, the cross-correlation is done onboard each satellite within the delay window defined by the orbit determination accuracy. The sub-mm baseline localization is done using the GNSS navigation, the altitude and orbit control (AOCS) sensors, and inertial navigation sensors, the inter-satellite velocity and range observables altogether. The image reconstruction is completed on the ground using sets of discrete readings of the cross-correlation function. The work results have been obtained using simulations of the synthesized array and the characteristics of the GNSS, the available technologies for the AOCS, and limitations of the radio communication regulations. The presented performance calculations and the instrument block diagram are in line with the available technology for sub-mm-class space-borne antennas, quasi-optics, amplifiers, mixers, and digitizers. This interferometer concept has potential to permit imaging of the shadow of the Sgr A* with the resolution of a few micro arc-seconds which is significantly sharper than achievable from the Earth surface. The presentation provides the current progress on the orbit simulations and the whole system, and the input information for the development of the key systems of the mission.

E1.8-0018-18 THE CHINESE SPACE VLBI PROPOSALS AND THE EARTH-MOON VLBI EXPERIMENT

Zheng Weimin, zhwm@shao.ac.cn

Shanghai Astronomical Observatory, Chinese Academy of Sciences, SHANGHAI, China

The Chinese VLBI (VeryLong Baseline Interferometry) Network - CVN consists of five radio telescopes and one data processing center. The earth-based CVN will plan to extend to the space in the future and there are several proposals. The first one is the mm Space VLBI Array, which includes two earth satellites with 10m antennas and the highest band of 46GHz. The research purpose of the mm Space VLBI Array is Super Massive Black Hole, Disk Structure and dynamics, mass of SMBH and Jets in Active Galactic Nuclei (AGN). Another proposal is the Radio Observatory in Space for Exploring the universe (ROSE), which is proposed to image the fine structure of compact celestial objects such as black hole, pulsar and so on. The mission plans to launch a 30 meter-diameter radio telescope into a 2000km x 70000km elliptical orbit, and works together with the earth-based VLBI network, Square Kilometre Array (SKA) and Five-hundred-meter Aperture Spherical radio Telescope (FAST) to get very high resolution and very high sensitivity. ROSE is operated at decimeter and long centimeter. In the subsequent China's Lunar Exploration Project, there will be an Earth-moon VLBI experiment, using the antenna of the lunar orbit Tracking and Data Relay Satellite (TDRS) to construct the first Earth moon space VLBI experimental system. We hope using this earth-moon VLBI system to verify the key space VLBI technology. Because the Earth moon VLBI baseline is over 300km, the experiments of astrometry, astrophysics and the deep-space tracking will be carried. After this, a 10 m antenna is planned to be constructed on the moon surface in the future.

E1.8-0019-18 ROADMAP TOWARDS A SPACE-BASED RADIO TELESCOPE FOR LOW FREQUENCY RADIO ASTRONOMY

Joint Institute for VLBI ERIC and TU Delft, Dwingeloo, Netherlands

Low-frequency radio astronomy to date has focused its operations mainly on the frequency regime above 30 MHz, for example through LOFAR, the Low Frequency Array, based in the Netherlands. Below 30 MHz, Earth-based observations are limited due to a combination of severe ionospheric distortions, full reflection of radio waves below 10-30 MHz, solar eruptions and the radio frequency interference (RFI) of man-made signals. There are, however, interesting scientific processes that naturally take place at these low frequencies. A spaceor Lunar-based low-frequency radio array would suffer significantly less from these limitations and hence would open up the last, virtually unexplored frequency domain in the electromagnetic spectrum. This is a region of the electromagnetic spectrum which is essentially unexplored by astronomy.

A roadmap has been initiated to explore the opportunity to build a swarm of satellites to observe the frequency band below 30 MHz, the Orbiting Low Frequency Antennas for Radio

Astronomy (OLFAR). OLFAR is a space-based low frequency radio telescope that will explore the universe's so-called dark ages, map

the interstellar medium, and discover planetary and solar bursts in other solar systems. The telescope, composed of a swarm of at least fifty distributed satellites working together as a single instrument, will be sent to a location far from Earth in order to avoid the high RFI found at frequencies below 30 MHz originating from Earth. The OLFAR telescope is a novel and complex system, requiring not-yet proven technologies and systems, therefore, a number of key technologies are still required to be developed and proven. Most of these can be tested on Earth, but several aspects require in-space verification.

The NCLE (Netherlands China Low Frequency Explorer) project will be the first milestone in this roadmap. In 2018, NCLE will be launched on the Chinese Chang'e 4 satellite. It will consist of a single antenna for the low frequency regime. The first data at low frequencies, far away from the RFI from Earth, will provide the first information of the possible science.

In this paper, the roadmap, science opportunities, and the technological and programmatic challenges will be presented.

E1.8-0020-18 THE SUN RADIO INTERFEROMETER SPACE EXPERIMENT (SUNRISE) MISSION CONCEPT: DEVELOPMENT STATUS

New Hampshire) Milan Maksimovic (CNRS) Baptiste Cecconi (Observatoire de Paris) Gregg Hallinan (CIT) Vratislav Krupar (USRA) Igor Sokolov (Univ. Michigan) Sofia Moschou (Harvard-Smithsonian CfA)

We present an overview of the development status of the Sun Radio Interferometer Space Experiment (SunRISE) mission concept. SunRISE is space-based sparse array, composed of six 6U small spacecraft (SmallSats), designed to localize the radio emission associated with coronal mass ejections (CMEs) from the Sun. Radio emission from CMEs is a direct tracer of the particle acceleration in the inner heliosphere and potential magnetic connections from the lower solar corona to the larger heliosphere. Furthermore, CME radio emission is quite strong such that only a relatively small number of antennas is required, and a small mission would make a fundamental advancement. Indeed, the state-of-the-art for tracking CME radio emission is defined by single antennas (Wind/ WAVES, Stereo/SWAVES) in which the tracking is accomplished by assuming a frequency-to-density mapping.

This type of Heliophysics mission would be inherently cost prohibitive in a traditional spacecraft paradigm. However, the use of SmallSats, accompanied by the miniaturization of sub-system components, enables the development of this concept at lower cost than ever before.

This paper presents the most recent updates on this mission concept, with a focus on the implementation and how it meets the science objectives. The science payload is described, with an initial "benchtop" unit having been constructed to demonstrate its performance. It then describes the mission concept of operations, which consists of six 6U SmallSats placed in a "graveyard orbit," just above geosynchronous orbit (GEO) for six months. A key aspect of the mission concept is that the SmallSats are in a passive formation, requiring only knowledge of their positions and minimal control, in order to form an interferometer.

The information presented about SunRISE is pre-decisional and is provided for planning and discussion purposes only. Part of this research was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration.

E1.8-0021-18 SPACE VLBI: FROM FIRST IDEAS TO THE OPERATIONAL MISSION

Leonid Gurvits, lgurvits@jive.eu

Joint Institute for VLBI ERIC and TU Delft, Dwingeloo, Netherlands

This COSPAR session is dedicated to the results of the Russia-led international Space VLBI (SVLBI) mission RadioAstron. De facto, this mission concludes the first generation of SVLBI facilities, which commenced with the Japan-led international mission VSOP (VLBI Space Observatory Programme) launched in 1997 and preceded by the SVLBI demonstration experiment with the Tracking and Data Relay Satellite System (TDRSS) in 1986-1988. While the comprehensive lessons learned from the first demonstration and two dedicated SVLBI missions are still awaiting thorough attention, several preliminary conclusions can be made. This presentation addresses some key scientific and technological issues as they progressed over four decades from the original SVLBI concepts to the operational missions.

E1.8-0023-18 RADIOASTRON AND THE RISC; A SENSE OF PLACES

David Jauncey, david.jauncey@csiro.au CSIRO, Weston, Australia

Since it was formed in 1988, the RISC, the RadioAstron International Science Council, has played a leading role in co-ordinating the science and the international involvement in this Russian-led International VLBI mission. For the 30th Anniversary of the RISC's formation, I have assembled a number of multi-wavelength sketches and images drawn from the places where, and near where the RISC has met over the past decade and a half. These are presented here as RISC reminiscences and re-views.

E1.8-0024-18 USING HIGH-RESOLUTION VLBI TO PROBE GAMMA-RAY EMISSION IN 3C 84

Jeff Hodgson, jhodgson@kasi.re.kr

Korea, Democratic People&#39s Republic of Bindu Rani, bindu. rani@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States 3C 84 is unique in that it is one of the few non-blazar AGN that is detected at ultra high energies (including MAGIC in addition to Fermi/LAT). The source itself has been increasing in flux density at both radio and Gamma-rays since approximately 2005 with VLBI observations showing that this rising emission is associated with a slowly moving component south of the jet-launching (C1) region, commonly known as "C3". Recent analysis of multi-wavelength Korean VLBI Network data has suggested multiple locations of Gamma-rays within 3C 84. In addition to the slowly rising trend in C3, smaller scale rapid variation of radio and Gamma-ray fluxes are associated with the C1 region, but that the correlations observed are due to random processes. We than applied wavelet analysis using the WISE package to the kinematics of 3C 84 using 43 GHz data from 2010 until now. We find that a large flare beginning in early 2015 and currently decaying is apparently due to the emission of a new component from the C3 region. Additionally, there appears to be evidence for helical trajectories with Gamma-ray flaring being possibly associated with when the helical path passes through our line-of-sight.

E1.8-0025-18 SHADOWS AROUND SUPERMASSIVE BLACK HOLES AS A TOOL TO TEST GR AND ALTERNATIVE THEORIES OF GRAVITY

Alexander Zakharov, zakharov@itep.ru

Institute of Theoretical and Experimental Physics, Moscow, Russia
Pavlina Jaluvkova, pavlina.jaluvkova@seznam.cz

Joint Institute for Nuclear Research, Dubna, Russia Zdenek Stuchlik, zdenek.stuchlik@fpf.slu.cz

Silesian University at Opava, OPAVA, Czech Republic Arman Tursunov, arman.tursunov@fpf.slu.cz

Silesian University in Opava, Opava, Czech Republic

We obtained analytical expression for shadows around supermassive black holes for a wide class of spherically symmetric black hole solutions, such a Reissner - Nordstrom with a tidal charge, dyonic Reissner - Nordstrom – (anti) de-Sitter, black hole in Horndeski gravity. Therefore, observations of such shadows could be indicator of an alternative theory of gravity. We also found properties of shadows around Kerr black holes. which could be observed in the future with the Event Horizon Telescope and projected space-ground interferometer Millimetron.

RESEARCH IN ASTROPHYSICS FROM SPACE (E)

ULTRAVIOLET ASTRONOMY AND THE QUEST FOR THE ORIGIN OF LIFE (E1.9)

E1.9-0001-18 THE EVOLUTION AND DISPERSAL OF PLANET-FORMING DISKS

Ilaria Pascucci, pascucci@lpl.arizona.edu

Lunar and Planetary Laboratory, Tucson, Arizona, United States

Disks of gas and dust around Myr-old stars are the birth sites of planets. Hence, their evolution and dispersal directly impact what type of planetary systems can form. I will review empirical constraints on disk evolution and dispersal with emphasis on those that come from disks caught in the act of clearing out planet-forming material. I will also discuss theoretical models that offer a physical interpretation and summarize their successes and shortcomings. I will conclude by highlighting which investigations are most promising to further constrain our physical understanding of disk evolution and dispersal.

E1.9-0002-18 THE SURFACE UV ENVIRONMENT ON PLANETS ORBITING M-DWARFS: NEED FOR EXPERIMENTS & IMPLICATIONS FOR ORIGINS-OF-LIFE CHEMISTRY

Sukrit Ranjan, sukrit@mit.edu

Massachusetts Institute of Technology, Cambridge, Massachusetts, United States Robin Wordsworth, rwordsworth@seas.harvard.edu

Harvard University, Cambridge, Massachusetts, United States Dimitar Sasselov, dsasselov@cfa.harvard.edu

Harvard-Smithsonian Center for Astrophysics, Cambridge, Massachusetts, United States

Rocky, temperate planets orbiting M-dwarf stars are of intense astrobiological interest because they are the only potentially habitable worlds accessible to biosignature search over the next 10+ years (e.g., Proxima Centauri b, LHS1140 b, TRAPPIST-1 system). Simultaneously, recent experimental and theoretical work suggests that ultraviolet (UV) light may have played a key role in the origin of life on Earth, and especially the origin of RNA. Characterizing the UV environment on M-dwarf planets is crucial to understanding whether life as we know it could emerge on such worlds.

In this work, we couple radiative transfer models to observed M-dwarf spectra to determine the surface UV environment on prebiotic Earth-analog planets orbiting M-dwarfs. We calculate dose rates to quantify the impact of different surface UV environments on prebiotically important photoprocesses. We consider factors that could influence the surface UV environment, including flares, atmospheric surface pressure, and varying UV output early in the star's life.

We find that M-dwarf planets have access to 1000 times less bioactive UV fluence than the young Earth. It is uncertain whether UV-dependent prebiotic chemistry, such as recently discovered pathways for the synthesis of ribonucleotides and sugars, could function on UVpoor M-dwarf planets. Laboratory studies are required to determine whether UV-dependent prebiotic chemistry can proceed on M-dwarf planets and, if not, whether elevated UV irradiation during stellar flares can substitute.

Our work suggests a potential advantage for active M-dwarfs relative to quiet M-dwarfs as habitable planet hosts. Further, if laboratory studies confirm that UV-dependent prebiotic chemistry cannot proceed on M-dwarf planets, then biosignature searches on such worlds will empirically test whether UV light is required for the emergence of life.

E1.9-0003-18 UV IRRADIATION AND DISK WINDS: THE IMPACT ON DISK EVOLUTION

Ana Gomez De Castro, aig@mat.ucm.es Universidad Complutense de Madrid, Madrid, Spain

The evolution and dispersal of protoplanetary discs is a key issue for understanding the star and planet formation processes. Photoevaporation processes play an important role and have been thoroughly analyzed. However, the role of outflows is often neglected. In this contribution, the role of disk-winds in disk evolution is analyzed. Magnetized disk winds are kept by ambipolar diffusion heating at a temperature of roughly 10,000 K. As a result, disks are illuminated from above (below) by thin veils of plasma. In this contribution, numerical calculations of the impact of the outflow radiation on the evolution of accretion disks is presented.

E1.9-0004-18 EXOPLANETARY RESEARCH IN THE UV

David Ehrenreich, david.ehrenreich@unige.ch Université de Genève, Versoix, Switzerland

Observing exoplanets in the ultraviolet enables the exploration of the outskirts of planetary atmospheres. Initial Hubble Space Telescope (HST) observations have shown that strongly irradiated gas giants experience atmospheric thermal escape (or "evaporation"). The refurbishment of HST during its last servicing mission, with the repair of the Space Telescope Imaging Spectrograph and installation of the Cosmic Origins Spectrograph, allowed extending these early results to a whole new class of planets in different masses and irradiation regimes. The discovery of a huge hydrogen cloud escaping from a gently irradiated Neptune-mass planets triggered renewed interest in the ultraviolet observation of transits and a window into the evolution of low-mass planets. This is of critical interest with respect to the "evaporation valley(s)" in the exoplanet population unveiled by the Kepler space telescope. I will review recent results and interpretation, especially from on-going observational efforts, including large HST programmes relevant to comparative exoplanetolgy, star-planet interaction and the search for water on habitable-zone planets.

E1.9-0005-18 EXPLORING HABITABILITY UNDER AN ENVIRONMENT OF STRONG SUPERFLARES AT A TIME WHEN THE OZONE LAYER FIRST FORMED ON EARTH

Raissa Estrela, rlf.estrela@gmail.com

Universidade Presbiteriana Mackenzie/CRAAM, Sao Paulo, Brazil
Adriana Valio, adrivalio@gmail.com

Universidade Presbiteriana Mackenzie/CRAAM, Sao Paulo, Brazil

Kepler-96 is an active solar-type star harbouring a Super-Earth planet in close orbit. Its age of 2.3 Gyr is the same as the Sun when there was a considerable increase of oxygen in Earth's atmosphere due to micro-organisms living in the ocean. We present the analysis of superflares seen on the transit lightcurves of Kepler-96b. The model used here simulates the planetary transit in a flaring star. By fitting the observational data with this model, it is possible to infer the physical properties of the flares, such as their duration and the energy released. We found 3 flares within the energy range of superflares, where the biggest superflare observed was found to have an energy of 1.81 1035 ergs. The goal is to analyse the biological impact of these superflares on a hypothetical Earth in the habitable zone of Kepler-96 assuming this planet has protection via different scenarios: an Archean and Present-day atmospheres. Also, we compute the attenuation of the flare UV radiation through an Archean ocean. The conclusion is that considering the increase in the UV flux by the strongest superflare emission, E. Coli and D. Radiodurans could survive on the surface of the planet only if there was an ozone layer present on the planet atmosphere. However, they could escape from the hazardous UV effects at a depth of 28m and 12m below the ocean surface, respectively. For smaller superflares contribution, D. Radiodurans could survive in the surface even in an Archean atmosphere with no ozone.

E1.9-0006-18 THE CORE PROGRAM CALL OF THE WSO-UV MISSION

Mikhail Sachkov, msachkov@inasan.ru Institute of Astronomy RAS, Moscow, Russia Ana Gomez De Castro, aig@mat.ucm.es

Universidad Complutense de Madrid, Madrid, Spain Boris M. Shustov, bshustov@inasan.ru

Russian Academy of Science, Moscow, Russia

The World Space Observatory – Ultraviolet (WSO-UV) mission will be the only 2-m class UV telescope with capabilities similar to those of the HST for the decade after finishing HST mission because of the fact that no large UV-observatories are planned to be launched by most of space agencies in the coming 10 - 15 years. The large UVOIR observatories of the future will appear not earlier than in 2030s. The WSO-UV has been described in detail in many publications. Here we would like to present updated characteristics of its instrumentation as well as the current state of the project. The special attention is paid to the Core Program of the WSO-UV and tools for Core Program Application. We plan to announce a Call for the WSO-UV Core Program at the end of 2018.

E1.9-0007-18 CHARACTERIZING THE IN-FLIGHT PERFORMANCE OF UVIT INSTRUMENT AND STAR FORMATION PROPERTIES OF A GALAXY

Rahna P T, 7rehanrenzin@gmail.com

Christ University, Bangalure, Bengaluru, India Jayant Murthy, jmurthy@yahoo.com

Indian Institute of Astrophysics, Bangalore, India Mousumi Das, mousumi@iiap.res.in

Indian Institute of Astrophysics, 560 034, India Margarita Safonova, rita@iiap.res.in

Indian Institute of Astrophysics, Bangalore, India Firoza Sutaria, fsutaria@iiap.res.in

Indian Institute of Astrophysics, Bangalore, India

Shivappa Gudennavar, shivappa.b.gudennavar@christuniversity.in Christ University, Bangalore, India

Ultra Violet Imaging Telescope (UVIT) is one of the instruments on India's first multi-wavelength mission, AstroSat, which provides a unique opportunity to observe the UV sky simultaneously in three channels. We have performed an independent characterization of the FUV and NUV detectors of UVIT payload on-board and found that the performance is close to that expected from the ground-based calibration. We have reduced and analysed the data using JUDE software and found that the photometric sensitivity is same as GALEX in the NUV broadband filter and about 35% that of GALEX in the FUV broadband filter. The PSF of the instrument is of the order of 1.2 to 1.6 arcsecs. We derived the distortion correction but recommend that it be applied post processing as part of the astrometric solution. Since the higher angular resolution, higher sensitivity and multiple filters of UVIT are well suited for the study of the detailed features of galaxies, the study of ultraviolet properties of a galaxy using UVIT data is in progress. The details of these studies will be presented during the meeting.

E1.9-0008-18 ULTRAVIOLET CHEMISTRY IN WARM LITTLE PONDS ON ROCKY PLANETS AROUND COOL STARS

Paul Rimmer, pbr27@cam.ac.uk

University of Cambridge, Cambridge, United Kingdom Jianfeng Xu, jxu@mrc-lmb.cam.ac.uk

University of Cambridge, Cambridge, United Kingdom Samantha Thompson, sjt20@cam.ac.uk

University of Cambridge, Cambridge, United Kingdom Ed Gillen, ecg41@cam.ac.uk

University of Cambridge, Cambridge, United Kingdom John Sutherland, johns@mrc-lmb.cam.ac.uk

University of Cambridge, Cambridge, United Kingdom Didier Queloz, dq212@cam.ac.uk

University of Cambridge, Cambridge, United Kingdom

It is likely that the building blocks of life were generated photochemically from hydrogen cyanide and an anion in liquid water. The generation of these building blocks depends on the ultraviolet spectrum of the host star. Comparing the rates of photochemical formation of simple sugars from hydrogen cyanide and an anion in liquid water ('light chemistry') versus the bimolecular formation of insert adducts in the absence of light ('dark chemistry'), alongside UV spectra of a variety of stars taken from the MUSCLES database, we can determine an 'abiogenesis zone' outside of which the building blocks of life cannot form via known photochemical pathways. The abiogenesis zone can be determined in terms of stellar effective temperature and the planet's semi-major axis. Our results indicate that rocky planets around quiet M dwarfs will not be able to generate the building blocks of life photochemically. I will finish with a brief discussion on the implications our results have for active M dwarfs.

E1.9-0009-18 THE GROWING CASE FOR LIFE AS A COSMIC PHENOMENON

Nalin Chandra Wickramasinghe, ncwick@gmail.com

Buckingham Centre for Astrobiology, University of Buckingham, UK, Cardiff, United Kingdom

A series of astronomical observations obtained over the period 1986-2017 are in striking evidence with the theory that comets harbour a viable biological component that led to the beginnings of life on Earth. These include (1) near infrared spectra of the dust from comet Halley obtained in 1986, (2) near and mid-infrared spectra of comet Hale-Bopp in 1997, (3) near and mid-infrared spectra of comet Tempel I in 2005, (4) the discovery of an amino acid and degradation products attributable to biology in the material recovered from the Stardust Mission in 2009, (5) jets from comet Lovejoy showing both a sugar and Ethyl alcohol and finally a diverse set of data from the Rosetta mission. The conjunction of all the available data points unerringly to the operation of cometary biology and interstellar panspermia rather than the much weaker claim of comets being the source of the chemical building blocks of life.

We conclude with specific predictions on the properties expected of extra terrestrial life if it is discovered on Enceladus, Europa and beyond. A radically different biochemistry elsewhere could be considered as a falsification of the theory of interstellar panspermia.

E1.9-0010-18 STELLAR DRIVERS FOR ATMOSPHERIC CHEMISTRY AND EVOLUTION: UV EXOPLANET CHARACTERIZATION FROM HUBBLE TO LUVOIR

Kevin France, kevin.france@colorado.edu

University of Colorado Boulder, Boulder, Colorado, United States

High-energy stellar photons and particles regulate the atmospheric temperature structure and photochemistry on orbiting planets, influencing the long-term stability of planetary atmospheres and the production of potential "biomarker" gases. In the first part of the talk, I will describe results from an ongoing panchromatic survey (Chandra/XMM/Hubble/ground) of M and K dwarf exoplanet hosts, focusing on two main results: 1) the evolution of the high-energy spectral energy distribution as a star's habitable zone moves inward from 1 to 0.1 AU, including implications for the possible abiotic production of the suggested biomarkers O2 and O3, and 2) new estimates of the high-energy particle fluxes (from CMEs/SEPs) from these stars based on solar UV flare/particle flux measurements. I will conclude by discussing UV spectroscopic characterization of exoplanetary systems in the era beyond Hubble. Using the UV capability and high sensitivity of future large space observatories, e.g, the Large/Ultraviolet/Optical/InfraRed Surveyor (LUVOIR) LUMOS spectrograph, we will not only be able to carry out high-fidelity host star characterization of every potentially inhabited planetary system studied by LUVOIR, we will also open the door to statistical-scale studies of atmospheric escape physics for the first time.

E1.9-0011-18 INVESTIGATING DIFFUSE ASTROPHYSICAL OBJECTS USING A MINIATURIZED UV SPATIAL SPECTROMETER

Raghvendra Sahai, raghvendra.sahai@jpl.nasa.gov JPL, Pasadena, California, United States

We describe a spectroscopic program to probe the physical properties of several important classes of astrophysical objects in our galaxy and beyond, that, by their nature, are faint, extended and diffuse. These classes include the astrospheres around dying stars, the interstellar medium of our Galaxy, supernova remnants, and the circumgalactic medium around nearby galaxies. Traditional slit spectrographs lack the sensitivityfor detecting the faint UV emission that can be used to characterize the diuse, hot gas in these objects. We utilize a novel spectroscopic instrument, called the Spatial Heterodyne Spectrometer (SHS), which provides significant gains in sensitivity over a slit-spectrograph, and makes it possible (in a relatively short time) to study important UV lines with high-spectral resolution, in order to probe the diuse gas in these objects.

E1.9-0012-18 DESIGN AND ANALYSIS OF MECHANICAL SYSTEMS ON BOARD A 6U CUBESAT BASED UV SPECTROGRAPH FOR TRANSIENT STUDIES

Binukumar Gopalakrishnan Nair, binukumarg@gmail.com Indian Institute of Astrophysics, Bangalore, India

CubeSat Based payloads for scientific missions gain considerably over dedicated large scale scientific missions in terms of cost, time and launch opportunities. We have designed a UV Spectrograph on borad a 6U CubeSat for a Lower Earth Orbit (LEO) mission, such a CubeSat provide a versatile platform to conduct a survey of FarUV (FUV) region. Survey of FUV region can provide insight into understanding of transient events such as Supernove, Novae and dynamics as well as evolution of 'hot gas' in our galaxy and interstellar medium etc. The instrument has a spectral coverage from 120 to 320 nm with a medium resolution of 5000. The detector is a GaN - Micro Channel Plate (MCP) based detector with photon counting capability. Mechanical structure and majority of sub-systems were made with Carbon fibre Reinforced Polymer (CFRP). CFRP was choosen due to its high tensile strength and low thermal expansion properties. In this work we present the aspects involving the design of mechanical structure and Finite Element based Stress, vibrational and thermal analysis of the various components of the payload and the entire assembly.

E1.9-0013-18 CUBESAT BASED UV SPECTROGRAPH (CUBS)

Joice Mathew, joice@iiap.res.in

Indian Institute of Astrophysics, Bengaluru, India Jayant Murthy, jmurthy@yahoo.com

Indian Institute of Astrophysics, Bangalore, India Noah Brosch, noah@wise.tau.ac.il

Tel Aviv University, Tel Aviv, Israel

CubeSats provide affordable launch opportunities and it is a cost-effective solution for space astronomy. CubeSats based payloads can make significant observations at the relatively underexplored regions of the UV spectrum. CubeSat Ultraviolet Bright Spectrograph (CUBS) is a near ultraviolet (200-300 nm) spectrograph designed to fit into a 2U CubeSat. The aggressive timeline drives the design to include only off-the-shelf items to minimize procurement delays and cost. The grating used is a ruled UV grating with 600 lines/mm with an efficiency of more than 65CUBS primary scientific objective is to look for M-Dwarf UV flares and this UV activity will have a strong impact on the habitability of any possible planet around the star. UV light may have played a key role in the origin of life on Earth and characterizing the UV environment on M-dwarf planets is important for understanding the potential habitability. Another interesting scientific objective is to look at the origin of the 2175 A° extinction bump. To detect the strength of extinction bump CUBS will acquire the spectrum of bright stars in the wavelength range 200-300 nm. CUBS will also acquire NUV spectrum of solar system objects which are not usually observed by other space telescopes because of brightness limitations, a CubeSat size spectrograph could look at solar system objects and even comets close to its perihelion. The main challenges in the design of the instrument were to use only off-the-shelf items and the size and weight constraints imposed by CubeSat standards. We will describe the scientific potential of CUBS and the various aspects of instrument design and development.

E1.9-0014-18 ROUND TABLE ON JOINT INITIATIVES ON CUBESAT SIZE PROJECTS

E1.9-0015-18 COMPUTATIONAL TEST ON BIOMARKERS DETECTABILITY IN EXOPLANETS ATMOSPHERES WITH WUVS

Pablo Marcos-Arenal, pablomarcosarenal@gmail.com Universidad Complutense de Madrid, Madrid, Spain Ana Gomez De Castro, aig@mat.ucm.es

Universidad Complutense de Madrid, Madrid, Spain Mikhail Sachkov, msachkov@inasan.ru

Institute of Astronomy RAS, Moscow, Russia

Transmission spectroscopy of exoplanets in the UV is a promising tool for the characterisation of Earth-like atmospheres. In particular, large abundances of molecular oxygen and ozone can be used as spectroscopic biosignatures on Earth. We want to tackle the detectability of biomarker species with the World Space Observatory - Ultraviolet (WSO-UV) instrumentation through simulations of transiting exoplanets.

The WSO-UV is a space telescope to be launched in 2023, equipped with a high resolution spectrograph (WUVS - WSO UltraViolet Spectrograph) that provides high resolution spectroscopy (R 55,000) to observe point sources in far and near UV. The spectral ranges of each channel, VUVES (102-180 nm) and UVES (174-310 nm), are in good agreement with the O2 and O3 spectral bands in the Earth atmosphere.

The detectability of these species in an exoplanet atmosphere can be evaluated from an appropriate overall instrument model through simulations of the expected observations. The instrumental performance of the observatory can be evaluated in terms of noise source response, data quality, and number of counts detected for different types of observing configurations. We have developed a WSO Simulator tool that includes each of the channels of the observatory for the validation of the expected instrumental response. This tool includes new functionalities as a response to the community to the preparatory activities prior to the launch of the mission. The simulator also allows for testing the feasibility of the scientific programs and as a preparatory step for the scientific data processing.

The WSO Simulator was implemented as a further development of the PLATO Simulator, but it has been adapted to the instrument specific characteristics of WSO-UV. In this work we discuss the WUVS echelle spectrographs. The implementation details of the WSO Simulator and the model describing the host star, the exoplanet, and its atmosphere are also described here.

Taking a host star-exoplanet configuration similar to Sun-Earth and an Earth atmosphere model, we use the WSO Simulator to generate synthetic time series of the resulting observations. Further analysis on the outcome of these images is provided, including the detectability of the molecular oxygen and ozone.

E1.9-0016-18 THE ROLE OF THE VISCOSITY ON THE DISPERSAL OF IRRADIATED PROTOPLANETARY DISCS

Juan Carlos Vallejo, juancval@ucm.es

Universidad Complutense de Madrid, Madrid, Spain Ana Gomez De Castro, aig@mat.ucm.es Universidad Complutense de Madrid, Madrid, Spain

The study of planet formation processes and life emergence in the Universe relies on the study of the evolution of the Pre-Main Sequence Stars (PMS stars). The available observational data point to the ubiquitousness of protoplanetary discs on these stars. These discs are the natural scenario for planet formation processes, and understanding their evolution and the mechanisms and time-scales by which the disc is eventually dispersed is a key issue in planet formation theories. The disc evolution and dispersal influences planet formation. Changes in the accretion processes modify the disc's chemistry, the dust-to-gas ratio and can starve the gas reservoir available for planet formation. The gas giant and terrestrial planets begin to form in between the accretion and post-accretion phases of the disc. Therefore, it is very important to analyse the mechanisms driving the accretion rate shutdown.

A first approach to this problem focuses on modelling the transport of angular momentum in the disc as a viscous process. This model can be enhanced by adding the effect of UV and RX gas photoevaporation. These photoevaporation processes, coupled with the viscous evolution, produce a gap in the inner disc at the point when the photoevaporation rate and the accretion rate become comparable, making it a convenient way to shutdown the mass accretion. The observed pile-up of Jupiter-mass planets can be also explained by the interaction between migrating planets and the gap-opening due to this photoevaporation. Unfortunately, the viscosity mechanism driving the disc evolution is not fully understood. Traditionally, these uncertainties have been bypassed through the use of the α-parametrisation introduced by Shakura and Sunyaev. However, the most adequate value (if any) for α has not been settled yet. A common value is $\alpha = 0.01$, because it provides evolutionary time-scales in line with some known properties of discs. But, one can find a wider range of values in the literature, ranging from 0.1 to 0.001 and even lower.

Our work addresses the impact of these viscosity values on some diagnostic tools that are used when comparing observational and theoretical data. We have implemented a grid of disc models, with the disc mass, the star mass and the stellar radiation (EUV and RX) as parametric space. We have evolved every grid system under different viscosity values. Then, we have compared the results with observed systems. As the viscosity decreases, the models get closer to the observed values more easily than when the values are higher. We describe the changes in the slopes of the relationships between accretion rate against disc mass (and also against stellar mass), with and without the effect of photoevaporative winds. The slopes of these relationships change with the age of the system. But, because these time-scales depend on the disc and stellar mass, the slopes change with these parameters accordingly. Moreover, these changes are more or less noticeable as the viscosity changes.

Our results indicate that, as foreseen, matching viscous models with observed systems is not trivial, and the results strongly depend on α. However, the analysis of how the theoretical curves evolve along the grid of models allow to better select the viscosity values in every case. And the study of the gap opening and the accretion shutdown times-scales in the grid provides some constraints for planet formation processes. Finally, we note that the EUV luminosities of stars are very poorly known at typical star-forming region distances, and they are at best indirectly determined. Because our simulations indicate they play a key role in disc evolution, one may conclude that future UV missions are required for providing further data in this area.

Knowledge of temperature, densities, and chemical abundances of hot plasmas that exist in stars including the Sun, in the interstellar and intergalactic medium, and in active galactic nuclei can be optimally determined through observations in key diagnostic spectral lines, many of which are in the far ultraviolet range (FUV, 100-200 nm), such as the Lyman series of atomic Hydrogen and Deuterium, and the Lyman bands of their molecules, along with lines of OI and OVI, CIV, etc. For habitable exoplanet search, the FUV spectrum of M stars is a useful diagnostic tool of biologically generated gases in planet atmospheres. Measuring the magnetic field in the different layers of the Sun's atmosphere can be optimally performed by means of polarimetry in the FUV and in the UV. The development of more efficient FUV coatings is key to advance in many fields of astrophysics and solar physics. With this goal, GOLD (Spanish acronym of Thin Film Optics Group) has been devoting a long effort to develop highperformance coatings to address specific targets. In this poster, GOLD's capacity to develop and measure FUV coatings will be summarized. A 75-cm diameter chamber in an ISO-6 clean room is used to prepare FUV coatings satisfying space requirements. The main deposition technique is evaporation and ion-beam-sputtering is also available. Coating performance is conveniently measured with an in-house reflectometer covering the 40-190 nm spectral range. The presentation will display the performance of FUV coatings that can be prepared at GOLD:

Transmittance filters peaked at Λ 120 nm with a strong peak-to-visible rejection

Broadband mirrors with enhanced FUV reflectance

Narrowband mirrors tuned at FUV wavelengths as short as H Lyman β (102.6 nm)

Polarizers at H Lyman α (121.6 nm) and other FUV and UV spectral lines

Structure, Evolution and Dynamics of Neutron Stars (E1.10)

E1.10-0001-18 MULTI-WAVELENGTH FACILITIES FOR NEUTRON STAR RESEARCH

Dipankar Bhattacharya, dipankar@iucaa.in

Inter University Centre for Astronomy and Astrophysics, Pune, India

Neutron stars are, in general, emitters of electromagnetic radiation over a very broad range of wavelengths. These sources also exhibit rapid multi-wavelength flux variability. Simultaneous or near-simultaneous observations of this variable emission reveal in detail the physical processes at play in and around these objects. Timely access to observing facilities spanning many wavebands is crucially important for this line of research, but this remains a difficult logistic challenge. This talk will present an overview of the facilities available for multi-wavelength rapid variability studies, with focus on broadband, fast-timing platforms such as AstroSat and Insight-HXMT.

E1.10-0002-18 OBSERVATIONAL TESTS OF ACCRETION-DRIVEN SPIN-UP/DOWN PROCESS IN X-RAY BINARY PULSARS WITH 7-YEAR MAXI AND FERMI/GBM DATA

Mutsumi Sugizaki, sugizaki@riken.jp RIKEN, Wako, Japan

Tatehiro Mihara, mihara@crab.riken.jp RIKEN, Wako, Saitama, Japan

Fumiaki Yatabe, fumiaki.yatabe@riken.jp RIKEN, Wako, Japan

The relation between the luminosity and the spin-period change in X-ray binary pulsars reflects the manner of mass accretion onto the magnetized neutron stars, and thus provides us information on the neutron-star physical parameters related to the mass M, radius R, and the surface magnetic field B. To observationally study the relation, we analyzed X-ray light curves obtained by the MAXI all-sky survey and pulse-period data taken by the Fermi Gamma-ray Burst Monitor pulsar project, both continuously cover 7 years since 2009 August.

In 4U 1626-67, a low-mass X-ray binary pulsar which repeated transitions between spin-up and spin-down phases every few ten years, the observed relation between the X-ray intensity and the pulse-period change has been successfully explained by the disk-magnetosphere interaction model proposed by Ghosh & Lamb (1979), including both the spin-up to the spin-down phases over the past 6 years. Assuming a distance of 10 kpc and using the surface magnetic field

B measured with the cyclotron resonance, the model indicates the mass M =1.8-1.9M0 and the radius R =11.4-11.5 km (Takagi et al. 2016). Thus, the method provides a new way of constraining the mass-radius relations.

For a more systematic study, we selected 12 Be binary pulsars which showed, in these 7 years, large outbursts with the peak luminosity exceeding 1037 erg s−1. In all the 12 objects, the luminosities and the spin-frequency derivatives, observed during the outbursts, were found to follow positive correlations that are close to the proportionality, as expected by most of the theoretical models. The coefficient of the proportionality agrees, within a factor of 3, with the prediction by the Ghosh & Lamb (1979) when assuming a typical mass and radius, and employing the surface magnetic field measured with the cyclotron resonance. The scatter of the observed coefficients around the model predictions is reasonably explained by uncertainties in the pulsed-emission anisotropy and the distance estimate (Sugizaki et al. 2017).

After calibrating the theoretical model, we also analyzed the data of X Persei, the Be binary pulsar with a low luminosity (S 2 1035 erg s−1), which once showed a transition from the spindown to spin-up in 2002 (Lutovinov et al. 2012). Although the Ghosh & Lamb (1979) model again successfully explained the observed relation between the luminosity and the spin-period change covering both the spin-up and spin-down phases, the data require a strong magnetic field

B 1013 G as well as a relatively high mass M 1.7M0. These results point to an intriguing possibility that X Persei is a magnetar-equivalent object in a binary, and such strong-field neutron stars possibly have somewhat higher mass than the ordinary ones with B ~ 1012 G.

E1.10-0003-18 EFFECTS OF THERMONUCLEAR X-RAY BURSTS ON NON-BURST EMISSIONS IN THE SOFT STATE OF 4U 1728-34 USING ASTROSAT/ LAXPC

Navin Sridhar, navins@iiserb.ac.in

Indian Institute of Science Education and Research, Bhopal, Bhauri, Bhopal, India AstroSat/LAXPC

Sudip Bhattacharyya, JS Yadav, Jai Verdhan Chauhan, PC Agrawal, HM Antia, Mayukh Pahari, Ranjeev Misra, Tilak Katoch, RK Manchanda, Biswajit Paul

The continuum spectrum from Neutron Star thermonuclear bursts can be used to measure the neutron star radius, which is a crucial parameter in probing the nature of the degenerate core matter of neutron stars. During a thermonuclear burst, we see a significant enhancement of the neutron star's persistent emission, the cause for which is not conclusively known. In this work, we attempt to comprehend the reasons for the evolution of persistent emission, as seen during the thermonuclear bursts in the soft state of 4U 1728-34. For the first time, we employ the Large Area X-ray Proportional Counter (LAXPC) instrument aboard AstroSat for such a science goal. The large surface area of LAXPC combined with its fine timing resolution allows us to probe the evolution of persistent and burst spectra within the short timescales of different phases of the burst. Our analysis shows that, the burst emission is not reprocessed by the corona covering the neutron star. Rather, the burst emission increases the accretion rate perhaps due to Poynting-Robertson drag on the accretion disk, and the resulting enhanced disk emission gets Comptonized by corona covering the disk. This finding provides a way to distinguish between the burst and non-burst emissions, which is necessary to reduce the systematics associated with neutron star radius measurements.

E1.10-0004-18 NASA'S NEUTRON STAR INTERIOR COMPOSITION EXPLORER (NICER): MISSION OVERVIEW AND INITIAL RESULTS

Zaven Arzoumanian, zaven.arzoumanian@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States NICER Science Team

Keith C. Gendreau, Craig B. Markwardt, and members of the NICER Science Team's topical Working Groups

In operation since July 2017 as an external attached payload on the International Space Station, NICER is the first high-energy astrophysics mission devoted to the study of neutron stars in their many guises. Offering a unique timing-spectroscopy capability in the soft X-ray (0.2–12 keV) band, NICER has observed a wide variety of rotation-, accretion-, and magneticallypowered neutron stars with the key aims of constraining the dense-matter physics of their interiors, understanding the processes that drive dynamic internal and external phenomena, and probing thermal and nonthermal emission mechanisms. We provide an overview of the instrumentation and performance that enable NICER's science objectives, and highlight results from the mission's first year of operations.

The Neutron Star Interior Composition Explorer (NICER) is NASA's new X-ray timing instrument onboard the ISS that was launched in June 2017. With a large effective area, low background, very precise absolute timing and great low energy response, NICER has been doing a fantastic job in observing many interesting phenomena related to neutron stars and black holes. One of the main objectives of the NICER mission is to study phenomena related to Type I X-ray bursts, which are thermonuclear flashes observed from the surfaces of accreting neutron stars in Low Mass X-ray Binaries, such as photospheric radius expansion and burst oscillations. NICER's large effective area and excellent low energy response enable new, detailed studies of these bursts in the soft X-ray band. In this talk I will present some of the early results from the first year of the NICER mission regarding Type I X-ray bursts and searches for burst oscillations.

E1.10-0006-18 CHARACTERIZING THE PROPERTIES OF NEUTRON STARS IN THE NUSTARNICER ERA

Renee Ludlam, rmludlam@umich.edu

University of Michigan, Ann Arbor, Michigan, United States Jon Miller, jonmm@umich.edu

University of Michigan, Ann Arbor, Michigan, United States

Over the past several years we have been able to perform inner disk measurements with NuSTAR that are unbiased by pile-up effects. From these measurements we are able to infer different properties about the neutron star itself, such as magnetic field strengths, boundary layers, and constraints on the equation of state. Observations of a number of neutron stars over range of Eddington ratios has allowed us to probe the extent of the inner disk over a range of mass accretion rates. There does not appear to be a clear trend between mass accretion rate and the location of the inner disk radius, consistent with several previous studies that were complicated by pile-up effects. When comparing the magnetic field strengths from reflection modeling methods to those seen for accreting millisecond X-ray pulsars (AMXPs), we find the magnetic field strengths to be consistent over comparable Eddington ratios; demonstrating that Fe lines can be used to place limits to first order. With the addition of NICER, we gain access to lower energy features below 3 keV that are also free from pile-up effects. Utilizing the combined bandpass and sensitivity of both NuSTAR and NICER opens a new opportunity to capture multiple emission features arising from bright sources to map out different observables within the disk and disentangle truncation mechanisms in systems.

E1.10-0007-18 THE EQUATION OF STATE OF NEUTRON STARS

Dipankar Bhattacharya, dipankar@iucaa.in

Inter University Centre for Astronomy and Astrophysics, Pune, India

The interiors of neutron stars present conditions of extremely high density at sub-Fermi temperatures, analogues of which are so far not reproducible in laboratory experiments. The exact nature of strong interaction at such close packing remains unknown, and this has led to a rich variety of predictions for the Equation of State (EoS) of neutron stars over many decades. Recent observations of pulsars, X-ray binaries and Gravitational Wave events hold much promise to narrow down the acceptable range of possible EoS. In this talk I will review the broad physics inputs in different families of Equations of State, and what remains viable in the light of existing observational constraints.

E1.10-0008-18 A 2.3 SOLAR-MASS NEUTRON STAR

Manuel Linares, manuel.linares@upc.edu

Universitat Politecnica de Catalunya, Barcelona, Spain Tariq Shahbaz, tsh@iac.es

Instituto de Astrofisica de Canarias, La Laguna, Spain Jorge Casares, jcv@iac.es

Instituto de Astrofisica de Canarias (IAC), Santa Cruz De Tenerife, Spain

The macroscopic properties of neutron stars depend on how sub-atomic particles interact in their interiors. These interactions, encoded in the equation of state, are specially uncertain in the central regions, where densities exceed that of an atomic nucleus. The maximum mass of a neutron star can discriminate between proposed equations of state. New millisecond pulsars in compact binaries provide a good opportunity to search for the most massive neutron stars. We present observations and detailed modeling of an extremely irradiated companion to a millisecond pulsar, using the largest optical telescope on Earth. We develop and apply a new method to measure the velocity of both sides of the companion star, and find that the binary hosts one of the most massive neutron stars known to date, with a mass of 2.27+0.17−0.15 MSun. A 2.3 Solar-mass neutron star would rule out most currently proposed equations of state, casting doubt on the existence of exotic forms of matter in the core.

E1.10-0009-18 PARAMETRIC HOT EQUATION OF STATE FOR NEUTRON STARS

Carolyn Raithel, craithel@email.arizona.edu University of Arizona, Tucson, Arizona, United States Feryal Ozel, fozel@email.arizona.edu

University of Arizona, Tucson, Arizona, United States Dimitrios Psaltis, dpsaltis@email.arizona.edu University of Arizona, Tucson, Arizona, United States

Observations of neutron stars provide one of the best ways of probing the ultra-dense matter equation of state (EOS). While many theoretical models of the cold EOS have been formulated, only a small number of EOS that include thermal effects have been calculated. However, such hot EOS are a necessary component for simulating and understanding observations from neutron star mergers, short gamma-ray bursts, or the formation of proto-neutron stars. In this talk, I will present a new parametric hot EOS that we have developed. This parametrization of thermal effects can be added to any cold EOS, even with no detailed knowledge of the particle potentials or interactions. I will compare our parametric hot EOS to existing models in order to highlight the wide range of physics that our parametrization can span, using a small number of physically-motivated parameters.

E1.10-0010-18 EVOLUTION OF NEUTRON STARS IN PROGENITORS OF BINARY MERGER GW SOURCES

Selma De Mink, s.e.demink@uva.nl

University of Amsterdam, Amsterdam, Netherlands

Evolution of binaries leading to mergers that are observable gravitational wave sources will be reviewed with particular attention to the formatıon and evolutıon of neutron stars in such binaries.

E1.10-0011-18 THE RADIUS OF THE QUIESCENT NEUTRON STAR IN THE GLOBULAR CLUSTER M13

Aarran Shaw, aarran@ualberta.ca University of Alberta, Edmonton, Canada Craig Heinke, heinke@ualberta.ca University of Alberta, Edmonton, Canada Andrew W. Steiner, awsteiner@utk.edu

University of Tennessee, Knoxville, Tennessee, United States Sergio Campana, sergio.campana@brera.inaf.it

INAF - Osservatorio Astronomico di Brera, Merate, Italy Haldan N. Cohn, cohn@indiana.edu

Indiana University, Bloomington, Indiana, United States Wynn C. G. Ho, wynnho@slac.stanford.edu

University of Southampton, Southampton, United Kingdom Phyllis M. Lugger, lugger@indiana.edu

Indiana University, Bloomington, Indiana, United States Mathieu Servillat, mathieu.servillat@obspm.fr Observatoire de Paris, Meudon, France

X-ray spectra of quiescent low-mass X-ray binaries (qLMXBs) containing neutron stars can be fit with atmosphere models to constrain the mass and the radius. Mass-radius constraints can then be used to place limits on the equation of state of dense matter. However, derived radius constraints depend heavily on the distance to the neutron star, a quantity which is often difficult to constrain without parallax measurements. We therefore turn to qLMXBs in globular clusters, whose distances are known to within 5 10%. We perform fits to the X-ray spectrum of a quiescent neutron star in the globular cluster M13, utilizing data from ROSAT, Chandra and XMM-Newton, and constrain the mass-radius relation. Assuming an atmosphere composed of hydrogen and a 1.4M0 neutron star, we find the radius to be 12.2+1.5

km, a significant improvement in precision over previous measurements. I will discuss how the composition of the atmosphere affects the derived radius, finding that a helium atmosphere implies a significantly larger radius. I will also discuss the results in the context of the recent binary neutron star merger, GW170817, which provided limits on the tidal deformability of neutron stars, in turn implying limits on the neutron star radius that are in agreement with our measurements for M13.

E1.10-0012-18 TESTING NUCLEAR PHYSICS FROM SPACE WITH QUIESCENT LOW-MASS X-RAY BINARIES

Sebastien Guillot, sebastien.guillot@irap.omp.eu

IRAP, University of Toulouse / CNRS, Toulouse, France Nicolas Baillot D'Etivaux, nbaillot@ipnl.in2p3.fr

Institut de Physique Nucleaire de Lyon, Lyon, France Jérôme Margueron, j.margueron@ipnl.in2p3.fr Institut de Physique Nucleaire de Lyon, Lyon, France

X-ray observations of quiescent low-mass X-ray binaries (qLMXBs) provide one of the methods to understand the internal structure of neutron stars and therefore place constraints on the nuclear physics of dense matter. The hot thermal emission from the surface of neutron stars in qLMXBs permits measurements of the neutron star radius. In the past few years, promising results were obtained from statistical analyses that combined the X-ray spectra of qLMXBs. These analyses have required simplistic or analytical parametrizations of the Equation of State of dense matter (the relation between pressure and density of matter). In this talk, I will summarize these previous results, and present new constraints obtained from the direct confrontation between a realistic parametrization of the equation of state and the astrophysical data from qLMXBs In an effort to be conservative with the observational constraints, I will also discuss the current limitations of the qLMXB method, and how they can be overcome with more observations of qLXMBs with current and future instrumentation.

E1.10-0013-18 FUNDAMENTAL PHYSICS WITH RADIO PULSARS

Paulo Freire, pfreire@mpifr-bonn.mpg.de

Max Planck Institute fur Radioastronomie, Bonn, Germany

In this talk, I will summarize some recent advances in the study of gravity, gravitational waves and nuclear physics that have emerged from the study of radio pulsars. These include extremely precise tests of general relativity from pulsar - neutron star binaries, constraints on the nature of gravitational radiation from timing of pulsar - white dwarf systems (binary and triple), and constraints on the strong nuclear force from mass measurements and limits on the moment of inertia of a few pulsars. I will offer some perspectives on future advancements on these topics, particularly in the context of upcoming work with ground-based gravitational wave detectors.

E1.10-0014-18 ENIGMATIC MODE-SWITCHING PULSARS POSE CHALLENGES TO PULSAR EMISSION THEORIES

Willem Hermsen, w.hermsen@sron.nl

SRON Netherlands Institute for Space Research, Utrecht, Netherlands

Simultaneous X-ray radio observations of three radio-mode switching pulsars revealed enigmatic results that pose challenging questions to pulsar emission theories. Synchronous X-ray and radio mode switching was discovered for the old and nearly aligned PSR B0943+10 (Hermsen et al. 2013). When this paragon of pulsar mode switching switches from a radio “bright” mode to a radio “quiet” mode, the X-ray flux in anti-correlation increases by a factor of 2.4 and the pulsed fraction changes in magnitude and as a function of energy (Mereghetti et al. 2016). But, in an X-ray radio campaign on the nearly orthogonal radio-mode switching PSR B1822-09 no evidence was found for mode switching in X-rays (Hermsen et al. 2017). Most surprisingly, for another nearly orthogonal pulsar, PSR 0823+26, we recently discovered correlated synchronous X-ray radio mode switching. The results might be broadly consistent with predictions of local phenomenon at the polar cap, but might also imply global magnetospheric rearrangements as proposed in radio studies of intermittent pulsars.

All three middle-aged/old pulsars exhibit thermal pulsed emission with very high pulsed fractions (up to about 80%) which cannot be modelled with isotropic thermal emission from hot spots on the magnetic poles. Magnetized partially ionized hydrogen atmosphere models can explain the observed general X-ray characteristics. However, we showed that the geometry (viewing angle and magnetic axis w.r.t. the rotation axis) derived from the X-ray data are not consistent with that derived from radio data. For an explanation, one might speculate that multi-pole fields near the star cause the radio and X-ray polar caps not to be in the same location.

E1.10-0015-18 THE POPULATION OF GALACTIC X-RAY BURSTERS AS SEEN BY INTEGRAL OVER 14 YEARS IN SPACE

Celia Sanchez-Fernandez, celia.sanchez@sciops.esa.int ESA/ESAC, Madrid, Spain

Type-I X-ray bursts are thermonuclear explosions on the surface of weakly magnetized accreting neutron stars (NS) in Low-Mass X-ray Binary (LMXB) systems where the mass donor is typically an evolved star. Observationally, X-ray bursts can show a large variety in profiles, but generally they exhibit a fast rise and a longer, usually power-law like, decay. Burst rise times vary from less than a second to 10 s, and decay times are in the range of seconds to minutes. Bursts radiate X-ray spectra with blackbody shapes, (kT 3 keV) that cool during the burst decay.

The Joint European Monitor for X-rays (JEM-X) onboard INTEGRAL is a coded-mask instrument operating in the 3-35 keV energy range, where the bulk of the X-ray burst energy is released. JEM-X provides a fully-coded field of view of 4.8 $\times$ 4.8 degrees, which allows concurrent monitoring of several X-ray bursters in one pointing.

In this talk I will provide an overview of the results of 14 years of INTEGRAL observations of the population of Galactic X-ray bursters.

E1.10-0016-18 TYPE-I X-RAY BURSTS: WHERE ARE WE (HEADED)?

Jean In 't Zand, jeanz@sron.nl SRON, Utrecht, Netherlands

It is almost time for celebration. It is almost 50 years ago that the first thermonuclear shell flash from a neutron star was detected as a type-I X-ray burst. While it took years between the detection of the first and second event, X-ray bursts are now detected once or twice a day on average, from a population of roughly 100 neutron stars in the Galaxy. Much has been learned and the learning curve has not flattened yet about the unstable thermonuclear fusion of hydrogen, helium, carbon etc. in the upper 100 m of neutron stars. Concept X-ray observatories such as eXTP (China and Europe) and Strobe-X (USA) can revolutionize the field by enabling detailed studies of, among others, flame spreading over the neutron star surface and constraining the equation of state of neutron star matter. We review the state and future of this field of research.

E1.10-0017-18 THE DEPENDENCE OF THE RATE OF TYPE I BURSTS ON ACCRETION AND SPIN RATE

Yuri Cavecchi, cavecchi@astro.princeton.edu

Princeton University, Princeton, New Jersey, United States Anna Watts, awatts@science.uva.nl

University of Amsterdam, Amsterdam, Netherlands Duncan Galloway, duncan.galloway@monash.edu Monash University, Clayton, Australia

The Type I Bursts are stupendous X-ray flashes from accreting neutron stars that are emitted when the accumulated matter undergoes a thermonuclear runaway which spreads over the whole surface of the star.

Nuclear burning and its dependence on the mass accretion rate are fundamental ingredients for describing the bursts complicated observational phenomenology. While theory predicts that the burst rate should constantly increase with increasing accretion rate until stabilization, many sources eventually experience decreasing burst rate versus increasing accretion rate.

I will show how, by considering different conditions across the stellar surface as a function of accretion rate and spin frequency, it is possible to resolve this apparent contradiction between theory and observations and I will discuss the implications of this scenario for our understanding of nuclear burning on neutron stars.

E1.10-0018-18 INSIGHT-HXMT AND SWIFT OBSERVATIONS OF RAPID BURSTER: TYPEI & TYPE-II X-RAY BURSTS BEHAVIOR

Yu-Peng Chen, chenyp@ihep.ac.cn

Institute of High Energy Physics, CAS, China, Beijing, China

Type II X-ray bursts remain largely a puzzle, only detected in two sources: Rapid Burster (MXB 1730-335,hereafter RB) and Burst Pulsar. We performed a visual inspection of all the HXMT and Swift/XRT light curves of RB. In total, from the RB, we identified 4 type I and 450 type II bursts by Swift/XRT, 321 type-II X-ray bursts by HXMT/LE. 1. Among them, 2 type-I X-ray bursts shows photospheric radius expansion (PRE), which is the only two PRE burst in this source since RB was discovered, and the second PRE burst is the first time reported. Here we report on the two PRE bursts, which allows us to constrain the mass and radius of the neutron star in RB. 2. All the type-II X-ray bursts spectra are combined, and the combined spectra are well fitted by absorbed two blackbody with BB temperatures of 0.3 and 1.7 keV,or absorbed nthcomp. The two BB, are thought to corresponding to the accretion disk and surface of neutron star, such explanations seem at odds with the observed phenomena that a type I burst taking place during a type II burst, because there is only one neutron star surface. We prefer the nthcomp model, i.e., the type-II bursts are only from the disk.

E1.10-0019-18 FORMATION AND STABILITY OF OSCILLATING SHOCKS IN INVISCID ADVECTIVE FLOWS AROUND NEUTRON STARS IN PRESENCE OF COOLING USING SMOOTHED PARTICLE HYDRODYNAMIC SIMULATIONS

Ayan Bhattacharjee, ayan12@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

We use the Smoothed Particle Hydrodynamics (SPH) method to simulate the behavior of inviscid flow accreting on a neutron star. For black holes, the lack of any hard surface allows matter to advect in supersonically. For neutron stars, however, the presence of a hard surface requires matter to settle down on the surface with zero radial velocity, essentially making the flow subsonic. Apart from this, near the compact object, the flow should be similar in both the cases. During the hard spectral state, the incoming flow has a negligible viscosity, leading to the absence of any disk blackbody emission. In such a state, the flow can be assumed to be purely inviscid for the computational purpose. We show that for a purely inviscid advective flow having angular momentum, the solution allows two shocks in the flow. The outer one, forms due to strong centrifugal barrier and is called CENtrifugal pressure dominated Boundary Layer or CENBOL, which is a common feature for both neutron stars and black holes. The inner shock forms very close to the surface of a neutron star, due to the presence of the physical boundary. We study 1) the formation of steady shocks in 2D, in absence of any cooling process, 2) the formation and variation of winds from the post-shock region when the angular momentum of the flow varied, 3) shock formation in strong winds, 4) the radial oscillation of shocks when cooling effects are added, 5) formation of asymmetries w.r.t. the Z=0 plane and instabilities due to the interaction of inflow and outgoing strong winds which leads to vertical oscillations,

6) the oscillation of NBOL and the variation of effective surface temperature when stronger cooling effects are present and accretion rate is varied. Our results capture both the low and high-frequency quasi-periodic oscillations observed in the power density spectra for the case of accretion around a neutron star.

E1.10-0020-18 IGR J17329-2731: THE BIRTH OF A SYMBIOTIC X-RAY BINARY

Enrico Bozzo, enrico.bozzo@unige.ch ISDC, Versoix, Switzerland

I will report on the results of the multi-wavelength campaign carried out after the discovery of the INTEGRAL transient IGR J17329-2731. The optical data collected with the SOAR telescope allowed us to identify the donor star in this system as a late M giant at a distance of 2.7(+3.4,-1.2) kpc. The data collected quasi-simultaneously with XMM-Newton and NuSTAR showed the presence of a modulation with a period of 6680±3 s in the X-ray lightcurves of the source. This unveils that the compact object hosted in this system is a slowly rotating neutron star. The broad-band X-ray spectrum showed the presence of a strong absorption (10^{23}cm^2) and prominent emission lines at 6.4keV, and 7.1keV. These features are usually found in wind–fed systems, with the emission lines resulting from the fluorescence of the X-rays from the accreting compact object on the surrounding stellar wind. The presence of a strong absorption line around ~ 21 keV in the NuSTAR spectrum suggests a cyclotron origin, thus allowing us to estimate the neutron star magnetic field as ~ 2.4×10^{12} G. All evidence thus points to IGR J17329-2731 being a symbiotic X-ray binary. As no X-ray emission was ever observed from the location of IGR J17329-2731 by INTEGRAL during the past 15 yr in orbit and considering that symbiotic X-ray binaries are known to be variable but persistent X-ray sources, we concluded that IGR J17329-2731 was most likely caught by INTEGRAL when the source shined as a symbiotic binary in X-rays for the very first time. The Swift XRT monitoring performed up to ~3 months after the discovery of the source, showed that it maintained a relatively stable X-ray flux and spectral properties. This supports the idea that IGR J17329-2731 might have become a persistent X-ray source in our Galaxy.

E1.10-0021-18 LOW ENERGY X-RAY LINE EMISSION FROM HER X-1: XMM-NEWTON/RGS OBSERVATIONS AROUND THE TURN-ON

Manuel Castro Avila, manuel.castro@inpe.br

National Institute for Space Research (INPE), São José Dos Campos, Brazil Matthias Kuehnel, matthias.kuehnel@sternwarte.uni-erlangen.de

Friedrich-Alexander University Erlangen-Nuermberg, Bamberg, Germany Joern Wilms, joern.wilms@sternwarte.uni-erlangen.de

Friedrich-Alexander University Erlangen-Nuermberg, Bamberg, Germany Joao Braga, joao.braga@inpe.br

INPE, Sao Jose Dos Campos, Brazil

Ruediger Staubert, staubert@astro.uni-tuebingen.de Germany

Her X-1 is a bright intermediate-mass X-ray binary system consisting of a pulsar with a 1.24- s rotational period and a 1.7-d orbital period. The neutron star accretes matter from its A/F donor through an accretion disk. The accretion disk is warped, tilted, and precessing causing a 35-d variation cycle that affects the emission from the central source. This 35-d cycle is characterised by states of high X-ray flux (main-on and short-on) and low-states with intensity of 3% of the main-on intensity. During the turn-on of the main-on the accretion disk completely opens up our view onto the neutron star. During this time we are able to observe emission directly from the central source, and scattering and absorption features caused by an atmosphere. We observed Her X-1 four times during this phase. We will present RGS data analysis, showing the detected lines at specific stages before, during, and after the turn-on. Measurements of the line evolution at each stage enables us to constrain the emission region and measure the structure and geometry of the disk atmosphere.

E1.10-0022-18 REVISITING SCO X-1 WITH KEPLER, MAXI AND HERMES

Simone Scaringi, simone.scaringi(at)canterbury.ac.nz University of Canterbury, NZ, Christchurch, New Zealand

Sco X-1 has been the subject of many multi-wavelength studies in the past, being the brightest persistent extra-solar X-ray source ever observed. Here I will revisit Sco X-1 and present simultaneous short cadence Kepler optical photometry, MAXI X-ray photometry and highresolution optical spectroscopy obtained with HERMES, over a continuous 78-day period. By characterising the highly variable nature of the dataset, I will show how the optical fluxes display a clear bimodality associated to two distinct optical states. These states display substantially different optical power spectral densities, and can be associated to the known flaring/normal branch X-ray states. Furthermore, by performing an optical/X-ray cross-correlation, I will show how a broad 12.5 hour optical lag is detected in the dataset, and discuss this in terms of a possible disk thermal reprocessing mechanism. This scenario is also supported by an echo detection in the optical lightcurve alone using the Cepstrum, which will also be introduced.

E1.10-0023-18 FALLBACK DISKS IN NEUTRON STAR EVOLUTION

Unal Ertan, unal@sabanciuniv.edu Sabanci University, Istanbul, Turkey

Evolution of neutron stars with fallback disks could produce rather different source properties due to the differences in the initial conditions of the systems (magnetic dipole moment, initial period, and disk mass). In addition, sources with similar initial conditions could exhibit dissimilar properties in different phases of the long-term evolution. We summarize the fallback disk model illustrating the effects of the initial conditions and the transitions between the accretion and the propeller phases on the long-term X-ray luminosity and the rotational properties of the neutron stars. We also present the results of the model applications to individual sources from different neutron star populations.

E1.10-0024-18 ON THE OPTICAL EXCESS OF DIM ISOLATED NEUTRON STARS

Sirin Caliskan, sirincaliskan@sabanciuniv.edu Sabanci University, Istanbul, Turkey

Unal Ertan, unal@sabanciuniv.edu Sabanci University, Istanbul, Turkey Mehmet Ali Alpar, alpar@sabanciuniv.edu Sabanci University, Istanbul, Turkey

The large optical excess in the spectrum is one of the defining characteristics of dim isolated neutron stars (XDINs). We have studied the optical excess of XDINs in the context of the fallback disk model. In this model, XDINs are neutron stars that evolve in the propeller phase, slowing down by the magnetic torques resulting from the disk-field interaction. In this work, we have shown through spectral fits that the optical excess of XDINs can be produced from the inner disk being heated by magnetic stresses. The blackbody temperature of the heated inner rim of the disk is higher than the temperatures sustained by X-ray irradiation and viscous dissipation alone. Since XDINs are in similar evolutionary phases, it is expected that they have similar torque mechanisms and ratios of the magnetic work that heats up the inner disk. Consistently with this idea, we have found that a similar and significant fraction of the work done by the magnetic torques can explain the optical excess of all XDINs. We have also found that heating by X-ray irradiation is negligible compared to the effects of magnetic heating. We propose that this is a common property of the systems with rotational power to LX ratios greater than about 10−2.

E1.10-0025-18 NEUTRON STARS AND THEIR ENVIRONMENTS IN THE INFRARED: THE INTRIGUING CASE OF RX J0806.4-4123

Bettina Posselt, posselt@psu.edu

Pennsylvania State University, University Park, Pennsylvania, United States George Pavlov, pavlov@astro.psu.edu

Pennsylvania State University, University Park, Pennsylvania, United States Unal Ertan, unal@sabanciuniv.edu

Sabanci University, Istanbul, Turkey

Sirin Caliskan, sirincaliskan@sabanciuniv.edu Sabanci University, Istanbul, Turkey

Most of our current constraints on neutron star structure and evolution are obtained from radio and high-energy observations. Few pulsars have been detected so far at optical or infrared wavelengths. Yet, these observational windows can provide valuable insights into the physical properties of neutron stars and their environments. At these wavelengths, in addition to studying magnetospheres and pulsar wind nebulae, one can also find and characterize (stellar and substellar) companions, or investigate circumpulsar disks. After an overview of the current observational constraints on neutron star properties from infrared observations, I will present our recent discovery and interpretation of extended near-infrared emission at the position of a nearby isolated neutron star. Finally, the talk will include an outlook on future infrared instrumentation capabilities and their relevance for neutron star exploration.

E1.10-0026-18 MAGNETARS' EVOLUTION

Nanda Rea, rea@ieec.uab.es

Consejo Superior de Investigaciones Cientificas (CSIC), Barcelona, Spain

I will review the latest results on magnetars' observations with particular attention to their outburst activity. I will show how their emission is in line with magneto-thermal evolution models, as well as connected with other classes of neutron stars.

E1.10-0027-18 RETURN CURRENT HEATING OF NEUTRON STAR ATMOSPHE

Michi Baubock, bauboeck@mpe.mpg.de

Max Planck Institute for Extraterrestrial Physics, Garching, Germany

Rotation-powered X-ray pulsars display pulsed emission originating from polar caps heated by incident particles from the magnetic return current. We model the atmospheric conditions in the polar caps under the influence of this energetic particle flux. We calculate the temperature profile of the atmosphere as well as the beaming function and spectrum of the emission. Highenergy particles penetrate to large optical depths, leading to a typical deep-heating radiative equilibrium atmosphere, while low-energy particles heat the upper regions of the atmosphere, leading to a temperature inversion. The resulting beaming patterns can significantly affect observed pulse profiles.

E1.10-0028-18 ATMOSPHERE OF MAGNETARS UNDER PARTICLE BOMBARDMENT

Denis Gonzalez-Caniulef, denis.caniulef.14@ucl.ac.uk University College London, Dorking, United Kingdom Silvia Zane, sz@mssl.ucl.ac.uk

University College London, Dorking, United Kingdom Roberto Turolla, turolla@pd.infn.it

University of Padova, Padova, Italy Kinwah Wu, kw@mssl.ucl.ac.uk

Mullard Space Science Laboratory, University College, Surrey, United Kingdom

Transient or persistent magnetars have strong surface magnetic fields B 1014 1015 G, and these fields could sustain large currents of charged particles in the star's magnetosphere. The charged particles attain very large Lorentz factors and they will flow back to the stellar surface moving along the magnetic field lines. The bombardment of these energetic particles lead to energy deposition, which in turns heats the stellar atmosphere. As such the radiation from the star would be substantially enhanced, surpassing the power expected for the radiation from a passively cooling neutron star. In this talk I will discuss radiation transport in an atmosphere heated by particle bombardment. Our calculations assume that the charged particles are stopped via magneto-coulomb interaction within the atmospheric layer. The particular case of a magnetized, grey (frequency integrated) atmosphere and the observational implications for magnetars will be addressed.

E1.10-0029-18 MULTIPOLAR ELECTROMAGNETIC FIELDS AROUND NEUTRON STARS: GENERAL-RELATIVISTIC VACUUM SOLUTIONS

Jérôme Pétri, jerome.petri@astro.unistra.fr

Observatoire Astronomique de Strasbourg, Strasbourg, France

Magnetic fields inside and around neutron stars are at the heart of pulsar magnetospheric activity. Strong magnetic fields are responsible for quantum effects, an essential ingredient to produce leptonic pairs and the subsequent broadband radiation. The variety of electromagnetic field topologies could lead to the observed diversity of neutron star classes. Thus it is important to include multipolar components to a presumably dominant dipolar magnetic field. Exact analytical solutions for these multipoles in Newtonian gravity have been computed in recent literature. However, flat spacetime is not adequate to describe physics in the immediate surrounding of neutron stars. We generalize the multipole expressions to the strong gravity regime by using a slowly rotating metric approximation such as the one expected around neutron stars. Approximate formulas for the electromagnetic field including frame dragging are computed from which we estimate the Poynting flux and the braking index. Corrections to leading order in compactness and spin parameter are presented. As far as spindown luminosity is concerned, it is shown that frame dragging remains irrelevant. For high order multipoles starting from the quadrupole, the electric part can radiate more efficiently than the magnetic part. Both analytical and numerical tools are employed.

E1.10-0030-18 NONEQUILIBRIUM DYNAMICS AND THE EVOLUTION OF SUPERFLUID NEUTRON STARS

Jame Sauls, sauls@northwestern.edu

Northwestern University, Evanston, Illinois, United States

The interior crust and the liquid core of neutron stars are predicted to be a mixture of neutron and proton superfluids and a liquid of relativistic electrons and muons. Quantized vortices in the neutron superfluid and quantized flux lines in the proton superconductor are topological defects of these hadronic condensates. I discuss the roles of nucleation, interaction and evolution of topological defects under non-equilibrium conditions in the context of our current understanding and models of the rotational dynamics of pulsars, as well as thermal and magnetic field evolution of neutron stars. I include some ideas on possible turbulent vortex states in neutron star interiors.

E1.10-0031-18 LARGE GLITCHES IN SUPERFLUID NEUTRON STARS

Marco Antonelli, marco.antonelli23@gmail.com

N. Copernicus Astronomical Center, Warsaw, Poland

Issues involving nuclear superfluidity are though to play key roles for neutron star phenomenology. In particular pulsar glitches (sudden jumps in the period of otherwise steadily spinning down pulsars) offer a glimpse into the superfluid interior of a neutron star: within the currently accepted scenario these timing irregularities are explained in terms of an expulsion of the quantized vortex lines that permeate the superfluid region. Vortex pinning to ions in the crust can provide the mechanism for storing the angular momentum which can be eventually released during a glitch. A consistent model for the angular momentum reservoir of pinned vorticity gives a general and quantitative inverse relation between size of the maximum glitch and the pulsar mass, allowing to put some limits on the mass of a pulsar.

E1.10-0032-18 INFLUENCE OF CRUSTAL MUTUAL FRICTION ON THE GLITCH RISE

Vanessa Graber, vanessa.graber@mcgill.ca McGill University, Montreal, Canada

Probing neutron star matter under extreme conditions relies on understanding the connection between macroscopic observables and microphysics. This plays an important role for pulsar glitches, where the post-glitch behaviour is typically modelled within a large-scale hydrodynamical framework. Physics on small scales enter the model in the form of vortex-averaged mutual friction, which directly controls the hydrodynamical coupling timescales. We address the frictional dynamics in the inner crust as a result of one specific mechanism, the excitation of kelvin vortex waves. We subsequently calculate the corresponding mutual friction strength for a set of realistic microscopic parameters and find it to be strongly density-dependent. Using a simple toymodel, we illustrate the implications of a strong and non-constant drag on the rotational evolution of the different neutron star components. We also highlight several uncertainties in our understanding of the microphysics and discuss how future observations of glitching pulsars could help to constrain these.

E1.10-0033-18 PROBING THE DYNAMICS OF NEUTRON STARS WITH PULSAR GLITCHES

Nicolas Chamel, nchamel@ulb.ac.be

Université Libre de Bruxelles, Brussels, Belgium

Pulsars are spinning very rapidly with extremely stable periods, thus providing the most accurate clocks in the Universe. Nevertheless, sudden spin ups have been detected in some of them such as the emblematic Vela pulsar. These abrupt changes in the pulsar's rotation period have long been thought to be the manifestation of a neutron superfluid permeating the inner crust of neutron stars. However, this superfluid has been recently found to be so strongly coupled to the crust due to non-dissipative entrainment effects that it does not carry enough angular momentum to explain the Vela timing data. After reviewing the physical origin of entrainment, the extent to which pulsar-timing observations can be reconciled with the standard glitch theory will be explored.

E1.10-0034-18 THE UNENDING PUZZLES OF NEUTRON STAR GLITCHES

Johnson Urama, johnson@hartrao.ac.za University of Nigeria, Nsukka, Nsukka, Nigeria Jibrin Alhassan, jibrin.alhassan@unn.edu.ng

University of Nigeria, Nsukka, Nigeria, Nsukka, Nigeria

More than 500 glitches have been observed from the conventional radio pulsars, binary pulsars, millisecond pulsars, Anomalous X-ray Pulsars (AXPs) and other manifestations of neutron stars. These glitches have continued to exhibit new features, thus making the understanding of the glitch processes and mechanisms quite intriguing and challenging. This paper discusses some of these features such as glitch size evolution, glitch signatures and recovery from glitches. The implications of these on the stability of neutron stars are discussed.

E1.10-0035-18 POINT VORTEX SIMULATIONS OF PULSAR GLITCHES

George Howitt, ghowitt@student.unimelb.edu.au University of Melbourne, Parkville, Australia

Pulsar glitches may be caused by a sudden collective unpinning of many superfluid vortices in a decelerating neutron star. This vortex avalanche model is similar to other systems in nature exhibiting “self-organised criticality” (SOC), such as sand piles and earthquakes. We have developed an N-body code that simulates the motion of many vortices in classical hydrodynamics. I present the results of the first simulations of a simple model decelerating neutron star and discuss how they compare to those expected by SOC. I also present a statistical analysis of the observed glitch size and waiting time distributions in the context of SOC.

E1.10-0036-18 MODELLING PULSAR GLITCHES

Brynmor Haskell, bhaskell@camk.edu.pl

Nicolaus Copernicus Astronomical Center, Warsaw, Poland

Pulsar glitches are thought to be a macroscopic, astrophysical, manifestation of the quantum nature of the neutron star interior. Nevertheless producing theoretical models that can link the small scale quantum behaviour of the fluid to the large scale astrophysical observables is computationally challenging and still an open problem. In this talk I will review recent advances in our theoretical understanding of the problem, from the microscopic scale of vortex-cluster interactions and pinning, to vortex motion and the large scale behaviour of the star. I will also discuss future directions and how upcoming observations can constrain our models.

E1.10-0037-18 LONG-TERM GLITCH EFFECTS

Cristobal Espinoza, cristobal.espinoza.r@usach.cl Universidad de Santiago de Chile, Santiago, Chile

Glitches are discrete positive steps in spin frequency (ν) that occasionally interrupt the smooth rotation of pulsars. Observations show a broad variety of glitch sizes, covering more than seven decades, and exhibiting a clear bimodal distribution. The largest events gather closely at around

$\Delta\nu/\nu$ 10−6, show different occurrence rates to the small glitches and more regular times between glitches. Furthermore, large glitches are followed by significant negative changes in slowdown rate ($\dot{\nu}$), with sizes $\Delta\dot{\nu}/\dot{\nu}$ 10−3. Enhanced spin-down rate regimes, known as glitch recoveries, are seen to last for months and slowly evolve towards pre-glitch values over years,

or even decades. We have recently characterized the long-term (>20 yr) evolution of a number of pulsars with 3 or more large glitches and found that all of them evolve with particularly low frequency second derivatives, leading to low long-term braking indices $n = \nu\ddot{\nu}/\dot{\nu}2$ 2. Such findings strongly suggest that large glitches and their transient recoveries are perturbations that can largely affect the observable spin evolution of pulsars over long periods of time. I will review the main consequences of this result and will present ongoing measurements that explore the properties of the large glitches and their recoveries.

E1.10-0038-18 MINIMUM GLITCH SIZE AND CRUSTQUAKE IN THE NEUTRON STARS

Onur Akbal, onurakbal@sabanciuniv.edu Sabanci University, Istanbul, Turkey Mehmet Ali Alpar, alpar@sabanciuniv.edu Sabanci University, Istanbul, Turkey

Glitches are likely triggered by crust breaking. The critical strain is the significant quantity determining the size of the broken plate. The minimum glitch size is related with the inertial moment of the region, in which the crustquake takes place, and the size of the broken plate. The broken crust plate size in turn determines the number of vortices involved in the unpinning avalanche that effects the size of the amplified glitch. This number, N 1013, is typical of all small and large glitches from Vela, Crab and PSR J1119-6127 analysed so far in terms of vortex unpinning, indicating a particular scale of the glitch trigger. The coincidence of the number of vortices is highly suggestive and is explained in terms of crust breaking with a typical plate size and critical strain angle which is found to be in agreement with theoretical and computational estimates ϑcr 0.1, corresponding to the unscreened Coulomb lattice in the neutron star crust.

The minimum glitch size and the regularity in the number of vortices involved in glitches are due to the large critical strain angle, ϑcr∼0.1, of the neutron star crust.

E1.10-0039-18 NEUTRON STAR ROTATIONAL EVOLUTION WITH TIME DEPENDENT EXTERNAL TORQUES

Erbil Gügercinoğlu, egugercinoglu@gmail.com Sabanci University, Istanbul, Turkey

The two-component model describes neutron star dynamics under the combined action of internal superfluid and external braking torques. Conventional applications involve only constant decelerating external torques, appropriate for steady braking of pulsars among life-time. However, in recent years there is growing evidence that magnetars, high magnetic field pulsars and some canonical radio pulsars display bursting activity and apparent variations in the spin-down rates on observational timescales. This fact indicates time dependent variability in the external torque of pulsars. We present the general solution of two-component neutron star dynamics under arbitrary time-dependent external torques, including the coupling with internal torques due to vortex creep against nuclei in the inner crust and flux tubes in the outer core. The two-component model can now be applied not only to canonical radio pulsars but also to magnetars and to neutron stars in binary systems showing variability and noise in the spin-down or spin-up rates. The methods extracting information about neutron star internal structure from such observations are also discussed.

E1.10-0040-18 NEUTRON STAR EVOLUTION

Evan Keane, evan.keane@gmail.com

SKA Organisation, Macclesfield, United Kingdom

The evolutionary paths of neutron stars post-supernova are not fully understood. Questions of cooling, magnetic field evolutions, spin down both steady and via glitches, evolving emission behaviour, environmental influences and more besides are each highly complex, and at the same time intertwined. Deciphering the full evolutionary picture is thus a messy job. Thankfully the discovery rate of neutron stars in comparison to that of said problems is respectable, and looks set to continue to increase so that such problems will hopefully be tractable and testable with observational data. Here I will present a few 'corner cases', neutron stars that one might think would be the same that exhibit radically different behaviours. I will argue that some studying such cases, with tests I will describe, can give insight into the overall evolutionary picture.

E1.10-0041-18 EVOLUTION OF HIGH-B RADIO PULSARS IN THE FALLBACK DISK MODEL

Onur Benli, onurbenli@sabanciuniv.edu Sabanci University, Istanbul, Turkey Unal Ertan, unal@sabanciuniv.edu Sabanci University, Istanbul, Turkey

We have investigated the X-ray luminosity and the rotational evolutions of the so-called “highmagnetic-field neutron stars” (HBRPs) in the frame of the fallback disk model that was also applied earlier to anomalous X-ray pulsars/soft gamma repeaters (AXPs/SGRs), and dim isolated neutron stars (XDINs). The estimated supernova ages and the measured braking indices of the three HBRPs, namely PSR J1734–3333, PSR J1119–6127 and PSR B1509-58, provide significant constraints on the models. We have shown that the individual source properties (period, period derivative, braking index and X-ray luminosity) can be reproduced simultaneously in the fallback disk model, consistently with the estimated supernova ages. Our results indicate that HBRPs are currently spinning down in the propeller phase without any accretion onto the star, while the X-ray luminosities are produced by the intrinsic cooling of the neutron star. This is in agreement with the observed pulsed radio emission of the sources. The strength of the dipole fields of HBRPs indicated by our simulations are one or two orders of magnitude smaller than the fields inferred from the dipole-torque formula. Furthermore, our results imply evolutionary connections of HBRPs with AXPs/SGRs and normal radio pulsars. We also discuss the initial conditions responsible for the evolutions producing these different neutron star populations.

E1.10-0042-18 INFERRING NEUTRON STAR'S MASS WITH PULSAR GLITCHES

Alessandro Montoli, alessandro.montoli@unimi.it University of Milano, Milano, Italy

In the interior of a neutron star, the differential rotation of the neutron superfluid component with respect to the normal component is believed to provide the angular momentum necessary to cause a pulsar glitch. We provide a relativistic generalization in the slow-rotation approximation of a previous Newtonian model that has been recently used to obtain maximum glitch amplitudes and to estimate upper bounds on the masses of glitching pulsars. We show that the Newtonian upper bounds on the masses of large glitchers obtained from observations of their largest recorded event differ by less than a few percent from those calculated within the relativistic framework. Finally, we present some preliminary results of a new analytical model for the raise of the angular velocity during a glitch event.

E1.10-0043-18 LOW-MASS X-RAY BINARIES IN THE LOW-LUMINOSITY REGIME

Eda Sonbas, edasonbas@yahoo.com Adiyaman University, Adiyaman, Turkey Kalvir S. Dhuga, dhuga@gwu.edu

George Washington University, United States Ersin Gogus, ersing@sabanciuniv.edu Sabanci University, Istanbul, Turkey

The spectra of a select group of neutron star (NS) low-mass X-ray binaries exhibit a significant softening compared to black hole (BH) binaries in the low-luminosity phase. This 'divergence' effect between the two groups appears in their spectral index Γ-Lx correlation at or near a threshold luminosity of a few x 1034 erg/s, a luminosity that represents a small fraction of Eddington, and one that is typically associated with the Low-Hard/quiescent states. We report on the spectral analysis of 27 X-ray binaries for which data are available in the Chandra and XMM-Newton archives. We present our results in the context of a correlation between the spectral index and the 0.5-10 keV X-ray luminosity and its possible interpretation in terms of Comptonization of seed photons via the hot corona in the vicinity of the central compact object.

E1.10-0044-18 X-RAY REPROCESSING: THROUGH THE ECLIPSE SPECTRA OF HIGH AND LOW MASS X-RAY BINARIES WITH XMM-NEWTON

Nafisa Aftab, nafisa@rri.res.in

Raman Research Institute, Bengaluru, India

Study of X-ray reprocessing is one of the key diagnostic tool to probe the environment in Xray binary systems. Difficult aspect to study X-ray reprocessing is the presence of primary radiation from the compact star along with the reprocessed radiation. Eclipsing X-ray binaries make an ideal condition to study reprocessed X-rays, as the X-rays detected during eclipse are purely reprocessed while the primary X-rays are blocked by the companion star. We carried out first comprehensive studies of X-ray reprocessing with a number of eclipsing High Mass X-ray Binary and Low Mass X-ray Binary (HMXB and LMXB) systems during and outside eclipse with XMM-NEWTON EPIC pn. Comparing eclipse and out-of-eclipse spectra of these sources we have found ample diversity in the X-ray reprocessing characteristics in HMXBs, even in the same source at different epochs the variation is quite large. In spite of having much weaker wind environment, the flux ratio of out-of-eclipse to eclipse in LMXBs is in a range comparable to the HMXBs. The analysis shows very strong Iron k emission line during eclipse phases in most of the HMXBs and week or no Iron emission lines in LMXBs. Equivalent width of Iron emission lines in Supergiant Fast X-ray Transients (SFXTs) are large during eclipse, similar to that in Supergiant HMXBs (SgHMXBs). There are some significant system to system differences. For example low equivalent width of Iron k emission line in HMXB Cen X-3 during eclipse, very week Iron emission line in HMXB SMC X-1, comparable out-of-eclipse to eclipse flux ratio in LMXB AXJ 1745.6-2901 irrespective of intensity state etc. Overall we try to infer the wind and accretion disk characteristics, which are the reprocessing agents in the HMXB and LMXB systems respectively.

E1.10-0045-18 THE FAINT 2016 OUTBURST OF MAXI J0556-332

David Russell, dave.russell@nyu.edu

Fraser Lewis, lewisf@cardiff.ac.uk

Liverpool John Moores University, Liverpool, United Kingdom

MAXI J0556–332 is a neutron star X-ray binary discovered by its first detected outburst in January 2011. Since its initial outburst it has remained in quiescence until a new outburst in January 2016. The source has a number of rare properties. It is one of the few transient Z-sources, has a strongly heated neutron star during quiescence, has partial X-ray eclipses suggesting a high inclination system, and has been suggested to lie at a large distance of sim45 kpc (this should soon be refined by Gaia).

Here we present optical monitoring observations of the 2016 outburst of MAXI J0556–332 with the 2-m Faulkes and 1-m Las Cumbres Observatory telescopes. We also analyse X-ray, UV and optical Swift data of the outburst. We find that the 2016 outburst was less luminous than the 2011 discovery outburst, at both X-ray and optical wavelengths. We detected the initial outburst rise with the Faulkes Telescopes eight days before the first X-ray detection by MAXI, and constrain the date of the onset of the outburst to be between 19 December and 29 December 2015. After the initial rise, several prominent dips and flares are evident in all optical filters, and there is a fairly tight correlation of Fopt F 0.5 between the optical and X-ray fluxes. The correlation slope and the optical spectral energy distributions are both consistent with a thermal origin to the optical emission from the accretion disc, with no evidence for a red excess from synchrotron emission in the optical data. The optical emission is likely due to reprocessed X-rays reflected on the accretion disc surface, with a characteristic temperature of 8,000 - 11,000 K during outburst. From the optical / X-ray ratio alone we favour a distance to the source greater than 3 kpc, whereas a 45 kpc distance would imply MAXI J0556–332 is one of the most luminous neutron star X-ray binaries at optical and X-ray wavelengths.

E1.10-0046-18 NEUTRON STAR COOLING

Craig Heinke, heinke@ualberta.ca University of Alberta, Edmonton, Canada

The cooling behavior of neutron stars (NSs) is a key observational test of the physics of their interiors, which can be probed through X-ray observations. While NSs are hot enough to be studied in the X-ray, their long-term cooling is dominated by neutrino emission from the core. This enables us to constrain the neutrino emission processes in NS cores by studying their thermal X-rays.

Young NSs, cooling after their birth in supernovae, provide the most straightforward tests of cooling theories. The diversity in their cooling tracks requires some variation in e.g. envelope composition. The youngest Galactic NS, in Cassiopeia A, may show evidence for rapid cooling, which if correct may indicate that neutrons in its core are transitioning to a superfluid state. However, monitoring its cooling taxes the limits of our observational capabilities, and it is not certain that the apparent flux decline actually indicates cooling.

Old NSs in X-ray binaries can also be used to probe cooling, by comparing their thermal surface emission (heat going out from the surface) with their long-term time-averaged accretion history (heat deposited inside), to determine the rate at which neutrinos must be removing heat from the core. Note that NSs also experience short-term cooling after episodes of intense accretion, which reveals information on the properties of the crust (see Cumming's talk). Intriguingly, a wide range of neutrino emission rates appear to be present within NSs in X-ray binaries. This wide range can be most easily explained if NSs have a wide range of masses, and if the most massive, and thus densest, NSs can access faster neutrino cooling mechanisms (such as the direct Urca process) in their cores.

E1.10-0047-18 A NEW PERSPECTIVE ON NEUTRON STAR COOLING

Andrew Cumming, cumming@physics.mcgill.ca McGill University, Montreal, Canada

Cooling of neutron stars has long been recognized as a way to investigate the physics of dense matter in neutron star interiors. Because cooling depends on the heat capacity and neutrino emissivity of the matter, it is sensitive to both the particle content, for example the proton fraction, and state of matter, for example whether the particles are paired to form a superfluid. The traditional way to study neutron star cooling is to compare theoretical models with the observed population, either the population of young isolated neutron stars with detected X-ray emission, or with neutron stars accreting from a companion in binary systems. However, there are significant uncertainties in this comparison and degeneracies in the inferred neutron star properties.

In this talk, I will focus on the new opportunity to probe neutron star interiors that comes from the ability to follow cooling of individual neutron stars on timescales of months to decades using long term monitoring with X-ray observatories. This has primarily been done for accreting neutron stars which are heated by nuclear reactions in their crust during accretion outbursts, and then cool afterwards. Models of the cooling allow us to determine how much energy was deposited and then observe the response of the core to the energy input (they also provide a way to determine the envelope composition, a significant uncertainty in population studies). I will describe how this has provided the first independent constraints on heat capacity and the neutrino emissivity of neutron star cores, and the implications for the physics of the interior: how it provides a way to break the degeneracies in the models and begin to untangle the different contributions such as the dependence of pairing gap with depth. These studies are very much continuing, so I will emphasize the future constraints that we expect to obtain, and discuss how they relate to other information about neutron stars coming up (e.g. radius or moment of inertia measurements).

E1.10-0048-18 HEATING AND COOLING OF THE CRUST OF ACCRETING NEUTRON STARS

Nathalie Degenaar, degenaar@uva.nl

University of Amsterdam, Amsterdam, Netherlands

The composition and structure of the 1 km thick, solid crust of neutron stars is responsible for many of their observable properties, and plays a fundamental role in the emission of gravitational waves and the evolution of their magnetic field. When residing in an X-ray binary, a neutron star accretes gas from a companion star. As matter accumulates on the neutron star surface, the underlying crust is compressed and heated due to nuclear reactions induced by this compression. These heating processes may have an important role in the observable properties of thermonuclear bursts and rapid variability (mHz QPOs) observed from accreting neutron stars.

Once accretion switches off, sensitive X-ray satellites can be employed to observe the thermal glow of the accretion-heated crust and how it cools in absence of accretion. Comparing these observations with theoretical simulations provides very valuable insight into the structure and composition of neutron star crusts, as well as the heating processes that occur during accretion episodes. One of the current puzzles is that the observations seem to point to much more heat generation than is currently accounted for in theoretical models. I will provide an overview of the various lines of evidence pointing to such "shallow heating" and describe what recent observational efforts seem to teach us about its properties and origin.

E1.10-0049-18 AN UPDATE ON THE X-RAY SPECTRAL EVOLUTION OF THE CENTRAL COMPACT OBJECT IN CAS A

Bettina Posselt, posselt@psu.edu

Pennsylvania State University, University Park, Pennsylvania, United States George Pavlov, pavlov@astro.psu.edu

Pennsylvania State University, University Park, Pennsylvania, United States

The Central Compact Object (CCO) in the Cassiopeia A supernova remnant (SNR) is a very young (300 years) neutron star. The temperature evolution of such a young neutron star is of great interest because of its implications for models of neutron star cooling. Heinke Ho 2010 reported a substantial drop of the CCO's X-ray flux within nine years based on Chandra ACIS observations of the SNR. Assuming that the observed thermal X-ray emission emerges from a carbon atmosphere of the neutron star, the drop was interpreted as a fast decrease of the effective surface temperature. The X-ray data of the CCO, however, were strongly affected by instrumental effects since the Chandra observations were optimized for the investigation of the SNR. Using a more suitable observational setup, Posselt et al. 2013 did not find any statistically significant temperature decrease over a time span of 5.5 years. Here, we present an update on the evolution of the CCO's spectral properties based on additional new Chandra data and improvements of the ACIS calibration.

E1.10-0050-18 PHASE-RESOLVED SPECTROSCOPY OF THE LOWER KHZ QPO IN 4U1608- 52

Abigail Stevens, abigailstev@gmail.com

Michigan State University, East Lansing, Michigan, United States Phil Uttley, p.uttley@uva.nl

University of Amsterdam, Amsterdam, Netherlands Diego Altamirano, d.altamirano@soton.ac.uk

University of Southampton, Southampton, United Kingdom

Kilohertz quasi-periodic oscillations (kHz QPOs) are the most rapid (quasi-)coherent kind of variability that have been detected in the light curves of accreting neutron star X-ray binaries. Previous spectral-timing work using the rms spectrum revealed that the QPO emission is a Comptonized blackbody, consistent with that expected from the boundary layer between the accretion flow and neutron star surface. Furthermore, the lag-energy spectra and covariance spectra indicate that the lower kHz QPO arises from a more complex energy-dependent variability than just an overall modulation in the flux normalization. To better interpret the spectral variability, we present phase-resolved spectroscopy of a kHz QPO for the first time, using a method based on the energy-dependent cross-correlation function (CCF). The bestfitting spectral parameterisation requires the power-law index, high-energy cut-off temperature and seed blackbody temperature of the Comptonized emission to vary with QPO phase. Additionally, the variations in these three parameters show small but non-zero phase differences, which together can explain the previously observed lag-energy dependence. We suggest that these spectral variations could be explained by a "breathing" oscillation in the Comptonizing boundary layer; this possibility can be explored in greater detail with current and future X-ray missions such as AstroSat, NICER, eXTP, and STROBE-X.

E1.10-0051-18 THE HIGHEST FREQUENCY KHZ QPOS IN NS-LMXBS

Marieke Van Doesburgh, mvdoesburgh@gmail.com University of Amsterdam, Amsterdam, Netherlands Michiel Van Der Klis, michiel@science.uva.nl University of Amsterdam, Amsterdam, Netherlands

We investigate the detections with RXTE of the highest-frequency kHz QPOs in neutron star low mass X-ray binaries. In particular, we compare recent findings on 4U 0614+09 and 4U 1728–34 to the properties of high frequency kHz QPOs detected in other sources. We find that the highest-frequency kHz QPO detected in 4U 0614+09 exceeds 1267 Hz with 3σ (99.73%) confidence, which is the highest 3σ lower limit on a kHz QPO frequency reported to date. This number is of direct physical interest as it can be used to constrain the supra-nuclear density equation of state (EoS). We compare our measured frequencies to maximum orbital frequencies predicted by models of rotating neutron stars with different realistic EoS.

E1.10-0052-18 AN ENIGMATIC HUMP AROUND 30 KEV IN SUZAKU SPECTRA OF AQUILA X-1

Megu Kubota, megu.kubota@riken.jp RIKEN, Wako, Japan

Motoko Serino, motoko@crab.riken.jp RIKEN, Wako, Japan

Mutsumi Sugizaki, sugizaki@riken.jp RIKEN, Wako, Japan

In Neutron Star Low Mass X-ray Binaries (NS-LMXBs), the matters accreting on the NS are compressed, heated, and eventually undergo thermonuclear flashes called Type-I bursts. Because the accreting materials mainly consist of hydrogen, the NS atmosphere is expected to be in a proton-rich environment. When type-I bursts ignite under such a condition, the rapidproton capture process (rp-process) should occur. The NS atmosphere is hence a promising site of the rp-process.

The typical NS-LMXB, Aquila X-1, was observed with Suzaku seven times in the decay phase of an outburst in 2007 September-October. Among them, the second to the fourth observations were performed 10 to 22 days after the outburst peak, when the source was in the Low/Hard State with a luminosity of 1036 erg/sec. In general, the Low/Hard state spectrum of an NS-LMXB is represented by a hard X-ray continuum up to 100 keV arising when blackbody photons from the NS surface is Comptonized, plus an optically thick disk emission appearing below a few keV (Sakurai et al. 2014). This model was able to approximately reproduce the Aqlila X-1 spectra obtained in the 2nd to the 4th observations. However, these three spectra all exhibited an enigmatic hump-like excess around 30 keV above the Comptonized continuum.

A similar feature is found in an RXTE spectrum of this object observed in the Low/Hard state (Lin et al. 2007). We quantify this feature, and attempt to interpret it in the context of rp-process products.

The excess feature was successfully represented by a Gaussian centered at 29–34 keV, with a width (sigma) of 3-11 keV and an equivalent width of about 8 keV. Alternatively, the feature can also be explained by a recombination edge (redge) model, that produces a quasi-continuum above an edge energy of 26 ± 1 keV with a plasma temperature of 6–32 keV.

Considering that the feature is K-shell structures of highly-ionized heavy elements produced via the rp-process, and taking into account the gravitational redshift on the NS surface, the Gaussian centroid energy indicates the atomic number of Z = 59 - 63, or Pr to Eu. Whereas the redge model results indicate Z = 47 and 48, namely, Ag and Cd. We discuss these results in the context of rp-process in X-ray bursts, and examine whether this scenario if feasible or not.

E1.10-0053-18 WHAT WILL THE SKA DO FOR NEUTRON STARS?

Evan Keane, evan.keane@gmail.com

SKA Organisation, Macclesfield, United Kingdom

In this poster I will give an overview of the Square Kilometre Array (SKA), its science case, and the status of its design and construction. Very briefly, the SKA will be the largest radio observatory on the planet, consisting of two telescopes each at different sites (one in Australia, one in South Africa). At present we are in the middle of a series of critical design reviews for SKA Phase 1, marking the final part of the pre-construction phase which has been running since 2013. I will describe what the SKA will do for neutron star science. The impact should be substantial with pulsar searches and timing amongst the top priority science goals which have driven the design.

E1.10-0054-18 LONG-TERM QUASI-PERIODICITY OF 4U 1636-536 RESULTING FROM ACCRETION DISC INSTABILITY

Mateusz Wisniewicz, m.wisniewicz@gmail.com

J. Gil Institute of Astronomy, University of Zielona Gora, Zielona Gora, Poland Dorota Rosinska, dorota@astro.ia.uz.zgora.pl

University of Zielona Gora, Zielona Gora, Poland Andrzej Zdziarski, aaz@camk.edu.pl

Center for Theoretical Physics of the Polish Academy of Sciences, Warsaw, Poland Agnieszka Slowikowska, aga@astro.ia.uz.zgora.pl

Institute of Astronomy, University of Zielona Gora, Zielona Góra, Poland

We present the results of a study of the neutron star low-mass X-ray binary 4U 1636-536. We have performed temporal analysis of all available RXTE/ASM, RXTE/PCA, Swift/BAT and MAXI data collected until 2017. We have confirmed the previously discovered quasi-periodicity of 45 d present during 2004, and we have found it continued to 2006. At other epochs, the quasi-periodicity is only transient, and the quasi-period, if present, drifts from 32 to 72 days. We have applied a time-dependent accretion disc model to the interval with the significant X-ray quasi-periodicity. Although 4U 1636-536 is persistent, the observed quasi-periodicity can be well modelled by the hydrogen thermal-ionization instability occurring in outer regions of the accretion disc. For our best model, the period and the amplitude of the theoretical light curve agree well with those observed.

E1.10-0055-18 MORPHOLOGY AND EVOLUTION OF THE 20 DAY SUPERORBITAL MODULATION IN THE HIGH-MASS X-RAY BINARY IGR J16493-4348

Joel Coley, joel.b.coley@nasa.gov

CRESST-UMBC / NASA-GSFC, Greenbelt, Maryland, United States Hans Krimm, hkrimm@nsf.gov

National Science Foundation, Alexandria, Virginia, United States

We report on Nuclear Spectroscopic Telescope Array (NuSTAR), Swift X-ray Telescope (XRT) and Swift Burst Alert Telescope (BAT) observations of IGR J16493-4348, a wind-fed Supergiant X-ray Binary (SGXB) showing significant superorbital variability. From a discrete Fourier transform of the BAT light curve, we refine its superorbital period to be 20.058 0.07 days. The BAT dynamic power spectrum and a fractional root mean square analysis both show strong variations in the amplitude of the superorbital modulation, but no observed changes in the period were found. The superorbital modulation is significantly weaker between MJD 55,700 and MJD 56,300. The joint NuSTAR and XRT observations, which coincide near the minimum and maximum of the superorbital modulation, reveal no significant changes in the 1093 s neutron star rotation period on superorbital timescales. We do not observe any significant changes in the pulse profiles in the 3–50 keV band and the 3–40 keV spectral continuum between superorbital minimum and maximum, suggesting a similar accretion regime. At superorbital maximum, we find a possible Fe K emission feature at 6.4 keV. The 6.4 keV emission feature is not significant at superorbital minimum. The spectral continuum shows no significant changes as a function of neutron star rotation period. We discuss different mechanisms that might drive the observed superorbital modulation.

E1.10-0056-18 TRANSPORT COEFFICIENTS OF LEPTONS IN SUPERCONDUCTING NEUTRON STAR CORES REVISITED

Petr Shternin, pshternin@gmail.com Ioffe Institute, St. Petersburg, Russia

I consider thermal conductivity and shear viscosity of electrons and muons in the nucleon NS cores where protons are in the superconducting state. The charged lepton collision frequencies are mainly determined by the transverse plasmon exchange and are mediated by the character of the plasma screening. When protons are in the paired state, they give the dominant contribution to the transverse screening. In previous works [Shternin, Yakovlev, Phys. Rev. D. 75, 103004 (2007); Phys. Rev. D. 78, 063006 (2008)] this contribution was considered in the Pippard limit Δ nqvF p, where Δ is the proton pairing gap, vF p is the proton Fermi velocity, and nq is the typical transferred momentum in collisions. However, for large critical temperatures Tcp (large Δ) and relatively small densities in the outer NS cores (small q), the Pippard limit may become invalid. Restricting the consideration for not too high temperatures (T ;S 0.3Tcp), when the lepton-proton collisions can be neglected, and employing the BCS expression for transverse screening, I revisit the transport coefficients calculations. It is found that older calculations indeed severely underestimated the screening in a certain range of parameters appropriate to NS core conditions. As a consequence, values of the transport coefficients at T Tcp are smaller than previously thought.

E1.10-0057-18 THE HIGH STATISTIC STUDY OF X-RAY EMISSION OF THE CRAB PULSAR

Mingyu Ge, gemy@mail.ihep.ac.cn 19B Yuquan Road, Shijingshan District, Beijing, China, Beijing, China Fangjun Lu, lufj@ihep.ac.cn

Institute of High Energy Physics, CAS, China, Beijing, China Shijie Zheng, zhengsj@ihep.ac.cn

Institute of High Energy Physics (IHEP), Beijing, China Shuang-Nan Zhang, zhangsn@ihep.ac.cn

Institute of High Energy Physics, Chinese Academy of Sciences, Beijing, China Hao Tong, tonghao@xao.ac.cn

Xinjiang Astronomical Observatory, Chinese Academy of Sciences, Urumqi, China

Using the Rossi X-Ray Timing Explorer (RXTE)observations of the Crab pulsar, we have systematically studied the pulsed X-ray emission from this pulsar, including the phase-resolved spectra, profile evolution, flux evolution and the phase lag between the X-ray and radio pulses. The phase resolved X-ray spectroscopy shows that the spectrum softens from the beginning of the first pulse, turns to harden right at the pulse peak and becomes the hardest at the bottom of the bridge, softens gradually until the second peak, and then softens rapidly. The X-ray profiles, as characterized by a few parameters, changed slightly, but with high statistical significance in the more than 10 years of observations: the separation of the two peaks increased with a rate of 0.88±0.20 degree per century, the flux ratio of the second pulse to the first pulse decreased by (3.64 0.86)×10−2per century, and the pulse widths of the two pulses represented by their full widths at half maxima decreased by 1.44 0.15 and 1.09 0.73 per century, respectively. The pulsed X-ray flux in 5-60 keV obtained by RXTE/PCA decreases with a rate of

(-2.4 0.4)×10−14 erg cm−2 s−1 per day, and it is significantly correlated with the spin-down power Lsd by LX Lsd1.6±0.3. Detail comparisons of the X-ray pulse phases and the radio ones show that their is no significant long time evolution, with a rate is (-0.3 1.8)×10−7period per day, which show that the distance of the X-ray and radio emission regions on the Crab pulsar does not change above the measured limit, and the timing-noises are unlikely resulted from any unique physical processes in the radio or X-ray emitting regions.

E1.10-0060-18 X-RAY STUDY OF VARIABLE GAMMA-RAY PULSAR PSR J2021+4026

Huihui Wang, wanghh@hust.edu.cn

Huazhong University of Science and Technology, Wuhan, China

Variable gamma ray pulsar PSR J2021+4026 showed a glitch around 2011, October 16. After the glitch, the pulsar stayed a low gamma ray flux state for 3 years, and then returned to the state before the glitch. To investigate any change in the X-ray emissions in low-gamma-ray flux state and after the relaxation, we analyze XMM-Newton data. We find no significant change in the X-ray emission in the two stages. We fit the X-ray light curve with the heated polar cap model, and discuss half hemisphere of the magnetosphere is less active.

E1.10-0061-18 EVOLUTION OF LOW-MASS X-RAY BINARIES: THE INFLUENCE OF DONOR EVAPORATION

Xiangdong Li, lixd@nju.edu.cn

Department of Astronomy, Nanjing University, Nanjing, China

Millisecond pulsars (MSPs) are thought to originate from low-mass X-ray binaries (LMXBs). The discovery of eclipsing radio MSPs, including redbacks and black widows, indicates that evaporation of the donor star by the MSP's irradiation takes place during the LMXB evolution. In this work, we investigate the effect of donor evaporation on the secular evolution of LMXBs, considering different evaporation efficiencies and related angular momentum loss. We find that for widening LMXBs, the donor star leaves a less massive white dwarf than without evaporation; for contracting systems, evaporation can speed up the evolution, resulting in dynamically unstable mass transfer and possibly the formation of isolated MSPs.

E1.10-0062-18 A MULTI-WAVELENGTH VIEW OF THE INTRIGUING PULSAR WIND NEBULA AROUND PSR J0855-4644

North-West University, Potchefstroom, South Africa Yashwant Gupta, ygupta@ncra.tifr.res.in

National Centre for Radio Astrophysics (TIFR), Pune, Pune, India

We present results from X-ray and radio observations of the region surrounding PSR J0855- 4644. PSR J0855-4644 is a nearby, fast spinning, and energetic radio pulsar in the south-eastern rim of the supernova remnant RX J0852.0-4622. X-ray observations with XMM Newton have shown an arcmin scale extended emission, the pulsar wind nebula (PWN), around the X-ray counterpart of the pulsar. Recent Chandra observations have revealed a further compact PWN (arcsecond scale) associated with the pulsar showing a possible double 'torus+jet 'morphology. This makes it only the third source of its kind, and being a nearby object provides us the golden opportunity to investigate the physics of equatorial and polar outflows in PWNe. We use the double torus PWN morphology and the radio light curve to constrain the geometry of the pulsar. Further using radio observations with GMRT at 1.4 GHz we have discovered the radio counterpart of the PWN. We model the radio PWN to study the energetics and the magnetic field strength of the PWN surrounding PSR J0855-4644.

E1.10-0063-18 THE INSIGHT-HXMT OBSERVATION OF THE NEWLY DISCOVERED TRANSIENT X-RAY PULSAR SWIFT J0243.6+6124

Youli Tuo, tuoyl@ihep.ac.cn

Institute of High Energy Physics, Chinese Academy of Sciences, Beijing, China Yue Zhang, zhangyue@ihep.ac.cn

Institute of High Energy Physics, Chinese Academy of Sciences, Beijing, China

Since the discovery of the Be/X-ray binary Swift J0243.6+6124 in an outburst showing up around 2017 October 3, Insight-HXMT has continuously monitored on this source in a broad energy band covering roughly 1-250 keV. With these observations the orbital ephemeris of the system are derived and refined later on, according to the variability of the spin frequency, which denotes a canonical Doppler effect endorsed by the orbital motion in a NS binary system. We therefore estimate the orbital ephemeris of Swift 0243.6+6124, thanks to the long term observations from Insight-HXMT. The orbital parameters are then obtained by us with a period around 27.35 days, a semi-major axis around 199 light-seconds, an eccentricity around 0.0842. We find from Insight-HXMT data that, both the pulse profile and phase-resolved spectrum evolve strongly with luminosity, which points to the complexity of the outburst exhibited by Swift J0243.6+6124.

E1.10-0064-18 ORBITAL PERIOD AND BREAKING LUMINOSITY RELATION IN LMXBS

Eda Vurgun, edavrgn@gmail.com

Istanbul University, Institute of Science, 34000, Turkey Armin Vahdat Motlagh, arminvahdat@sabanciuniv.edu Istanbul Technical University, Istanbul, Turkey

Istanbul University, Faculty of Science, Istanbul, Turkey Kazim Eksi, eksi@itu.edu.tr

Istanbul Technical University, Istanbul, Turkey

It has been long debated that whether the sharp luminosity drop in X-ray binaries is due to the transition from accretion to the propeller stage or is the result of the ionization of the disc due to irradiation from the central source. The latter model predicts a positive correlation between the critical luminosity at which transition to rapid decay stage occurs and the size of the disc which depends on the binary separation and hence the orbital period of the binary system. We have searched for such a relation among the 5 black hole and 9 neutron star hosting low mass X-ray binary systems. We find no correlation between the critical transition luminosity and the orbital period.

E1.10-0065-18 CLEAR ANTI-CORRELATION BETWEEN X-RAY LUMINOSITY AND PULSED FRACTION IN THE SMALL MAGELLANIC CLOUD PULSAR SXP 1323

Harvard-Smithsonian Center for Astrophysics, Cambridge, Massachusetts, United States Jaesub Hong, jhong@cfa.harvard.edu

Harvard-Smithsonian Center for Astrophysics, Cambridge, Massachusetts, United States

We report the anti-correlation between pulsed fraction (PF) and luminosity of the X-ray pulsar SXP 1323, found for the first time in a luminosity range 1035–1037 erg s–1 from observations spanning 15 years. The phenomenon of a decrease in X-ray PF when the source flux increases has been observed in our pipeline analysis of other X-ray pulsars in the Small Magellanic Cloud (SMC). It is expected that the luminosity under a certain value decreases as the PF decreases due to the propeller effect. Above the propeller region, an anti-correlation between the PF and flux might occur either as a result of an increase in the un-pulsed component of the total emission or a decrease of the pulsed component. Additional modes of accretion may also be possible, such as spherical accretion and a change in emission geometry. At higher mass accretion rates, the accretion disk could also extend closer to the neutron star (NS) surface, where a reduced inner radius leads to hotter inner disk emission. We will discuss the implication of the accretion model and the beam configuration.

E1.10-0066-18 STUDY OF HIGH MASS X-RAY BINARY PARAMETERS: SAMPLE DEFINITION AND PHYSICAL PROPERTIES

Ali Taani, ali82taani@gmail.com

Al-Balqa' Applied University-Aqaba university college, Aqaba, Jordan

The variability of measured cyclotron resonant scattering features (cyclotron lines) are of fundamental importance to understanding the physics of magnetized X-ray systems. We investigate the statistics of available data sets of cyclotron lines for several High-Mass X-ray Binaries (HMXBs). An application of the presence of observational data of cyclotron lines allow the formation mechanism of magnetic field strengths to be analyzed and studied through their X-ray spectra. Thus, we divide the data into transient and persistent sources, since the comparison of these sources would provide useful information on their origin and evolution. The orbital parameters of these systems are also investigated. Among the persistent sources, 75long spin period (Pspin 100 s) suggesting that all the persistent sources are supergiant HMXB systems and most of them wind-fed when they feature long spin periods. The transient sources exhibit rapidly rotating main-sequence stars which are deep inside their Roche lob, and thus exhibit emission phases associated with long orbital periods, during which they eject mass from their equatorial regions. Furthermore, a plot of magnetic field against orbital period shows that the transient systems occupy separate regions of the parameter space, akin to the separated regions on the Corbet diagram, suggesting that their accretion rates are changed due to variations in the stellar wind, or possibly associated with the formation of a temporary accretion disk. We briefly discuss the implications of these results on our understanding of the properties of neutron stars and the accretion geometry in these sources.

E1.10-0068-18 CLUMPY WIND ACCRETION IN SUPERGIANT X-RAY BINARIES

Ileyk El Mellah, ielmhk@gmail.com KU Leuven, Leuven, Belgium

Jon Sundqvist, jon.sundqvist@kuleuven.be KU Leuven, Leuven, Belgium

Rony Keppens, rony.keppens@kuleuven.be KU Leuven, Leuven, Belgium

Supergiant X-ray Binaries (SgXB) host a neutron star (NS) accreting a fraction of the intense wind from an evolved O/B Supergiant companion. The X-ray emission associated to accretion displays photometric and spectroscopic variability in time which has partly been attributed to overdensities (aka clumps) in the stellar wind. Recently, the micro-structure of the wind mass and dimension of these clumps. To evaluate the impact of the serendipitous a has been computed by Sundqvist et al (2017), shedding new light the on the mass and dimension of these clumps. To evaluate the impact of their serendipitous accretion on the time variability of the mass accretion rates, we plunge the NS into the wind and performed 3D simulations of the accretion process. We follow the inhomogeneous flow over several orders of magnitude, from the hydrodynamical bow shock down to the NS magnetosphere, and identify the conditions favorable to the formation of a transient disc-like structure within the shocked region. We also account for the variable absorption due to unaccreted clumps passing by the line-of-sight and estimate the final effective variability of the mass accretion rate for different orbital separations. By confronting our results to observations of Vela X-1 by Grinberg et al (2017), we conclude that, if the variability at low luminosity is essentially due to clumps, they can not explain, per se, the flaring activity which must find its origin within the NS magnetosphere.

Glitches are typical events of pulsars, observed as sudden jumps in rotational frequency nu, usually followed by a stage of recovery, in which nu and its derivative dotnu evolve to the preglitch value gradually. The recovery is interpreted as the result of angular momentum transfer between the inner superfluid and the outer crust. However, exactly how the recovery starts has never been observed before. Here we report the discovery of the missing link

between the glitch and recovery processes in the Crab pulsar, during the first-light observation of sl InsightHXMT, China's first X-ray astronomy satellite launched on June 15th, 2017. This missing link could be used to probe the equation of state and the structure of the material inside a neutron star.

Among the many exotic objects at the center of our Galaxy is the closest supermassive black hole, weighing in at 4 million solar masses. Our proximity to it provides the best opportunity to closely study it as a proxy for the physical conditions and phenomenology around supermassive black holes in galactic nuclei. Sagittarius A* (Sgr A*) is the fluctuating source of electromagnetic radiation associated with the accretion of matter onto the black hole. In the NIR, the brightness of Sgr A* is dramatically changing. At times, it can become 30 times brighter than average within 10 min (and in the X-rays even up to 500 times). Its variable emission has been routinely detected with ground-based observatories in the NIR, radio, and submm during the last 15 years. However, many basic questions about this extraordinary source have not been answered yet because of the time limitations of ground-based observations.

We will report the results of a recent multi-wavelength study of Sgr A*. New NIR observations with Spitzer Space Telescope/ IRAC between 2013 and 2017 opened an unexpected window to continuous measurements of variability timescales up to 24-hours - unobservable with ground-based observatories. We observed together with the Chandra Space Telescope and ground-based telescopes like SMA, ALMA, the VLT, and the Keck telescopes. As a result we obtained a rich dataset that provides new insights into the correlation between the wavelengths, and thus into the origin of the variability and the radiative processes. Our eight 24-hour NIR Spitzer datasets in concert with the massive amount of historic ground-based NIR light curves from Keck and the VLT enabled us to determine the characteristic variably timescale with unprecedented precision, and to characterize the NIR spectral properties of the variability. Additionally, We will report our latest results on G2, the putative gas cloud that 3 years ago passed through periapsis in its orbit around the back hole, and its impact on the variability of Sgr A*.

E1.11-0002-18 RADIATION PHYSICS FROM EVENT HORIZON SCALE BLACK HOLE IMAGES

Jason Dexter, jdexter@mpe.mpg.de

Max Planck Institute for Extraterrestrial Physics, Garching, Germany

The ongoing VLTI GRAVITY and Event Horizon Telescope experiments resolve event horizon scales around Sgr A*. I will discuss what we expect them to see, and what it might teach us about low-luminosity accretion, plasma physics, and strong gravity.

E1.11-0003-18 ALMA POLARIMETRY OF SAGITTARIUS A*: PROBING THE ACCRETION FLOW ON SCALES FROM THE EVENT HORIZON TO THE BONDI RADIUS

Geoffrey Bower, gbower@asiaa.sinica.edu.tw

Academica Sinica, Institute of Astronomy and Astrophysics, Hilo, Hawaii, United States

Polarization of millimeter wavelength emission from Sagittarius A* provides a unique probe of thermal and non-thermal gas in the accretion flow, jet, and outflow on scales as small as the event horizon and as large as the Bondi radius. The large degree of Faraday rotation seen towards Sgr A* has demonstrated conclusively the presence of a radiatively inefficient accretion flow (RIAF) and provided a strong constraint on the mass accretion rate. Intrinsic variability of the linear polarization fraction and angle probe the synchrotron-emitting gas close to the event horizon. New observations with ALMA provide an exquisite and complex picture of the Faraday rotation and intrinsic polarization. For the first time, we are able to conclusively separate intrinsic and Faraday effects, providing insights into the radial profile of the accretion flow including the magnetic field, the distribution of thermal and non-thermal electrons, and the degree of turbulence on a range of spatial scales not accessible to any other technique. Interpretation of these results is essential for providing the boundary conditions of physical models that will be used to evaluate images and models obtained by the Event Horizon Telescope.

The origin and radiative mechanism of the flares of Sgr A* are still not completely understood. Indeed, even though 15 years have passed since the discovery of the flaring activity of Sgr A*, simultaneous X-ray and NIR spectra of flares are scarce. I will present the first fully simultaneous fits to the NIR and X-ray spectral slope (and its evolution) during a very bright flare from Sgr A*. The difference in spectral slopes (=0.57±0.09) between the NIR and X-ray slopes strongly supports synchrotron emission with a cooling break. The spectral variations are consistent with the evolution of the high energy cut-off in the electron distribution that induces an initial cut-off in the optical-UV band that evolves slowly into the X-ray band. I will also report hints for a variation of the cooling break that might be induced by an evolution of the magnetic field. I will conclude that synchrotron emission with a cooling break is a viable process for Sgr A*'s flaring emission.

E1.11-0005-18 PROBING GENERAL RELATIVITY WITH HORIZON-RESOLVING IMAGES OF SGR A*

Avery Broderick, abroderick@perimeterinstitute.ca University of Waterloo, Waterloo, Canada

In April, 2017, the full Event Horizon Telescope, a global millimeter-wavelength interferometer capable of resolving the horizons of nearby supermassive black holes, observed Sgr A* for the first time. This new capability promises to transform our understanding of black hole astrophysics and provide a window onto the structure of spacetime itself around astrophysical black holes. I will describe what we already know from a set of precursor experiments with a smaller array, and discuss some of the opportunities for probing the nature and strong gravity of black holes presented by these observations in the future.

E1.11-0006-18 RECENT RESULTS FROM EVENT HORIZON TELESCOPE OBSERVATIONS OF SGR A*

Michael Johnson, mjohnson@cfa.harvard.edu

Harvard-Smithsonian Center for Astrophysics, Cambridge, Massachusetts, United States

The Event Horizon Telescope (EHT) is a global interferometric array operating at 1.3mm. The EHT currently achieves an angular resolution of approximately 10 microarcseconds – comparable to the angular size of the Schwarzschild radius of Sgr A*. Previous EHT observations of Sgr A* have demonstrated that the 1.3mm emission region subtends only a few Schwarzschild radii, and they have detected image asymmetry and substructure on these scales. The EHT also discovered ordered magnetic fields with vigorous activity near the event horizon. With the 2017 expansion to eight sites, including the ALMA array, the EHT now has the potential to directly image the black hole and its surrounding magnetic fields. I will discuss recent EHT progress and results, including the emerging capabilities of the EHT to study relativistic dynamics of accretion flows, to elucidate the role of magnetic fields in jet launching, and to track structural evolution during flares of Sgr A*.

E1.11-0007-18 INTERACTING STELLAR WINDS: CLUMP FORMATION AND ACCRETION ONTO SGR A*

Diego Calderón, dcaldero@astro.puc.cl

Pontificia Universidad Catolica de Chile, Santiago, Chile Jorge Cuadra, jcuadra@astro.puc.cl

Pontificia Universidad Catolica de Chile, Santiago, Chile Marc Schartmann, schartmann@mpe.mpg.de

Ludwig-Maximilian University of Munich, Munich, Germany Andreas Burkert, burkert@usm.uni-muenchen.de

Max Planck Institute for Extraterrestrial Physics, Munich, Germany

The central parsec of the Milky Way is one of the most intriguing environment in the galaxy. The presence of enigmatic G2-like objects as well as the rate and way in which the gas travels towards Sgr A* are remaining unknowns that have attracted special attention in the last decade. The region is populated by tens of Wolf-Rayet stars whose strong outflows fill the ISM with hot, diffuse plasma. Therefore, it is expected that multiple stellar wind collisions are constantly taking place. In this context, we aim to study: i) the hypothesis of G2 being a clump formed in any of the known massive binaries, ii) properties and final fate of clumps formed in unstable wind interactions. Based on analytical analyses and test-particle simulations we found that the properties and dynamics of the clumps produced in the binaries are not consistent with G2's. Thus, an origin in such systems is not possible. On the other hand, we performed adaptive-mesh refinement hydrodynamical simulation of colliding winds in order characterize the clump formation process. Currently, we are conducting a parameter study of wind velocity and stellar separation. Our preliminary results show that clumps are about a thousand times less massive compared with the theoretical upper limit. Furthermore, the ejection velocity from the system is about one third of the terminal speed of the wind. These results combined with our knowledge of the stellar orbits of the Wolf-Rayet stars will allow us to quantify the amount of cold, dense material, and its chances of being accreted.

E1.11-0008-18 IMAGING BLACK HOLES NOW AND IN THE FUTURE

Heino Falcke, h.falcke@astro.ru.nl

Radboud Universiteit Nijmegen, Nijmegen, Netherlands

One of the most fundamental predictions of general relativity are black holes. Their defining feature is the event horizon, the surface that even light cannot escape. So far, we have never seen the event horizon, but this is about to change. Advanced computer simulations make clear predictions of how the shadow of black holes should look like and global interferometric radio observations with the Event Horizon Telescope are now trying to image the supermassive black hole in the center of our own Milky Way and the radio galaxy M87 for the very first time. To improve the imaging quality further more telescopes should be added to the array, in particular in Africa. The more distant future will belong to higher frequencies and space-based interferometry. The talk will give an overview of the ongoing research to image and simulate black holes, as well as of plans for future expansions.

E1.11-0009-18 GRAVITY IN THE GALACTIC CENTER

Frank Eisenhauer, eisenhau@mpe.mpg.de

Max Planck Institute for Extraterrestrial Physics, Garching, Germany

The GRAVITY interferometer will have finished more than a full year of repeated Galactic Center observations by the time of the conference, including the peri-passage of the fast orbiting star S2 in May 2018. With its unprecedented angular resolution of only few milliarcseconds, GRAVITY overcomes the crowding limit of single telescope observations, thereby revealing the infrared counterpart of SgrA* at all times and directly measuring the orbit of S2 to better than hundred microarcsecond precision. We will present the results from the ongoing GRAVITY observations, and give an outlook on what to expect in the next years from ever deeper imaging and a longer astrometric timeline.

E1.11-0010-18 STELLAR ORBITS AT THE GALACTIC CENTER

Andrea Ghez, ghez@astro.ucla.edu UCLA, Los Angeles, United States

In this talk I will review the work of the Galactic Center Orbits Initiative, a two decade long program of high angular resolution imaging and spectroscopy measurements from W. M. Keck Observatory of stellar orbits at the Galactic Center. The orbits of the shortest period stars have provided the best evidence to date for the existence of supermassive black hole holes and have become unique probes of the laws of gravity. While these probes become more powerful with time, the closest approach of S0-2 during the summer of 2018 provides the first opportunity to test Einstein's theory of General relativity in the unexplored regimes near a supermassive black hole. The orbits of longer period stars have revealed the dynamical structures within the nuclear star cluster, including the unexpected populations of young stars and stars experiencing tidal interactions.

E1.11-0011-18 THE INNER PARSEC OF THE GALACTIC CENTER: HYDRODYNAMICS, X-RAY MODELING, AND 360-DEGREE VIDEOS

Christopher M. P. Russell, crussell@udel.edu

Pontificia Universidad Catolica de Chile, Santiago, Chile Jorge Cuadra, jcuadra@astro.puc.cl

Pontificia Universidad Catolica de Chile, Santiago, Chile

Q. Daniel Wang, wqd@astro.umass.edu

University of Massachusetts, Amherst, Massachusetts, United States

The Galactic Center's inner parsec is a hotbed of astrophysical activity, with the injection of wind material from 30 Wolf-Rayet (WR) stars orbiting the supermassive black hole (SMBH) playing an important role. We compute the thermal X-ray emission from a suite of Galacticcenter hydrodynamic simulations that have various SMBH feedback mechanisms, which are compared to Chandra X-ray Visionary Program observations of the region. Over a 2-5″ ring centered on our galaxy's SMBH (Sgr A*), the spectral shape is well matched, indicating that the WR winds are the dominant source of the thermal X-ray emission. Furthermore, the X-ray flux depends on the SMBH feedback due to the feedback's ability to clear out material from the central parsec. A moderate outburst is necessary to explain the current thermal X-ray flux, even though the outburst ended ~100 yr ago. We will report on our efforts to expand this modeling by including the ~100 O stars and the 'S' stars in the region.

Additionally, we will present our 360-degree videos of the aforementioned Galactic-center simulations. These movies render an image over all 4π steradian, and therefore provide a unique and immersive way to visualize astrophysical simulations. Viewed from the perspective of Sgr A*, the most striking aspect of our latest video, which renders column density, is the inspiraling and stretching of clumps of WR-wind material as they make their way towards the SMBH. Video sharing sites such as YouTube allow these videos to be shared with the masses; they can be viewed in their 360-degree nature on computer screens, with smartphones, or, best of all, in virtual-reality (VR) goggles. Our latest video, powered by a Chandra press release, went viral and has been viewed on multiple platforms over 1.2 million times!

E1.11-0012-18 ESTIMATION OF ACCRETING GAS MASS AROUND SGRA* USING DEEP SPECTRO-IMAGING OBSERVATIONS OF NIR RECOMBINATION LINE BRY

Anna Ciurlo, ciurlo@astro.ucla.edu

UCLA, Los Angeles, California, United States Mark Morris, morris@astro.ucla.edu

University of California, Los Angeles, Los Angeles, California, United States Randy Campbell, randyc@keck.hawaii.edu

Hawaii, United States

The accretion rate of hot gas through the Bondi radius of the central supermassive black hole at the center of our Galaxy (Sgr A*) can be estimated from X-ray observations, but the amount of cooler gas very near the black hole is not strongly constrained. Murchikova (2016, IAUS 322, 21) placed an upper limit on the gas mass within 0.015 pc around Sgr A*, of 2 Jupiter masses using the H30α radio recombination line. The UCLA Galactic center group has been gathering data on this region (2 arcseconds around Sgr A*) with the near-infrared integral field spectrograph OSIRIS at Keck for over 12 years, for a total of more than 20 epochs of deep observations. These observations have been taken with the primary goal of determining radial velocities of the young stars orbiting Sgr A*. With this large dataset we propose to investigate emission in the Brγ recombination line at 2.166 μm arising from the immediate vicinity of Sgr A* (0.06 arcseconds). The line in this region is expected to be very broad (several thousand km/s) but the width of the observed band, Kn3, is large enough to cover the extent of a potentially broad Brγ line (+-7000 km/s). We are in the process of carefully aligning and combining these 12 years of observations to produce the highest signal-to-noise spectrum of the immediate vicinity of SgrA *. Foreground and background gas components detected in this direction can be easily disentangled from Sgr A* because of their limited velocity extent. An upper limit on the accreting gas mass will be reported and compared with previous estimates of the accretion rate and with Murchikova's limit.

E1.11-0013-18 STUDYING AGN FROM THE MILKY WAY TO Z=4 WITH SOFIA

Eric Becklin, ebecklin@sofia.usra.edu

Universities Space Research Association, Moffett Field, California, United States

I will review the extensive work on SOFIA with imaging and spectroscopy of the central 5pc of the Milky Way from 5 to 250 microns. A comparison will be make with other AGN which are 5 to 10 orders of magnitude brighter, but show similar structure in the dust. Observations of AGN that are gravitationally lensed now have been observed with SOFIA to z 4 and will be discussed.

E1.11-0014-18 DIFFUSE X-RAY EMISSION FROM THE CENTRAL DEGREES OF THE MILKY WAY

Sensitive X-ray observations of the center of our Galaxy have revealed the presence of warm and hot plasma associated with energetic energy releases and particle acceleration. I will present the deepest X-ray maps of the central few degrees of the Galaxy, discussing newly-discovered extended features, such as supernova remnants, super-bubbles and X-ray filaments. In addition, I will also discuss the discovery of warm plasma at high Galactic latitude, showing a sharp edge to its distribution that correlates with the location of known radio/mid-IR features such as the "GC Lobe". These features might be associated with an inhomogeneous hot "atmosphere" over the GC, perhaps fed by continuous or episodic outflows of mass and energy from the GC region.

E1.11-0015-18 ORIGINS OF THE GALACTIC CENTER DIFFUSE X-RAYS

Masayoshi Nobukawa, nobukawa@nara-edu.ac.jp Nara University of Education, Nara, Japan Katsuji Koyama, koyama@cr.scphys.kyoto-u.ac.jp Kyoto University, Kyoto, Japan

Kumiko Nobukawa, kumiko@cc.nara-wu.ac.jp Nara Women's University, Nara, Japan

Shigeo Yamauchi, yamauchi@cc.nara-wu.ac.jp Nara Women's University, Nara, Japan

Galactic diffuse X-ray emission (GDXE) is unresolved X-rays prevailing over the Galactic center and ridge. Its origin, whether from unresolved point sources, or truly diffuse plasma, has been under debate for a long time. In the point source scenario, the candidate active X-ray stars (AXSs) have been mainly cataclysmic variables (CVs) and coronally active binaries. One of the most remarkable features of the GDXE is strong K-shell iron lines: FeI-Kα, FeXXV-Heα, and FeXXVI-Lyα lines. For the examination of the GDXE origin, we focus on the three iron lines. We measured spatial distributions of the three iron lines associated with the GDXE and confirmed that the GDXE is decomposed into the Galactic Center X-ray Emission (GCXE;

e-folding scales of Δl = 0.°62 0.°72 and Δb = 0.°22 0.°26) and the Galactic Bulge X-ray Emission (GBXE; Δl = 8° 10° and Δb = 1° 2°) as well as the Galactic Ridge X-ray Emission (GRXE; Δl = 45° 57° and Δb = 0.°5 1.°0) [1, 2]. The scale heights of the three lines in the

GCXE are similar to the central molecular zone (CMZ). We also constructed the global spectra of the GDXE in the iron K-shell band and fit them with a combination of the mean spectra of AXSs. The GBXE spectrum is reproduced by a combination of AXSs, and the most fraction is occupied by non-magnetic CVs. On the other hand, the GCXE spectrum shows large excesses in the three iron lines [3]. Together with the fact that the scale heights of the iron lines are similar to that of the CMZ, the excess components would be related to high-energy activity in the Galactic center, such as the past big flares of Sgr A*.

[1] Uchiyama et al., 2013, PASJ, 65, 19 [2] Yamauchi et al., 2016, PASJ, 68, 59 [3] Nobukawa et al., 2016, ApJ, 833, 268

E1.11-0016-18 HIGH FREQUENCY PULSED RADIO EMISSION VARIABILITY FROM THE GALACTIC CENTER MAGNETAR PSR J1745-2900

Aaron B. Pearlman, aaron.b.pearlman@caltech.edu

California Institute of Technology, Pasadena, California, United States Walid A. Majid, walid.a.majid@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Thomas A. Prince, prince@caltech.edu

California Institute of Technology, Pasadena, California, United States

Radio observations of the Galactic Center (GC) magnetar, PSR J1745-2900, provide valuable insight into the missing population of pulsars near the GC and the turbulent environment near Sgr A*. We present simultaneous high frequency radio observations at S-band (2.3 GHz) and Xband (8.4 GHz) between 2015 July 30 and 2016 August 20 from the NASA Deep Space Network (DSN) 70 m antenna (DSS-43), located in Tinbinbilla, Australia. The radio spectrum steepened between 2.3 GHz and 8.4 GHz, compared to measurements performed approximately 5 months prior, and then flattened considerably towards the end of our observations. We carried out a search for single pulses at S-band and X-band, which revealed bright X-band events displaying multiple emission components with significant temporal variability between the components. The structure of the single pulse events changed on substantially shorter time scales than the pulsar rotation period, with some events showing strong evidence of pulse broadening. Unusual frequency dependent behavior was also observed in the dynamic spectra of the X-band single pulse emission components. We will discuss the pulse morphology observed from this magnetar, possible mechanisms that could explain the variability, and the implications of these observations on multipath scattering near the GC through the interstellar medium.

E1.11-0017-18 SIGNIFICANT DUST SCATTERING EFFECTS FOR X-RAY SOURCES IN THE GALACTIC CENTRE

Chichuan Jin, jinchichuan@gmail.com

Johns Hopkins University, 21218, Maryland, United States

The Galactic Centre (GC) region contains many bright X-ray sources and has a high column density of foreground gas and dust. This suggests that X-ray dust scattering should be ubiquitous and intensive in the GC direction. In this presentation, I will report our recent major progress in discovering various significant effects of dust scattering for GC X-ray sources. As an example, I will show that X-ray dust scattering can severely bias the observed spectrum of the GC LMXB AX J1745.6-2901 at 1.45 arcmin away from Sgr A*, and explain its peculiar eclipse light curves. This study also allows us to put constraints on the GC foreground dust distribution, which indicate that most of the dust along the line-of-sight should reside in the Galactic disk rather than in the GC. I will also show that dust scattering halo is commonly observed around many GC sources, and so its spectral timing effects should be seriously considered for all these sources, including Sgr A*. Finally, I will introduce our Xspec models for the spectral correction of GC foreground dust scattering.

E1.11-0018-18 A NEW CHANDRA PERSPECTIVE OF X-RAY SOURCE POPULATIONS IN THE NUCLEAR STAR CLUSTER

Zhiyuan Li, lizy@nju.edu.cn Nanjing University, Nanjing, China Mark Morris, morris@astro.ucla.edu

University of California, Los Angeles, Los Angeles, California, United States Zhenlin Zhu, zzlcd610000@yeah.net

Nanjing University, Nanjing, China

Based on decade-long, ultra-deep Chandra observations towards the Nuclear Star Cluster (NSC), we have catalogued about 3600 X-ray sources down to a luminosity of 1E31 erg/s, which are presumably close binaries that evolve in the most dynamic environment in our Galaxy. The unprecedented X-ray data allow us to revisit the global (temporal, spectral and spatial) properties of these X-ray sources and obtain new insights on the constituent stellar populations.

E1.11-0019-18 A REVIEW ON THE DISTRIBUTION OF GAS AND YOUNG STARS IN THE INNER 500 PC OF THE GALAXY

Steven Longmore, s.n.longmore@ljmu.ac.uk

Liverpool John Moores University, Liverpool, United Kingdom

I will give a review of recent progress on our understanding of the mass flows and energy cycles in the Central Molecular Zone – the inner 500pc of the Galaxy – focusing on the distribution of molecular/ionised gas and the star formation history over the last few Myr.

E1.11-0020-18 JOINT VENTURE OF SGR A*'S X-RAY FLARES AND MOLECULAR CLOUDS IN THE GALACTIC CENTER REGION

Eugene Churazov, churazov@mpa-garching.mpg.de MPA, IKI, Garching, Germany

Ildar Khabibullin, khabibullin@iki.rssi.ru

Space Research Institute (IKI), Moscow, Russia Rashid Sunyaev, sunyaev@mpa-garching.mpg.de MPA, IKI, Germany

Gabriele Ponti, ponti@mpe.mpg.de

Max Planck Institute for Extraterrestrial Physics, Garching, Germany

Thanks to the ubiquity of molecular clouds in the Galactic Center region that can reflect Xrays, we have learned that Sgr A* experienced short and powerful flares in the recent past. In turn, these flares offer a truly unique opportunity to probe the properties of the molecular clouds themselves, namely their 3D location (at 100 pc scales) and inner structure (down to 0.1 pc scales), statistics of the gas density distribution, and potentially properties of the velocity field. Short duration of the flare(s), combined with X-rays high penetration power and insensitivity to the thermoand chemo-dynamical state of the gas, makes such X-ray probing almost free of the projection and opacity effects. Currently available data already provide us with (i) an estimate of the flare age, (iii) an estimate of the total emitted during it energy,

(ii) upper limit on its duration and a lower limit on the mean luminosity. The same data also allow one to determine the line-of-sight positions of the brightest reflecting clouds and measure statistics of the molecular gas density distribution over a 3.5 pc thick slice inside them. Future X-ray observatories featuring polarimeters and cryogenic bolometers will be able to measure velocities and polarization degrees of the reflected emission, allowing to model-independently reconstruct 3D geometry of the problem, probe velocity fields and cross-match the X-ray data with velocity-resolved emission of various molecular species.

E1.11-0021-18 MAGNETIC FIELD LINES DISTORTED BY COLLIMATED OUTFLOWS FROM THE GALACTIC CENTER

Mark Morris, morris@astro.ucla.edu

University of California, Los Angeles, Los Angeles, California, United States Jun-Hui Zhao, jzhao@cfa.harvard.edu

W. Miller Goss, mgoss@nrao.edu

National Radio Astronomy Observatory, Socorro, New Mexico, United States

Images of the Sgr A radio complex made by combining continuum data from multiple configurations of the Jansky Very Large Array at 6cm wavelength show two bundles of strongly curved nonthermal filaments on opposite sides of the central parsec at average distances of 10 pc. While numerous nonthermal filaments have been reported throughout the Galaxy's central molecular zone, most are only gently curved, the curled filaments ("curls") that we report here have unusually small radii of curvature. Furthermore, both curls are concave toward the central parsec. We interpret these features as distortions in the ambient magnetic field caused by collimated winds from the central parsec, with the most likely source of the winds being the Galactic Black Hole. The intensity of synchrotron emission from the curls correlates roughly with their local curvature, suggesting either that the collimated wind carries relativistic particles that illuminate the compressed field lines at the magnetopause, or that the impact of the wind on the magnetopause drives a shock acceleration process that generates the relativistic particles.

X-ray observations of the diffuse emission at the Galactic center have been performed for more than two decades, revealing an intense and highly-variable non-thermal component spatially correlated with the main molecular complexes. This reflection signal has been identified as echoes created by the past activity of the central supermassive black hole, Sagittarius A*. In particular, the time behaviors and spectra characterized across the whole central molecular zone are successfully explained by several short outbursts during which the black hole was at least a million times brighter than it is today. However, the precise description of the corresponding past catastrophic events is difficult to assess, mainly because the properties of the reflection features that they create while propagating away from Sgr A* depend on the line-of-sight distance, the size, and the morphology of the reflecting clouds, all of which are poorly known. I will review the different attempts to reconstruct Sgr A*'s past activity from the constraints obtained through the observation of the reflection features in the Galactic center, including the 2015-2017 Chandra monitoring and recent NuSTAR observations.

E1.11-0023-18 NUSTAR'S VIEW OF THE GALACTIC CENTER DIFFUSE EMISSION

Kerstin Perez, kmperez@mit.edu

Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

The Galactic diffuse X-ray emission, an unresolved X-ray emission that fills the Galactic center and extends over 100° along the Galactic plane, has been extensively studied since its discovery over 30 years ago. The NuSTAR observatory, due to its angular resolution of 18// for focused photons (< 1 pc at the Galactic center) and its wide aperture for unfocused photons, provides the unique ability to separately measure the diffuse emission of the inner 10 pc, 100 pc, and several hundreds of parsecs of the Galaxy using the same instrument. Conclusions about the dominant underlying stellar remnant populations in the innermost parsecs have already been updated by NuSTAR observations, which indicate that the Galactic center is dominated by intermediate polar systems with heavier white dwarfs than previously assumed. In this contribution, we exploit the wide NuSTAR solid angle aperture for unfocused photons to add to this picture the broad-band measurement of the diffuse emission in the inner 1 3° of the Galactic bulge. This allows for a picture of the changing nature of the high-energy X-ray stellar remnant population on various length scales from the Galactic center. In addition, these same NuSTAR observations constrain possible X-ray line signatures from the radiative decay of sterile neutrino dark matter. In most of the mass range 10-50 keV, these (along with those derived from NuSTAR blank-sky observations) are now the strongest limits on this leading dark matter candidate.

E1.11-0024-18 DIVERSE ORIGIN OF GALACTIC CENTER NON-THERMAL X-RAY FILAMENTS

Shuo Zhang, shuo@mit.edu

Massachusetts Institute of Technology, Cambridge, Massachusetts, United States Chuck Hailey, chuckh@astro.columbia.edu

Columbia University, New York, New York, United States Kaya Mori, kaya@astro.columbia.edu

Columbia University, New York, New York, United States Frederick Baganoff, fkb@space.mit.edu

United States

A unique phenomenon of the Galactic center region is the existence of numerous non-thermal filamentary structures, whose source nature has been under debate. The NuSTAR Galactic center and Galactic plane observation campaign allowed us to detect four non-thermal X-ray filaments above 10 keV: G359.89-0.08 or Sgr A-E, G359.97-0.038, G0.13-0.11 and G359.950.04. These hard X-ray filaments are among the brightest in soft X-ray band of 2-8 keV, with luminosities above 8e32 erg/s at a distance of 8 kpc. The broadband 3-79 keV NuSTAR data points to a diverse origin for these filamentary structures: Sgr A-E is best explained by a magnetic flux tube trapping 100 TeV cosmic-ray electrons; G359.97-0.038 can be best interpreted as Sgr A East shell interacting with the 50 km/s cloud; G0.13-0.11 and G359.950.04 are pulsar wind nebula candidates. Future deeper X-ray Galactic center surveys will be able to detect more X-ray filaments and reveal whether there is dominant source origin for this unique type of sources.

E1.11-0025-18 RECONSTRUCTING THE PAST LIGHT CURVE OF SGR A* WITH DETAILED SPECTRA OF X-RAY ECHOES

Dimitri Chuard, dimitri.chuard@cea.fr CEA Saclay, Gif-sur-Yvette, France Regis Terrier, terrier.regis@gmail.com

University of California, Los Angeles, Los Angeles, California, United States Gabriele Ponti, ponti@mpe.mpg.de

Max Planck Institute for Extraterrestrial Physics, Garching, Germany

The bygone activity of the supermassive black hole Sgr A* is traced by the ongoing reflection of past X-ray flares off molecular clouds located within the central molecular zone of the Galaxy. However, until recently, no proper reconstruction of the light curve of Sgr A* was possible since the exact positions of the clouds, and hence the propagation delay of the echoes, remained unknown. With the development of Monte Carlo-simulated reflection spectra, we are now able to place the best constraints to date on the line-of-sight positions of the bright clumps and, consequently, to provide an estimation of the outburst ages. A detailed study of the main subregions of the molecular complex Sgr C based on Chandra and XMM-Newton observations collected between 2000 and 2014 will be presented. The extension of this approach to other nearby regions, such as Sgr A, B and D, will also be discussed.

E1.11-0026-18 DISCOVERY OF A RECOMBINING PLASMA IN SAGITTARIUS A EAST: A RELIC OF PHOTO-IONIZATION BY THE PAST ACTIVITY OF SAGITTARIUS A*?

Arisa Hirayama, raa_hirayama@cc.nara-wu.ac.jp Nara Women's University, Nara, Japan

Sagittarius (Sgr) A∗ is a supermassive black hole located at the Galactic Center (GC). Recent observations suggest that Sgr A∗ exhibited bright X-ray flares in the past (e.g., the X-ray reflection nebula located at the GC region, Sunyaev et al. 1993, ApJ, 407, 606; Koyama et al. 1996, PASJ, 48, 249; the recombining plasma in the south of the GC, Nakashima et al. 2013, ApJ, 773, 20). Sgr A East is a supernova remnant (SNR) with a high temperature plasma

(Maeda et al. 2002, ApJ, 570, 671; Koyama et al. 2007, PASJ, 59, 237). Sgr A∗ is located inside of the SNR.

Using the Suzaku archive data, we have obtained a high quality X-ray spectrum upto 12 keV. As a result, we have discovered a recombination continuum feature of Fe at 9 keV, indicating the recombining plasma (RP). The electron temperature, the initial ionization temperature and recombination parameters (plasma density multiplied by the recombination time) are 1.5 keV, 13 keV and 7×1011 s cm3, respectively. In the RP spectrum, we discovered Heα lines of Cr and Mn for the first time. We found a hint that the ionization temperature in the near side from

Sgr A∗ is larger than that of far side. Then one possible origin of the RP is photo-ionization by past X-ray flares of Sgr A∗. Using the mean distance of Sgr A East from Sgr A∗, best-fit initial ionization temperature and recombination parameter, we estimate the flare luminosity of Sgr A∗ in the past to be ~1042 erg s–1.

E1.11-0027-18 TIDAL DISRUPTION EVENTS: SHORT-LIVED LUMINOUS FLARES AND LONG-LASTING TRACES

Lixin Dai, phycosimo@gmail.com

Niels Bohr Institute, Copenhagen, Denmark

Tidal disruption events (TDEs) happen in the centers of galaxies, where stars that pass too close by are destroyed by the tidal force from the central supermassive black holes. In a TDE, a large amount of stellar material is fed to the black hole in only a few years, forming a transient accretion disk and sometimes a relativistic jet. A bright flare is produced, the luminosity of which can change by two orders of magnitude in one year following a deterministic decline pattern. Moreover, as the stellar material is accreted onto the black hole at a rate largely exceeding the Eddington accretion rate, a thick super-Eddington disk forms, which launches wide-angle, ultra-fast outflows. These allow TDEs to be a unique probe to the inner regions of galaxies. The luminous flare and powerful outflows can help us map out the inner regions of galaxies through signatures such as radio signals produced when outflows shock the circumnuclear gas, emission line echoes and dust echoes produced by photoionization, and echoes by molecular clouds in the central region. While (fortunately) we have not seen a bright TDE from our Galactic Center, we have possibly observed several traces from past TDEs, including an X-ray echo which might be due to a TDE happened a hundred years ago.

E1.11-0028-18 DARK MATTER AT THE GALACTIC CENTER AND THE GALACTIC CENTER GAMMA-RAY EXCESS

Tim Linden, linden.70@osu.edu

Ohio State University, Columbus, Ohio, United States

Over the last seven years, Fermi-LAT observations have convincingly found an excess in gammaray emission emanating from the center of the Milky Way galaxy. The excess has three definitive properties: (1) it has a hard spectrum that peaks at an energy of 2 GeV, (2) it extends from within 0.1 degrees to more than 10 degrees from Sgr A* with a three-dimensional intensity that falls roughly as r–2, (3) it is approximately spherically symmetric. Several models for this excess have been formulated, including the collective emission from a population of individually dim gamma-ray pulsars, outbursts of cosmic-ray electrons from the central molecular zone, or potentially dark matter annihilation. In this talk, I will discuss the arguments for and against each model, focusing specifically on constraints from multi-wavelength observations. Additionally, I will discuss the future observations that are critical for understanding the origin of the gamma-ray excess.

E1.11-0029-18 UNIVERSAL ENERGY SPECTRUM OF COSMIC RAYS IN DIFFUSE MOLECULAR CLOUDS: EFFECT ON GAMMA-RAY EMISSION

University of Hong Kong, Hong Kong, Hong Kong, China

We propose a generic model of CR penetration into molecular clouds through their diffuse envelopes, and identify the leading physical processes controlling their transport on the way from a highly ionized interstellar medium to a dense interior of the cloud. The model allows us to describe a transition between a free streaming of CRs and their diffusive propagation, determined by the scattering on the self-generated disturbances. We demonstrate a remarkable mutual complementarity of different mechanisms leading to the onset of the diffusive regime, which results in a universal energy spectrum of the modulated CRs. The model is applied to estimate the expected gamma-ray emission from molecular clouds. In particular, it can provide insights into the origin of the so-called GeV excess of diffuse gamma-ray emission from the Galactic center.

E1.11-0030-18 POSSIBLE CONSEQUENCES OF STELLAR CAPTURE AND TIDAL DISRUPTION BY SUPERMASSIVE BLACK HOLES

Kwong Sang Cheng, hrspksc@hkucc.hku.hk

University of Hong Kong, Hong Kong, Hong Kong, China Presenting author: Dmitry Chernyshov, dmit.mipt@gmail.com

Lebedev Physical Institute of Russian Academy of Sciences, Moscow, Russia Dmitry Chernyshov, dmit.mipt@gmail.com

P. N. Lebedev Institute, Moscow, Russia Chung-Ming Ko, cmko@astro.ncu.edu.tw

National Central University, Taiwan, Taoyuan, Taiwan, China

Stars captured by the supermassive black holes in the galactic centers are common phenomena. Capture events occurred in distant galaxies have been observed by various of X-ray satellites. The capture rate is roughly once every tens to hundreds thousand years for normal galaxies. These capture events should also occur in the past of Milky Way. In this talk we will review some observed high energy phenomena in the galactic centers, which may be the consequences of the stellar capture events including Fermi Bubbles, positron annihilation lines, X-ray emission from Swift 1644+57 etc.

E1.11-0031-18 VERY HIGH ENERGY EMISSION FROM THE GALACTIC CENTRE

Regis Terrier, terrier.regis@gmail.com

APC AstroParticle & Cosmology, Paris, France

Very High Energy (VHE) gamma-rays offer a very rich perspective of the Galactic centre (GC) and the surrounding 300 pc. We review observational results at VHE and discuss their physical implications. In particular, we discuss the nature of the gamma-ray source at the GC and its possible connection with the supermassive black hole. We also present the measurements of the interstellar emission and their impact on our knowledge of the cosmic-ray population production and propagation in the region. We finally discuss perspectives, in particular with the Cherenkov Telescope Array.

E1.11-0032-18 VERY HIGH ENERGY GAMMA RAY EMISSION FROM THE GALACTIC CENTER WITH VERITAS

Matthew Buchovecky, mbuchove@ucla.edu

University of California, Los Angeles, Los Angeles, California, United States

The Galactic Center (GC) is an energetic and exciting region that is host to various forms of nonthermal gamma-ray emission in the very-high-energy regime above 100 GeV. Among the possible origins of the central gamma-ray emission are point sources such as the central supermassive black hole Sagittarius A*, supernova remnants, and pulsar wind nebulae. The mechanism of emission from Sgr A* is unknown, and many candidate models have been proposed for this important astrophysical process. A study of the spectrum, morphology, and potential variability of emission in this region can help to discriminate between models capable of creating such high energy particles, and may give hints about the past activity in the region. The GC also has a large diffuse component of gamma-ray emission that correlates with large molecular clouds such as Sgr B2. Examining the combined spectral behavior of Sgr A* and the surrounding diffuse emission could indicate the presence of a significant source of Galactic cosmic rays. The GC has undergone deep observations by VERITAS, an array of atmospheric Cherenkov telescopes designed to detect very high energy gamma rays. When observing the Galactic Center, VERITAS is sensitive to gamma rays with energies between 2 and 30 TeV, among the highest of any gamma ray observatory. Here we will provide an overview of the spectral and morphological results of VERITAS observations of the Galactic Center taken between 2008 and 2017. These results will be used to confront the various models available for the different forms of observed emission.

E1.11-0033-18 DETAILED STUDY OF THE DIFFUSE EMISSION IN THE CENTRAL 200 PC OF OUR GALAXY WITH H.E.S.S.

Anne Lemiere, alemiere@apc.in2p3.fr Laboratoire APC, Paris, France Regis Terrier, terrier.regis@gmail.com

APC AstroParticle & Cosmology, Paris, France Léa Jouvin, ljouvin@ifae.es

IFAE, Barcelona, Spain

H.E.S.S. Collaboration

H.E.S.S.S Collaboration

In 2006 a diffuse emission was discovered around the Galactic Center (GC) by the High Energy Stereoscopic System (H.E.S.S.) array and interpreted as the result of an overabundance of cosmic-rays interacting with the dense matter distribution of the Central Molecular Zone (CMZ). Since then, the GC region has been constantly monitored by the H.E.S.S. I array accumulating more that 200 hrs of additional data. We report the results of a detailed spectral and morphological analysis of the diffuse emission and discuss the implications on the existence and origin of a cosmic-ray excess in the region.

E1.11-0034-18 ACTIVITY OF THE SMBH AND OTHER ENERGETIC PROCESSES AT THE GC: HIGHLIGHTS AND CONCLUDING REMARKS

Vladimir Dogiel, dogiel@td.lpi.ru

P. N. Lebedev Institute, Moscow, Russia Andrea Goldwurm, andrea.goldwurm@cea.fr CEA/Saclay & APC, Gif Sur Yvette, France

The scientific organizers of the event provide in this talk a summary of the highlights presented during the conference, proposing to the audience a number of issues for comments and discussion.

E1.11-0035-18 SEARCH FOR TRANSIENT RADIO SOURCES NEAR GALACTIC CENTRE REGION

Sabyasachi Pal, sabya.pal@gmail.com

Indian Centre for Space Physics, Calcutta, India

Galactic centre region is best suited to search for transient radio sources. Transient radio sources are mostly compact objects. Dynamic radio sky is not properly studied due to various reasons. There are different kind of compact sources which show highly variable radio emission from nano second to month time scale for different kind of physical reasons. We are systematically searching transient sources in Galactic centre region using Giant Meterwave Radio Telescope (GMRT) and Janskey Very Large Array (JVLA). We have already discovered few transient sources, most of which are characterised with high spectral index and presence of circular polarization. In this paper we will summarize different methods to search transient radio sources and will summarize our effort to search transient sources. We will also summary different properties of newly discovered transient sources and multi-wavelength followup of these sources.

E1.11-0036-18 AN OUTBURST FROM A NEW GALACTIC BULGE INTERMEDIATE POLAR CANDIDATE IN THE XMM-NEWTON GALACTIC CENTER LOBE SURVEY

Florian Hofmann, fhofmann@mpe.mpg.de

Max Planck Institute for Extraterrestrial Physics, Garching, Germany
Gabriele Ponti, ponti@mpe.mpg.de

Frank Haberl, fwh@mpe.mpg.de

Max Planck Institute for Extraterrestrial Physics, Garching, Germany
Maïca Clavel, maica.clavel@univ-grenoble-alpes.fr

Institut de Planétologie et d'Astrophysique de Grenoble, Grenoble, France

For the past decades a rare subclass of cataclysmic variables, with magnetized white dwarfs (WD) as accretors has been studied and called intermediate polars (IP). IPs are very numerous but mostly faint X-ray sources in the Galactic center and bulge (GC/GB) region and there is evidence that they are responsible for a large fraction of the diffuse X-ray emission due to unresolved sources in the GB. In an ongoing deep X-ray survey (0.5-10 keV energy band) of 3x3 deg around the GC with the XMM-Newton observatory we conducted a systematic search for transient X-ray sources. Promising systems were analyzed for spectral, timing, and multi-wavelength properties to constrain their nature. We discovered a new highly variable (factor >20) X-ray source about 1.25 deg south of the GC. We found evidence making the newly discovered system a candidate IP. The X-ray light curve shows a period of 511 10 s which can be interpreted as the spin period of the WD. The X-ray spectrum is well fit by a bremsstrahlung model with a temperature of 13.9 2.5 keV, suggesting a WD of 0.4-0.5 solar masses. High X-ray absorption and absence of an optical counterpart are evidence that the source is most likely located in the GB. This system will help to understand the population of rarely observed IPs in the GB. In extension of this work a full study of the diffuse X-ray emission and point source population in the ongoing (to be completed this year) XMM-Newton GC survey is currently under way.

E1.12-0001-18 X-RAY SURVEYS OF DISTANT ACTIVE GALACTIC NUCLEI: DEEP TO WIDE

William Brandt, wnbrandt@gmail.com

Penn State University, University Park, Pennsylvania, United States

I will review the results from cosmic X-ray surveys of active galactic nuclei (AGNs) over the past 20 yr that have dramatically improved our understanding of growing supermassive black holes over most of cosmic time. The relevant X-ray surveys range from ultradeep ones, such as the Chandra Deep Fields, to much wider field surveys covering 1-10 square degrees or more. I will briefly describe these surveys, the essential roles of complementary multiwavelength data, and how AGNs are selected and identified. I will then highlight selected key results on the AGN population and its evolution ("demographics"), the physical processes operating in AGNs ("physics"), and the interactions between AGNs and their hosts/environments ("ecology"). I will conclude by describing some significant unresolved questions and prospects for advancing the field with new observations and future missions.

E1.12-0002-18 X-RAY SURVEYS: SOFT TO HARD - PROBING OBSCURED BLACK HOLE GROWTH OVER COSMIC TIME

James Aird, james.aird@leicester.ac.uk

University of Leicester, Leicester, United Kingdom

I will review recent results from large X-ray surveys that probe the evolution of Active Galactic Nuclei (AGNs) at both soft and hard X-ray energies and provide crucial insights into obscured black hole growth over cosmic time.

Chandra and XMM-Newton have provided the most sensitive X-ray surveys to date, probing from 0.5-8 keV in energy. However, these surveys still suffer complex selection effects against obscured AGNs. A number of recent studies have developed new techniques, exploiting the soft-to-hard energy coverage of Chandra and XMM-Newton, to address these selection biases and provide accurate measurements of the evolution of the AGN luminosity function and the distribution of obscuring column densities (the "NH function"). These studies show that the bulk of black hole growth took place at high redshifts (z>1) and is obscured, although the fraction of the most heavily obscured, Compton-thick AGNs and its evolution remains somewhat uncertain.

Moving to harder energies, the NuSTAR observatory is providing the first high-sensitivity Xray surveys at >8keV, enabling new studies of the evolution of obscured AGN to high redshifts. I will give an overview of the results from the NuSTAR survey program, including the first measurements of the evolution of the AGN luminosity function at >8keV, constraints on the fraction of obscured and Compton-thick AGNs, and studies of the spectral properties of AGNs at these hard energies.

Finally, I will briefly discuss future missions, in particular the Athena X-ray observatory that will probe obscured black hole growth out to very high redshifts.

E1.12-0003-18 X-RAY SURVEY'S SPECTRAL ANALYSIS

Johannes Buchner, jbuchner@astro.puc.cl

Pontificia Universidad Catolica de Chile, Santiago, Chile

X-ray surveys are a fundamental tool for characterising the AGN population. They simultaneously provide accretion luminosities and line-of-sight column densities, but more importantly a well-understood selection function. After detecting X-ray sources crucial steps include 1) finding multi-wavelength counterparts, 2) constraining redshifts (spec-z/photo-z/XZ) and 3) X-ray spectral analysis; each step however has pitfalls. In this talk I will focus on characterising the X-ray spectra in the low/high-count, low/high-z and Compton-thin/thick regimes with spectral models of realistic complexity. Care has to be taken with choosing the right methods, including: fitting statistic, background handling, redshift uncertainty propagation, parameter space exploration methods and model comparison technique. Finally, I discuss how to rigorously infer population distributions from a limited, biased sample with uncertain properties using hierarchical Bayesian inference.

E1.12-0004-18 AGN OBSCURATION, EDDINGTON RATIO DISTRIBUTION AND CLUSTERING: DEEP AND WIDE X-RAY SURVEYS WITH NUSTAR AND CHANDRA IN THE UKIDSS-UDS AND BOOTES FIELDS

Alberto Masini, alberto.masini@dartmouth.edu

Dartmouth College, Hanover, New Hampshire, United States

X-ray surveys are one of the most efficient ways to detect active galactic nuclei (AGN) and perform statistically meaningful population studies. In the past decade, important results in this field came from both wide and deep X-ray surveys of the sky performed by the Chandra and XMM-Newton observatories. The launch of NuSTAR in 2012 allowed to extend such sensitive surveys to higher energies, starting a fruitful synergy between soft and hard X-rays. On one side, recent deep hard X-ray surveys confirmed the presence of a population of heavily obscured AGN: related to this, I will present the results coming from a deep NuSTAR survey of the UKIDSSUDS field, as well as the aggregated results in the COSMOS, ECDFS and UDS fields obtained exploiting three new hard NuSTAR bands, focusing on an interesting source in the COSMOS field barely detected by Chandra due to heavy obscuration, but standing out in the NuSTAR 8- 16 keV band. On the other side, the first steps and perspectives for a new Chandra survey in the central 6 deg2of theBootesf ield(theChandraDeepW ideF ieldSurvey, CDW F S)willbediscussed.T heCDW scaleclusteringof AGN andtheirEddington – ratiodistribution.

E1.12-0005-18 THE ELUSIVE AGN POPULATION

Francesca Civano, francesca.civano@gmail.com

Harvard-Smithsonian Center for Astrophysics, Cambridge, Massachusetts, United States

X-ray surveys conducted in the previous 20 years with both Chandra and XMM-Newton have provided large samples of Active Galactic Nuclei spanning a large range of intrinsic properties. To perform astrophysics studies of these sources, it is vital to couple X-ray with multiwavelength observations, providing key properties and enabling us to fully characterize them. I will give an overview of the multiwavelength findings about X-ray selected AGN and the unexpected difference with optical selected sources.I will focus on the discovery of the elusive AGN population, not recognized as such at other wavelength and the importance of X-ray surveys to obtain a complete census of active SMBH in the Universe.

E1.12-0006-18 REVEALING RARE AGN THROUGH THE STRIPE 82X SURVEY

Yale University, New Haven, Connecticut, United States Mara Salvato, mara@mpe.mpg.de

MPI Extraterrestrische Physik, Garching, Germany

Stripe 82X is a 31 deg2 survey in the legacy SDSS Stripe 82 field, which harbors a rich investment of multiwav date, and on−going projects to unveil how these AGN evolve over cosmic time, typical environments that host this AGN population, and planned catalog releases and value added products that will be made available to the community.

E1.12-0007-18 A HARD X-RAY VIEW OF THE AGN POPULATION WITH THE NUSTAR SERENDIPITOUS SURVEY

George Lansbury, gbl23@ast.cam.ac.uk

Institute of Astronomy, University of Cambridge, Cambridge, United Kingdom

New insights into AGN are being provided by NuSTAR, the first focusing telescope with high sensitivity at hard X-ray energies (E>8 keV), and therefore close to the peak of the cosmic X-ray background (CXB). The NuSTAR serendipitous survey is the largest blind survey performed with NuSTAR, with 13 sq. degrees of coverage (over the first 40 months), and has yielded a large sample of 500 hard X-ray sources (primarily AGNs). I will present X-ray and multiwavelength properties of the NuSTAR survey sources, comparing to local hard X-ray samples (e.g., from Swift BAT). An important part of the AGN census is to identify and characterise the most highly obscured (Compton-thick) AGNs, which may contribute a large fraction of the overall cosmic growth of black holes, but are normally hidden from view by gas and dust. The NuSTAR survey is beginning to uncover new Compton-thick AGNs which were elusive at other wavelengths, thus informing AGN population models.

E1.12-0008-18 HUNTING HEAVILY OBSCURED AGN: THE X-RAY MULTI-OBSERVATORY APPROACH

Stefano Marchesi, smarche@clemson.edu

Clemson University, Clemson, South Carolina, United States Marco Ajello, majello@slac.stanford.edu

SLAC, Menlo Park, California, United States Lea Marcotulli, lmarcot@g.clemson.edu

INAF - Osservatorio Astronomico di Bologna, Bologna, Italy Cristian Vignali, cristian.vignali@unibo.it

Università di Bologna, Bologna, Italy

According to the different models of Cosmic X-ray Background (CXB), the diffuse X-ray emission observed in the 1 to 200-300 keV band, is mainly caused by accreting supermassive black holes, the so-called active Galactic Nuclei (AGN). Particularly, at the peak of the CXB (30 keV) a significant fraction of emission (10-25%) is expected to be produced by a numerous population of heavily obscured, Compton thick (CT-) AGN, having intrinsic column density

NH 1024 cm−2. Nonetheless, in the nearby Universe (z 0.1) the observed fraction of CTAGN with respect to the total population appears to be lower than the one expected on the basis of the majority of CXB model predictions (20-30%), being between 5 and 10%. This discrepancy between data and models is one of the open challenges for X-ray astronomers, and needs to be solved to get a complete understanding of the AGN population. In this presentation, I will discuss a multi-observatory X-ray approach to find and characterize heavily obscured AGN. Candidate sources are first selected in the 100-month Swift-BAT catalog, the result of a 7 years all-sky survey in the 15-150 keV band. These objects are then targeted with snapshot (5-10 ks) observations with Chandra andSwift-XRT, which allow us to constrain the intrinsic absorption value within a 20-30% uncertainty. Finally, deep (25-50 ks) observations with XMM-Newton and NuSTAR allow us to study the physics of these complex and elusive sources.

E1.12-0009-18 OBSCURATION PROPERTIES OF AGN

Claudio Ricci, claudio.ricci.astro@gmail.com

Pontificia Universidad Catolica de Chile, Santiago, Chile

Most of the accretion onto supermassive black holes (SMBHs) happens during a phase in which the AGN is obscured. However, to date it is not clear what is the mechanism regulating the amount of obscuration around supermassive black holes, and how obscuration is related to the host galaxy and to the accretion properties of the SMBH. In my talk I will review our current understanding of obscuration in AGN from an X-ray perspective, and discuss recent studies aimed at understanding the origin of obscuration, and its relation with the accretion properties of the black hole.

E1.12-0010-18 THE BAT AGN SPECTROSCOPIC SURVEY (BASS) SECOND DATA RELEASE

Michael Koss, mike.koss@eurekasci.com

Eureka Scientific, Kirkland, Washington, United States

The Burst Alert Telescope (BAT) instrument on the Swift satellite has surveyed the sky to unprecedented depth, increasing the all sky hard X-ray sensitivity by a factor of more than 20 compared to previous satellites. The goal of the BAT AGN Spectroscopic Survey (BASS) is to complete the first large (>1000) survey of hard X-ray selected AGN with optical spectroscopy. This work will place constraints on the growth and structure around nearby black holes and provide a baseline for future European X-ray missions, such as ATHENA, that will perform deeper observations of more distant AGN. Here we present an overview of the 11 recent papers published by our collaboration using the first data release and an overview of the second data release which includes redshift determination, absorption and emission line measurements, and black hole mass and accretion rate estimates via broad lines and velocity dispersion for over 1000 AGN.

E1.12-0011-18 THE COMPLETE IR VIEW OF THE SWIFT/BAT 70 MONTH AGN CATALOG

Kohei Ichikawa, k.ichikawa@astro.columbia.edu

Columbia University, New York, New York, United States

We systematically investigate the nearto far-infrared (FIR) photometric properties of a nearly complete sample of local active galactic nuclei (AGN) detected in the Swift/Burst Alert Telescope (BAT) all-sky ultra-hard X-ray (14-195 keV) survey. Out of 606 non-blazar AGNs in the

Swift/BAT 70 month catalog at high galactic latitudes of $b > 10°$, we obtain IR photometric data of 604 objects by cross-matching the AGN positions with catalogs from the WISE,

AKARI, IRAS, and Herschel infrared observatories. We find a good correlation between the ultra-hard X-ray and mid-IR luminosities over five orders of magnitude ($41 < \log L14{-}195 < 46$). Informed by previous measurements of the intrinsic spectral energy distribution of AGNs, we find FIR pure-AGN candidates whose FIR emission is thought to be AGN-dominated with low star-formation activity. We also demonstrate that the X-ray obscuration fraction always exceeds the dust covering factor above the peak of log Lbol > 42.5. We also show that the completeness of the WISE color-color cut in selecting Swift/BAT AGN increases strongly with 14-195 keV luminosity.

E1.12-0012-18 THE NON-THERMAL SKY ABOVE 15 KEV

Eugenio Bottacini, eugenio.bottacini@unipd.it University of Padova, Padova, Italy

We are living in prosperous times for high-energy astronomy with many missions currently keeping watch of the non-thermal sky. After more than a decade of observations, Swift/BAT and INTEGRAL/IBIS still perform surveys. Their shallowness is largely complemented by deep surveys of NuSTAR, which are driven by its one-of-a-kind focusing optics. Yet, to study the evolution of AGNs in the local universe we rely on wide-field surveys with the coded-mask detectors of BAT and IBIS. However, coded-mask technology suffers from an inevitable low sensitivity due to the optics. In this talk I will show how the sensitivity of the wide-field surveys with BAT and IBIS can be boosted by combining their independent observations. Especially the INTEGRAL mission has performed with IBIS deep observations to allow this technique reaching unmatched survey sensitivity. I will review this observing technique and show how the combined observations of BAT and IBIS tie in well with deep NuSTAR surveys.

E1.12-0013-18 MILDLY OBSCURED ACTIVE GALAXIES AND THE COSMIC X-RAY BACKGROUND

Roland Walter, roland.walter@unige.ch ISDC, Versoix, Switzerland

The diffuse cosmic X-ray background (CXB) is the sum of the emission of discrete sources, mostly massive black-holes accreting matter in active galactic nuclei (AGN). The CXB spectrum differs from the integration of the spectra of individual sources, calling for a large population, undetected so far, of strongly obscured Compton thick AGN. Such objects are predicted by unified models, which attribute most of the AGN diversity to their inclination on the line of sight, and play an important role for the understanding of the growth of black holes in the early Universe. The fraction of obscured AGN at low redshift can be derived from the observed CXB spectrum assuming AGN spectral templates and luminosity functions. We show that high signal-to-noise average hard X-ray spectra, derived from more than a billion seconds of effective exposure time with the Swift/BAT instrument, imply that mildly obscured Compton thin AGN feature a strong reflection and contribute massively to the CXB. A population of Compton thick AGN larger than that effectively detected is not required, as no more than 6% of the CXB flux can be attributed to them. The stronger reflection observed in mildly obscured AGN suggests that the covering fraction of the gas and dust surrounding their central engines is a key factor in shaping their appearance. These mildly obscured AGN are easier to study at high redshift than Compton thick sources.

E1.12-0014-18 A SEMI-EMPIRICAL MODEL FOR THE LARGE-SCALE DISRIBUTION OF ACTIVE GALACTIC NUCLEI

Antonis Georgakakis, age@noa.gr

National Observatory of Athens, Athens, Greece

I will combine cosmological dark-matter simulations with the latest observational results on the galaxy occupation of active supermassive black holes to construct a semi-empirical model for the large-scale distribution of Active Galactic Nuclei. Using forward-modeling techniques I will then compare the semi-empirical model against observational results on the clustering and halo-occupation distribution of Active Galactic Nuclei. I will discuss the results in the context of black-hole fueling modes and comment on claims that the environment of AGN is related (or not) to the physics of black-hole growth.

E1.12-0015-18 AGN EVOLUTION FROM WIDE EXTRAGALACTIC SURVEYS: WITNESSING THE IMPACT OF THE LARGE SCALE ENVIROMENT

Sotiria Fotopoulou, sotiria.fotopoulou@durham.ac.uk Durham University, Durham, United Kingdom

Extragalactic X-ray surveys with XMM-Newton and Chandra have revealed the evolution of active galactic nuclei (AGN) across time and space. The analysis of X-ray fields targeted on galaxy clusters have shown that AGNs tend to be abundant in the outskirts of clusters, and their surface density drops towards the centers of galaxy clusters. This observation is similar to the transition galaxies under go as they fall into clusters. Namely, the removal of interstellar medium from galaxies depletes the cold gas reservoir essential for star-formation.

With a combined 60 sq. deg. sky coverage and X-ray flux limit of about 10–15erg/s/cm² the XXL and the X-COP surveys are unique laboratories to assess the transformation of AGN. Due to the large collecting area of XMM, ideal for providing extended sky coverage, and the ancillary multiwavelength photometric and spectroscopic data we are in position to probe the AGN population across different environments, from the field all the way into galaxy cluster cores. Our sample consists of 200 clusters with masses 1014-1015 solar masses up to redshift of one and several thousands of AGN. In this talk, I will present the first direct determination of the X-ray luminosity function of AGN inside clusters and the field up to redshift of one and discuss the implications on the unified model of AGN.

E1.12-0016-18 PROBING CLUSTERING OF X-RAY AGN USING CHANDRA COSMOS LEGACY

Viola Allevato, viola.allevato@sns.it Scuola Normale Superiore, Pisa, Italy

The presence of a SMBH in almost all galaxies in the Universe is an accepted paradigm in astronomy. How these BHs form and how they co-evolve with the host galaxy is one of the most intriguing unanswered problems in modern Cosmology and of extreme relevance to understand the issue of galaxy formation. Clustering measurements can powerfully test theoretical model predictions of BH triggering scenarios and put constraints on the typical environment where AGN live in, through the connection with their host dark matter halos. In this presentation I will talk about the clustering properties of X-ray AGN from both an observational and theoretical point of view, using the new catalog of AGN detected by Chandra in COSMOS and semi-empirical models. The Chandra COSMOS-Legacy catalog is the largest available sample of X-ray AGN for clustering studies, allowing clustering measurements as a function of obscuration, luminosity and AGN host galaxy properties. I will also present mock catalogs of galaxies and BHs assigned via semi-empirical relations to large samples of dark matter halos and how BH/galaxy properties drive the AGN clustering measurements, via detailed comparisons of the predictions from the mocks with the AGN clustering at different scales and redshifts.

E1.12-0017-18 PAST TO FUTURE: ROSAT TO EROSITA

Mara Salvato, mara@mpe.mpg.de

MPI Extraterrestrische Physik, Garching, Germany eROSITA (extended ROentgen Survey with an Imaging Telescope Array) is the core instrument on the Russian/German Spektrum-Roentgen-Gamma (SRG) mission which is current scheduled for launch in 2018. In the soft band (0.5-2 keV), the deep All-sky survey will be 30 times more sensitive than the previous ROSAT All-sky survey, while the first ever true all-sky survey will be mapped in the hard band (2-8 keV). Although its design driving science is the detection of large samples of galaxy clusters for studying the large scale structure in the Universe and test cosmological models, eROSITA will yield a sample of around 3 million active galactic nuclei. This is bound to revolutionize our view of the evolution of supermassive black holes and their impact on the process of structure formation in the Universe. The talk reports on the eROSITA scientific prospect and how the German eROSITA consortium is activated for ensuring an adequate follow-up of the sources to be discovered. The talk will also reports the work in progress in the follow-up and scietific exploitation of those AGN that ROSAT have already discovered and eROSITA will revisit.

E1.12-0018-18 UNCOVERING OBSCURED AGN WITH X-RAY AND MID-INFRARED SURVEYS

Silvia Mateos, mateos@ifca.unican.es

Instituto de Fisica de Cantabria (CSIC-UC), Santander, Spain

Providing a complete census of the obscured Active Galactic Nuclei (AGN) is crucial to fully understand the cosmological growth of supermassive black holes (SMBH). Nevertheless, the majority of the highly obscured accretion phenomenon still evades our census.

Hard X-ray surveys (>few keV) are the most efficient and effective method to trace accretion onto SMBHs, but miss Compton-thick AGNs. Since most of the absorbed AGN energy is reemitted in the mid-infrared (mid-IR), surveys at these wavelengths can potentially trace, at least in part, the elusive highly obscured accretion phenomenon.

In this talk I will review recent progress on the identification of obscured AGN at infrared wavelengths using photometric data from Spitzer/IRAC and the Wide-field Infrared Survey Explorer. I will also discuss how AGN selection at mid-IR wavelengths can allow us to complete our census of AGN activity.

E1.12-0019-18 MULTIWAVELENGTH STUDIES OF ACTIVE GALACTIC NUCLEI OVER DIVERSE TIMESCALES

Aditi Agarwal, aditi.agarwal@iiap.res.in

Indian Institute of Astrophysics, Bangalore, India

Active galactic nuclei (AGNs) are generally characterized by extremely high luminosities as they are powered by accretion of matter onto a super massive black hole (SMBH) surrounded by an accretion disk. The accretion of matter onto SMBHs yields high radiative efficiencies. They also show significant rapid variability over diverse timescales i.e. from 100 s to months and years. To probe the location of the emission processes taking place in the targets in different electro-magnetic bands, we first use variability over diverse timescales which includes analysis of observational data using different statistics. As flux variations are often followed by spectral changes, we also examine their colour - magnitude relationship on diverse timescales which helps us to understand the origin of variability. Presence or absence of correlation among multiple frequencies, characteristic variability timescales in the light curves or a quasi-periodic oscillation can be used to infer the origin of variability, constraint the size of emitting region and also derive SMBH mass. As a part of this, we have developed a suite of time series analysis techniques consisting of the Structure Function, Discrete Correlation Function, Lomb Scargle Periodogram, Wavelet analysis and Power Spectral Density which are applied to analyze light curves of our source sample. Although with the advent of large telescopes, the numbers of known AGNs have grown considerably in the past decade, nevertheless, many aspects remain uncertain. The mechanism under play for their active nature, their formation, evolution, taxonomy and their interaction with its immediate environment requires systematic studies. Thus we explore complex phenomena governing AGNs through the analysis of observational data and its applications using various theoretical models which further helps us to understand the physics of the inner regions of AGNs.

E1.12-0020-18 OBSCURATION AND HOST GALAXY STAR FORMATION FOR AGNS IN DEEP AND WIDE X-RAY SURVEYS

Chien-Ting Chen, chienting@gmail.com

Penn State University, University Park, Pennsylvania, United States William Brandt, wnbrandt@gmail.com

Penn State University, University Park, Pennsylvania, United States Ryan Hickox, ryan.c.hickox@dartmouth.edu

Dartmouth College, Hanover, United States Bin Luo, bluo@nju.edu.cn

Nanjing University, Nanjing, China

The wealth of multiwavelength observations and the discovery of different AGN populations led to the paradigm of AGN unification, in which the unobscured and obscured AGN populations are similar in nature, and the observed differences are simply caused by the dust in the smallscale "torus" that only enters the line-of-sight for the obscured AGNs. With the advances in recent X-ray surveys and the launch of Herschel Space Observatory, there have been increasing evidence suggesting that in addition to the small-scale torus, galactic star-forming dust is also connected to AGN obscuration. I will review recent studies on this topic using data from both deep and wide X-ray surveys. I will also describe results from the latest "deep-wide" XMM-Newton survey in the XMM-LSS field. With 1.3 Ms new XMM-Newton observations,

the central 5.3 deg2 region of XMM-LSS has uniform X-ray coverage reaching < 2 10–15 erg s–1 cm–2 in the 0.5 2.0 keV band for 90% of the survey area. XMM-LSS is the first part of the XMM-SERVS survey, which is comprised of three separate extragalactic fields: XMMLSS, W-CDF-S, and ELAIS-S1. With the uniform X-ray coverage, wide survey area, and excellent ancillary multiwavelength observations, I will also describe how XMM-SERVS will enable detailed studies on the connection between obscuration and host galaxy star formation in the next few years.

E1.12-0021-18 A REVIEW OF RECENT INSIGHTS IN AGN RESEARCH GAINED THROUGH COMBINING X-RAY SURVEY DATA WITH OTHER MULTIWAVELENGTH DATA

James Mullaney, j.mullaney@sheffield.ac.uk University of Sheffield, Sheffield, United Kingdom

I will present a review of what I consider to be the most important developments in AGN research that have come from combining X-ray survey data with that collected from other parts of the electromagnetic spectrum. My talk will largely focus on "population studies", considering general trends within the AGN population, with an emphasis on the relationship between AGNs and their host galaxies. I will finish with a consideration of key outstanding questions, and how future observing technologies will help to address these.

E1.12-0022-18 AGN FEEDBACK: LESSONS LEARNED FROM X-RAY SURVEYS AND MULTIWAVELENGTH SYNERGIES

Marcella Brusa, marcella.brusa3@unibo.it Bologna University, Bologna, Italy

Outflowing winds are now revealed routinely in Active Galactic Nuclei and Quasars across the entire electromagnetic spectrum and are invoked in many co-evolutionary models to link the growth of SMBH and galaxies through feedback phenomena. Both numerical simulations and observations have shown that the nature of AGN outflows is multiphase, and that each gas phase embeds a fundamental piece of information on the driving mechanism and on the effect on the host galaxy.

I will review recent results on the detection of strong winds at different scales through dedicated NIR infrared and ALMA follow-ups of luminous obscured AGN, and the implications for AGNgalaxy co-evolution. I will also discuss the unique power of AGN X-ray surveys in selecting the most promising targets, and the perspectives for future high-energy missions to advance in our understanding of these important phenomena.

E1.12-0023-18 INTERMEDIATE-MASS BLACK HOLES IN DWARF GALAXIES OUT TO REDSHIFT=2 IN THE CHANDRA COSMOS LEGACY SURVEY

Mar Mezcua, marmezcua.astro@gmail.com

Instituto de Astronomia UNAM Ensenada, Ensenada, Mexico

How supermassive black holes form is still one of the long-standing questions in astronomy. In order to reach 109 solar masses when the Universe was less than 1 Gyr old, they should have started as seed intermediate-mass black holes (IMBHs) of 100-106 Msun. The presence of IMBHs at z>7 is difficult to prove; however, those seed IMBHs that did not grow into supermassive black holes should be found in local dwarf galaxies resembling the first galaxies formed at early epochs. I will present observational evidence that a population of IMBHs exists in dwarf galaxies based on the X-ray stacking analysis of low-mass galaxies in the Chandra COSMOS-Legacy survey and on the finding of AGN X-ray emission in 40 dwarf galaxies at redshifts 2. One of the dwarf galaxies has a stellar mass of 7e7 Msun and is the least massive galaxy found so far to host an AGN. Unlike massive galaxies, the AGN fraction of lowmass galaxies is found to decrease with redshift, suggesting that AGN in dwarf galaxies evolve differently than those in high-mass galaxies. The future large, deep, multiwavelength surveys that will result from the synergy of next decade missions such as Athena with major optical/IR facilities will allow us to detect IMBHs in fainter (less massive) and more distant galaxies and thus to better understand how supermassive black holes in the early Universe formed.

E1.12-0024-18 PHYSICAL PROPERTIES OF THE HIGHEST REDSHIFT SUPERMASSIVE BLACK HOLES

Benny Trakhtenbrot, benny.trakhtenbrot@phys.ethz.ch ETH Zürich, Zurich, Switzerland

I will review the current understanding of key physical properties of some of the first generation of growing supermassive black holes (SMBHs). This includes their accretion rates and history, their host galaxies, and the large-scale environments that enabled their emergence about a billion years after the big bang. The available multi-wavelength data show that these SMBHs are consistent with Eddington-limited, radiatively efficient accretion that had to proceed almost continuously since very early epochs. New ALMA data confirms high SFRs and gas content in the host galaxies, and moreover a high fraction of companion, interacting galaxies, separated by 10-50 kpc. This clearly supports the idea that the first generation of luminous SMBHs grew in overdense environments, and that major mergers are important drivers for rapid early SMBH and host galaxy growth, although other fueling processes and accretion modes may still be required. Current X-ray surveys cannot access the lower-mass counterparts of these rare massive quasars, which would elucidate the earliest stages of BH formation and growth. Such low-mass nuclear BHs will be the prime targets of the deepest surveys foreseen for the next generation of X-ray space observatories, such as the upcoming ESA Athena mission and the NASA Lynx mission concept.

E1.12-0025-18 INVESTIGATING THE EVOLUTION OF SUPERMASSIVE BLACK HOLES (SMBHS) AS A FUNCTION OF REDSHIFT

Nasser Abu Seif, nasser_astro@hotmail.com

National Research Institute of Astronomy and Geophysics (NRIAG), Cairo, Egypt Demosthenes Kazanas, demos.kazanas@nasa.gov

NASA/GSFC, Greenbelt, Maryland, United States Sylvain Veilleux, veilleux@astro.umd.edu

University of Maryland, College Park, College Park, Maryland, United States Mohamed El-Nawawy, msnawawy@yahoo.com

Cairo UNiversity/ Faculty of Science, Giza, Egypt

We aim to establish a new database to obtain a large statistical sample of SMBH in QSOs at different values of redshift, the database having the width of an emission line (e.g., H, Mg II and C IV). These advantages allow us to obtain many of L (5100 Acirc) and MBH estimates of QSO to show significant evolution for any value of MBH as a function of redshift and cosmic time. We also, investigated the evolution and distribution of SMBH masses over cosmic time with concentration on SMBH at high redshift. We aimed to answer the question: how does the black hole grow with cosmic time and how does the mass of SMBHs correlate to other QSO properties, such as their luminosity and optical line FWHM to show the existence of any significant evolution over cosmic time. This study may provide a useful way to probe for tracing the history of BH growth in distant Compton-thin QSOs; and in the universe and also display the birth and growth of the first Black Hole. We found poor correlations between H FWHM and Mg II FWHM and also between Mg II and C IV FWHMs interesting, as this implies different MBH for the same object. The fact of the matter is that MBH (H) are the most reliable of these measurements, MBH (Mg II) are slightly less reliable and MBH (C IV) are not reliable due to the effects of winds and reddening. Our research found that the maximum peak of the mass of QSOs (BHs) grows with increased redshift. Here, we found that the more massive BHs achieve most of their growth at a very early epoch in high redshift, such as Z > 5.5, while QSOs tend to have a lower mass black hole at lower redshift. This process is called Downsizing. We find the maximum peak in the mass of QSOs for all samples of QSOs is 109 M, with a few exceptionally massive objects reaching 1010 M. So, a SMBH containing between a million and a billion times the mass of the Sun gives off as much as 10 billion times the Sun's energy. One of the most interesting results from this work is the relatively poor correlations between H and Mg II FWHM and between Mg II and CIV FWHMs. This implies different M BH for the same object.

E1.12-0027-18 X-RAY SELECTED AGNS BEHIND THE SMC

Chandreyee Maitra, cmaitra@mpe.mpg.de

Max Planck Institute for Extraterrestrial Physics, 85741, Germany Frank Haberl, fwh@mpe.mpg.de

Max Planck Institute for Extraterrestrial Physics, Garching, Germany Valentin D. Ivanov, vivanov@eso.org

ESO, Garching, Germany

Finding Active Galactic Nuclei (AGNs) behind the Magellanic Clouds is difficult because of the high stellar density in these fields. Although the first AGNs behind the Small Magellanic Cloud (SMC) was reported in the 1980's, it is only recently that the number of AGNs behind the SMC has increased by several orders of magnitude. AGNs behind the SMC are of several scientific interests, including an astrometric reference system needed to derive precise coordinates, especially for proper motion studies. The mid-infrared color selection technique has been proven to be an efficient mean of identifying AGNs, especially obscured sources. The X-ray regime is also complimentary in this regard. We present a catalog of AGNs behind the SMC by correlating the XMM-Newton X-ray point source catalog of the SMC with already known AGNs from literature, as well as candidates obtained from the ALLWISE mid-infrared color selection criterion. The redshift and luminosity distribution of the sample indicate that we detect sources from nearby Seyfert galaxies to distant and obscured quasars. The X-ray hardness ratios are compatible with those typically expected for AGNs. The near-infrared colors and variability are also consistent in this regard. We also present a sample of new candidate AGNs and candidates for highly obscured AGNs. All of these make an interesting subset for further follow-up studies.

Pontificia Universidad Catolica de Chile, Santiago, Chile

Thick gas and dust obscures most active galactic nuclei. However, little is currently known about its geometry, origin and why the covering factors are so high. With NuSTAR spectroscopy, we can now probe the geometry of the obscurer through its X-ray reprocessing effects at 8-40keV. We quickly learn that current models have severe difficulties, and do not produce the observed spectral shapes. To highlight this, I present a new hard X-ray color-color diagram, contrasting Compton-humps of observations and existing models. We also illuminate new physically-motivated AGN obscurer geometries. The observed colors that are difficult to reach by models allow general conclusions about the arrangement of gas and dust around AGN, and directions for future models.

E1.12-0030-18 A GLOBAL MILLIMETER VLBI ARRAY SURVEY OF COMPACT EXTRA GALACTIC RADIO SOURCES AT 86 GHZ

Very Long Baseline Interferometry (VLBI) Observations at 86 GHz reach a resolution of about 50 µas and sample the scales as small as 103 - 104 Schwarzschild radii of the central black hole in Active Galactic Nuclei (AGN), and uncover the jet regions where acceleration and collimation of the relativistic flow takes place. We present the results from a large global VLBI survey of 162 ultra compact radio sources at 86 GHz conducted in 2010-2011. This survey has contributed an increase of 2 on the total number of AGN imaged with VLBI at 86 GHz. The survey data attained a baseline sensitivity of 0.1 Jy and a typical image sensitivity of 5 mJy/beam.

We have used Gaussian model fitting to represent the structure of the observed sources and to estimate the flux densities and sizes of the core and jet components. The model fitting yields estimates of the brightness temperature (Tb) of the VLBI bright core (base) of the jet and inner jet components of AGN, taking into account the resolution limits of the data at 3 mm. The modelfit-based estimates of Tb were compared to the estimates of brightness temperature limits made directly from the visibility data, demonstrating a good correlation between the two methods.

We have applied a basic population model with a single value of intrinsic brightness temperature, T0, in order to reproduce the observed distribution of Tb. Our data are consistent with a population of sources that have T0 = (3.77 0.14)×1011 K in the VLBI cores, implying that the inverse Compton losses dominate the emission and T0 = (1.42 0.19)×1011 K in the jets, which is slightly higher than the equipartition limit of 5.0×1010 K expected for these jet regions. For objects with sufficient structural detail detected, we also investigated the effect of adiabatic energy losses on the evolution of brightness temperature along the jet.

Under the equipartition condition between the magnetic field energy and particle energy density, the absolute distance of the VLBI core from the central engine can be estimated. The brightness temperature measurements obtained from this survey at 86 GHz are combined with the database of VLBI survey at lower frequencies (2, 8 and 15 GHz) to study the brightness temperatures in source frame in the sub-parsec scale of the ultra compact radio sources. From the vicinity of the central engine, the brightness temperature increases slowly and then rises with a steeper slope and then slow down. This gives a strong implication that the jets are accelerated and collimated by the magnetically driven force, as predicted by the relativistic inner jet models for the magnetic acceleration.

E1.13-0001-18 PULSATING ULXS: HIGHLY MAGNETISED NEUTRON STARS AT EXTREME MASS ACCRETION RATES

Alexander Mushtukov, al.mushtukov@gmail.com University of Amsterdam, Amsterdam, Netherlands

X-ray pulsars (XRPs) form a special class in a family of accreting neutron stars (NSs). They stand out from the other classes due to their strong magnetic field, which typically exceeds 1012 G and affects even fundamental properties of matter. Magnetic field funnels the accretion flow and its gravitational energy is released in the form of X-rays coming from the compact area on the NS surface. Recent discoveries of pulsations from ultra-luminous X-ray sources (ULXs) have opened a new chapter in studies of XRPs. The classical theoretical limitation for luminosity is given by the Eddington value, which is about 2 1038 erg/s for NSs. Discovery of ULXs powered by accreting NSs is a challenge for theoretical astrophysics opening new questions on how accreting NSs can exceed the Eddington limit by at least two orders of magnitude.

I will discuss the features of XRPs, which arise and become essential at extremely high mass accretion rates: (1) accretion columns, which arise at super-critical mass accretion rates and provide a principal possibility to exceed the Eddington value, (2) optically thick envelopes, which are formed by hot accretion flow at the magnetospheric surface and can affect the spectral and timing properties of ULX pulsars, and (3) possibly strong neutrino emission at extreme mass accretion rates.

The discovery that some ultraluminous X-ray sources (ULXs) are powered by accretion on to neutron stars has revolutionized the field of super-Eddington accretion. Given their observed luminosities, these neutron stars are exceeding their Eddington limits by factors of up to 500. Much debate has taken place regarding the strength of their magnetic fields, which may provide the answer as to how these compact objects can shine so brightly. We have recently discovered a cyclotron resonance scattering feature in the X-ray spectrum of a ULX. Not only does this identify the source as another neutron-star-powered ULX, but it offers us a direct measurement of the magnetic field strength of the neutron star. I will present the observational constraints on the feature and what interpretations can be drawn from it.

E1.13-0003-18 NUMERICAL SIMULATIONS OF SUEPER-EDDINGTON ACCRETION FLOWS AND OUTFLOWS AROUND BLACK HOLES AND NEUTRON STARS

Ken Ohsuga, ken.ohsuga@gmail.com

National Astronomical Observatory of Japan, Mitaka, Japan

By performing multi-dimensional radiation-MHD simulations, we reveal the inflow-outflow structure around the black holes (BHs) and the neutron stars (NSs). In both cases, the quasisteady, super-Eddington disk forms around the central objects. The disk is supported by the strong radiation pressure and the radiatively-driven outflows are launched from the disk surface. The hot outflow produces the high-energy X-ray photons via Comptonization. In addition, powerful outflows fragments into many gas clouds by the radiation RT instability. Such gas clouds would lead to the X-ray time variation with several seconds for the stellar mass black holes. Our results basically consistent with the recent observations of ultraluminous X-ray sources.

E1.13-0004-18 SUPER-EDDINGTON X-RAY PULSAR SWIFT J0243.6+6124 AS SEEN WITH ASTROSAT

Swift J0243.6+6124 is a newly discovered X-ray pulsar, with a spin period of 9.85 sec, that went into outburst in October 2017. This system is of particular interest because it exhibited a super-Eddington X-ray luminosity (Lx 5x1038 erg/sec, assuming a source distance of 4 kpc) within a month of outburst onset. In contrast to what is seen in other similar sources (like 4U 0115+63), a radio jet was observed at peak Lx. I will present results of a 50,000 sec observation made by the Large Area X-ray Proportional Counter (LAXPC) and Soft X-ray Telescope (SXT) onboard Astrosat at the beginning of the outburst, when Lx 3x1037 erg/sec. The LAXPC data shows clear pulsations at around 9.85 seconds and a pulse-profile that varies significantly with energy. Our analysis of SXT and LAXPC data finds the broadband spectrum is well-fit by a two-component model (an absorbed blackbody plus cut-off power-law model). Finally, I will discuss the link between the pulse-profile characteristics and broadband spectrum.

E1.13-0005-18 DISK OUTFLOWS AND X-RAY SPECTRAL APPEARANCE OF NEUTRON STAR VERSUS BLACK HOLE ULXS

Roberto Soria, roberto.soria@curtin.edu.au

University of the Chinese Academy of Sciences, Beijing, China

The standard model for super-Eddington accretion flows (based on analytical work and GRMHD simulations) consists of a lower-density polar funnel and a thick disk outflow. SuperEddington sources viewed down the funnel are predicted to have harder X-ray spectra and higher apparent luminosity; the same sources viewed at higher inclination would have a softer spectrum (due to Compton down-scattering in the wind) and appear fainter. Although this scenario is probably applicable to some individual sources, we will argue that it is not consistent with the observed statistical properties of the ULX population. It is also difficult to reconcile this collimated scenario with the quasi-spherical ionized bubbles observed around several ULXs.

The reason why the funnel/outflow scenario struggles against the observations may be that it is only applicable to black holes and to weakly magnetized neutron stars. No strong outflows and funnels are expected for strongly magnetized, super-Eddington neutron stars, whose X-ray spectra would appear harder even at high inclination. If so, it means that the majority of ULXs are neutron stars (consistent with the shape of the cumulative luminosity distribution of this population). We will briefly discuss other tests to identify a neutron star ULX when X-ray pulsations are not detected.

Ultraluminous X-ray sources are an enigmatic population of X-ray binary with luminosities that exceed the Eddington limit for a standard 10 Msun stellar remnant black hole. Following a series of remarkable recent discoveries, primarily led by the NuSTAR X-ray observatory, we now know that some of the most luminous members of this population are actually powered by highly super-Eddington pulsars. These remarkable sources can reach apparent X-ray luminosities of 500 Eddington, making them the most extreme persistent accretors known! I will discuss the broadband X-ray characteristics of the known pulsar ULXs and their connection with the broader ULX population, focusing in particular on the implications for the demographics of the accretors powering these sources.

E1.13-0007-18 DISCOVERY OF A RELATIVISTIC JET IN A SUPER-EDDINGTON X-RAY PULSAR

University of Alberta, Edmonton, Canada

Relativistic jets are a universal phenomenon in accreting systems, yet the physical process underlying their formation is poorly understood. A key approach to understanding jet formation is constraining the conditions in which jets are launched. We present the discovery of a relativistic jet in the newly-discovered transient X-ray pulsar Swift J0243.6+6143 with the Very Large Array. While no radio emission is detected at the start of the outburst, optically thin radio emission emerges as the source accretes at super-Eddington rates. Subsequently, it transitions into optically thick emission as the outbursts decays below the Eddington limit, suggesting that the jet transitions from discrete ejecta into a steady, compact jet. This jet detection disproves the long-standing paradigm that strong neutron star magnetic fields (B > 1012 G), as in Swift J0243.6+6143, inhibit the formation of jets. It also constitutes the first monitoring of the evolution of a super-Eddington accretor jet and the first detection of disk-jet coupling in such a system. We will discuss the implications of these results for the formation of jets in accreting NSs specifically and super-Eddington accreting compact objects in general.

E1.13-0008-18 CHANDRA/HETGS OBSERVATIONS OF SMC X-3 AT A LUMINOSITY OF 10 L_EDD.

The discovery that 3 ultra luminous X-ray sources are powered by accretion onto highly magnetized neutron stars has been a breakthrough in our understanding of super-Eddington accretion. These results suggest that neutron stars contribute to a large fraction of the observed ULX population. The sample of local high magnetic field neutron stars present an opportunity to study such high luminosity accretion flows. The Be/X-ray binary systems are excellent targets, with large magnetic fields (>1e12 G) and quasi-regular outbursts that reach values far in excess of the Eddington limit for a canonical neutron star (Lx 2e38 erg/s). We will present the re- sults of a high spectral resolution Chandra/ HETGS observation of the Small Magellanic Cloud Be/X-ray binary SMC X-3 during a giant/type-II outburst in 2016. The source was observed at a luminosity of Lx 2e39 erg/s or approximately 10 times the Eddington limit. The high quality grating data reveal numerous highly ionized emission lines. We will discuss the constraints these spectra place on our understanding of models for the super Eddington accretion flow onto a highly magnetized neutron star.

E1.13-0009-18 TIME-DEPENDENT NUMERICAL SIMULATION OF EDDINGTON AND SUPEREDDINGTON ACCRETION FLOWS ONTO BLACK HOLES AND NEUTRON STARS USING SMOOTHED PARTICLE HYDRODYNAMICS

Ayan Bhattacharjee, ayan12@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

We use Smoothed Particle Hydrodynamics (SPH) technique to simulate the formation of TwoComponent Advective Flow (TCAF) for accretion onto black holes and neutron stars in presence of cooling and viscous effects. We vary the accretion rates from sub-Eddington to superEddington for flows having different values of injected angular momentum and viscosity. We study the time-dependent variation of the accretion disk and the outflow geometry for such cases when the radiative pressure of the flow (for both BHs and NSs) and of the normal boundary layer (NBOL, for NS) is included. We show 1)for black holes and neutron stars, super-Eddington accretion is highly likely when strong outflows are present, 2)how the value of viscosity limits the accretion rate, 3)how the limiting value is decreased for the case of NS due to the presence of NBOL. We also compare our findings from the numerical simulation with the observed X-ray data for a few black holes and neutron stars.

E1.13-0010-18 DISK-OUTFLOW COUPLING: MAGNETIZED SUBTO SUPER-EDDINGTON ACCRETION FLOWS AROUND BLACK HOLES

Tushar Mondal, mtushar@iisc.ac.in

Indian Institute of Science, Bangalore, India Banibrata Mukhopadhyay, bm@iisc.ac.in Indian Institute of Science, Bangalore, India

Symbiotic description of accretion and outflow/jet appears to be indispensable, when there are lots of evidence that accretion and outflow influence each other. The most self-consistent approach towards this venture is the coupled 2.5-dimensional disk-outflow system, which we explore in the presence of large-scale magnetic field enabling angular momentum transport, when the magnetic field plays an indispensable role in order to generate vertical flux. Here, we discuss the importance of large scale strong magnetic field in the removal of angular momentum outward, as well as the possible origin of different kinds of magnetic barrier in advective, geometrically thick, sub-Keplerian accretion flows around black holes. The origin of this large scale strong magnetic field near the event horizon is due to the advection of the magnetic flux by the accreting gas from the environment, say, the interstellar medium or a companion star, because of flux freezing. In this circumstance, the accreting gas either decelerates or faces the magnetic barrier near the event horizon by the accumulated magnetic field depending on the geometry. We suggest that these types of flow are the building block to produce jets and outflows in the accreting system. We also find that in some cases, when matter is trying to go back to infinity after knocking the barrier, it is prevented being escaped by the cumulative action of strong gravity and the magnetic tension, hence by another barrier. In this way, magnetic field can lock the matter in between these two barriers and it might be a plausible explanation for the formation of episodic jet. Note that generally the episodic jets occur during the transition from hard to soft states, while the continuous jets only in the hard state. Finally, we try to reproduce the observed luminosity in various accretion/jet cases: from AGNs, Blazars to ultra-luminous X-ray sources (which often are argued to be super-Eddington accretors), at different combinations of mass and spin of the black holes, ratio of specific heats and accretion rate.

E1.13-0011-18 PROPERTIES OF THE 2015 OUTBURST OF V404-CYGNI FROM SPECTRAL ANALYSIS WITH THE TCAF SOLUTION

Galactic black hole candidate V404-Cygni went through a violent outburst on June 2015 after 26 years of inactivity. Several radio and X-ray flare were observed during the 2015 outburst. We have analyzed rising phase of the outburst using 0.5-150.0 keV Swift/XRT and Swift/BAT data with two component advective flow (TCAF) model fits file in XSPEC. We have also analyzed two NuSTAR data available during our analyzing period. We find that the accretion flow during the outburst was dominated by sub-Keplerian matter. Shock was found to move closer to the black hole as outburst progressed. We did not observe a constant value of normalization, since there were high jet activity. We find the source was in hard state during the initial phase of the outburst. It become softer as outburst progressed but we could not conclude if there is any state transition due to the violent, i.e., rapidly changing accretion nature of the outburst. Spectral state was found softer after radio flare indicating mass ejection from the base of the jet or post-shock region. From the spectral analysis with the TCAF solution, we also obtain mass of the central black hole in the range of 9 – 12 M0.

V404 Cyg is one of black-hole X-ray transients, which are characterized by sporadic outbursts lasting for a few hundreds days (Tanaka & Shibazaki 1996). This object entered outbursts twice in 2015 after the 26-years quiescence, and we performed their optical photometry through the Variable Star Network (VSNET) team. We detected its optical short-term and large-amplitude variations for the first time in the 2015 June-July outburst. Some of them have repetitive patterns with amplitudes of 0.1-2.5 mag on timescales of 5-150 min, and we found these optical variations chased the simultaneous X-ray variations by comparing the simultaneous optical data and X-ray data which were taken by Swift/INTEGRAL satellites. Additionally, their optical flux were not explained only by Synchrotron emission expected by the radio flux. We thus concluded that the X-ray reprocessing was dominant in these variations (Kimura et al. 2016). Also in the 2015 December outburst, the rapid and high-amplitude optical variations were observed, and we confirmed the dominant X-ray reprocessing in these variations by the 30-s optical delay against the simultaneous X-ray variations (Kimura et al. 2017). Repetitive variability is also observed in a few other X-ray binaries. It was always observed when the luminosity was close to the Eddington luminosity, and hence, existing theory assumes the Eddington luminosity is a key condition. V404 Cyg sometimes exceeds the Eddington luminosity in the June outburst, but the repetitive patterns of optical variability in this object were detected even at low luminosity. In this presentation, we focus on the violent variability in this system and discuss its mechanism.

E1.13-0013-18 GRS 1915+105 AND MAXI J1535-571 OBSERVED BY ASTROSAT

Tomaso Belloni, tomaso.belloni@brera.inaf.it INAF, Merate, Italy

Dipankar Bhattacharya, dipankar@iucaa.in

Inter University Centre for Astronomy and Astrophysics, Pune, India

A.R. Rao, arrao@tifr.res.in

Tata Institute of Fundamental Research, Mumbai, India

I will present the results of the analysis of Astrosat observations of the two bright blackhole binaries GRS 1915+105 and MAXI J1535-571, concentrating on the data from the laxpc instrument. For GRS 1915+105 the detection of a high-frequency QPO will be presented and compared with the previous results from RXTE. For MAXI J1535-571, which was observed at a flux increasing from 2 to 3 Crab, the evolution of the low-frequency QPO and its relation to spectral and fluc changes will be analyzed.

E1.13-0014-18 THE STRANGE CASE OF IGR J17091-3624: A SUB-EDDINGTON GRS 1915+105?

James Court, j.m.court@soton.ac.uk

University of Southampton, Southampton, United Kingdom

IGR J17091-3624 is a Low Mass X-ray Binary. This object shows highly complex X-ray variability over timescales of seconds to minutes, strongly reminiscent of that seen in GRS 1915+105. The mechanism behind this variability is poorly understood, but has generally been described as being caused by the near-Eddington accretion rate of GRS 1915. We have analysed RXTE data of the 2011 outburst of IGR J17091-3624 to compare and contrast this object with GRS 1915, and have found that IGR J17091 is likely accreting at a significantly sub-Eddington rate. As such, we conclude that Eddington-limited accretion can no longer be considered a sufficient or necessary criterion for GRS 1915+105-like variability to occur in Low Mass X-Ray Binaries. We discuss the implications of these results on our understanding of these enigmatic objects.

E1.13-0015-18 SPECTRAL EVOLUTION AND SUPER EDDINGTON ACCRETION OF THE NEW BLACK HOLE CANDIDATE MAXI J1535-571 DURING ITS 2017 OUTBURST

The black hole candidate MAXI J1535-571 is a recently discovered X-ray transient. We report on the observations with Insight-HXMT and other X-ray telescopes during the outburst. We present the state transition from the hard state to the soft state overall observation duration. When the source is not in the hard state, detailed spectral analyses using a multi-temperature disk model reveal that the disk luminosity is flatter than the inner disk temperature to the fourth power, and the disk temperature profile varies as the disk radius raised to the power of −0.5, consistent with the behavior of a slim disk, implying that the disk structure has been modified due to the high luminosity of ∼ 1039 erg s−1.

E1.13-0016-18 SUPER-EDDINGTON DRIVEN WINDS IN ULTRALUMINOUS X-RAY SOURCES

Ciro Pinto, ciropinto1982@gmail.com

University of Cambridge, Cambridge, United Kingdom

The detection of fully-grown supermassive black holes powering active galactic nuclei at high redshift, when the Universe was young, challenges the theories of black holes growth, requiring long periods of high accretion, most likely above the Eddington limit. This is a focus of the next generation large missions, such as ATHENA, but cannot be done with the current instrumentation due to the large distances. Therefore, we need to study objects accreting at high Eddington rates in the nearby Universe. Most ultraluminous X-ray sources (ULXs, luminosities above 1039erg/s) show X-ray spectra that are consistent with stellar mass black holes or neutron stars accreting at or above Eddington and provide the best workbench to study super-Eddington accretion and fast growth rates. The detection of pulsations in a few ULXs confirms that some of them must be powered by neutron stars and support their compact nature and extreme accretion rates. It is not clear though how strong are their magnetic fields and what are their effects on the accretion discs. For instance, do magnetic fields inhibit radiationpressure driven winds? In this talk I will discuss our recent discoveries of relativistic outflows in archetypal ULXs and the most recent results obtained with high-resolution X-ray spectroscopy of ultra-luminous X-ray pulsars.

E1.13-0017-18 THE VERTICAL PROFILE OF ACCRETION DISKS CLOSE TO THE EDDINGTON LIMIT

Ari Laor, laor@physics.technion.ac.il Technion, Haifa, Israel

I will describe a simple analytic argument concerning the vertical profile of accretion disks close to the Eddington limit, and its implication on the observed SED and possibly on the onset of winds.

E1.13-0018-18 MODIFIED VISCOSITY AND WINDS IN ACCRETION DISKS

Mikolaj Grzedzielski, mikolaj.grzedzielski@gmail.com

Center for Theoretical Physics Polish Academy of Sciences, Warsaw, Poland Agnieszka Janiuk, agnes@cft.edu.pl

Center for Theoretical Physics of the Polish Academy of Sciences, Warsaw, Poland Bozena Czerny, bcz@camk.edu.pl

Center for Theoretical Physics of the Polish Academy of Sciences, Warsaw, Poland

Black holes surrounded by accretion disks are present in the Universe in different scales of masses, from microquasars, up to Active Galactic Nuclei. Standard geometrically thin optically thick disks based on alpha description leads to disk thermal and viscous instability when the radiation pressure dominates.

This could result in a limit-cycle behaviour operatating in this broad mass scale range. Such behaviour is observed in sources like like GRS1915+105 and IGR 17091-3624, having high (close to 1) value of Eddington ratio, with the timescales of order of ten to hundreds of seconds. In AGN the timescales are from hundreds of thousand of years, and the arguments are indirect. We will discuss the dependence of the outburst parameters on the description of the viscosity and the presence of strong winds. For example, in IGR J17091-3694 the limit-cycle oscillations are supressed by the wind launch, visible via spectral observations. We examined large grid of accretion disk models with generalized description of viscosity, which allows for an easy comparison of the theoretical model parameters and the measured observables.

As an example, we show the application of the model to determine the mass of the intermediate mass black hole of HLX-1 and its accretion rate from the observed flares, detected by the Swift X-ray satellite.

One of the great revelations of the last 20 years, and one of the great legacies of RXTE, is the discovery of the “disk-jet connection,” a strong coupling between the behavior of accretion disks and relativistic jets around stellar mass BHs. But it has also become clear that this picture of black hole accretion is incomplete, as we have amassed a growing body of evidence from high-resolution spectroscopy with Chandra that accretion disk winds play a critical role in black hole outbursts. Once thought to be simple ionized disk atmospheres, we now know that X-ray absorption lines represent outflowing winds that carry away the vast majority of the infalling matter. Focusing on observations of GRO J1655-40, I will argue that these massive winds don’t merely regulate the accretion rate at the event horizon: they can control the course of black hole outbursts. I will discuss the implications for wind driving mechanisms and, time permitting, highlight some open questions illustrated by NICER and NuSTAR observations of the recent super-Eddington outburst of MAXI J1535-571.

E1.13-0020-18 OPTICAL INTERFEROMETRY OF A MICROQUASAR: RESOLVING SUPEREDDINGTON OUTFLOWS IN SS 433

Idel Waisberg, idelw@mpe.mpg.de

Max Planck Institute for Extraterrestrial Physics, Garching Bei Muenchen, Germany Jason Dexter, jdexter@mpe.mpg.de

Institut de Planétologie et d'Astrophysique de Grenoble, Grenoble, France

SS 433 rose to astrophysical stardom in the late 1970s with the discovery of its moving optical emission lines of hydrogen and helium which were shown to originate in a mildly relativistic (0.26c), precessing baryonic jet and which established it as the first microquasar. It remains the only known super-Eddington accretor in the Galaxy, possibly an edge-on Galactic ULX. The connection between SS 433 and ULXs, the latter discovered through X-ray observations since the 1980s, has been strengthened by the recent discovery of massive outflows in ULXs akin to those seen in SS 433 and even a second system containing a baryonic relativistic jet. The VLTI instrument GRAVITY achieves sub-milliarcsecond spatial resolution in the nearinfrared, sufficient to spatially resolve both SS 433's optical massive winds and baryonic jets for the first time. Over multiple epochs, we find evidence for both a circumbinary disk and polar outflow. The jet structures are emitted closer to the compact object than predicted from optical spectroscopy, but with a consistent exponential emission profile. Using spectro-interferometry, we can further isolate discrete jet ejections and resolve the activity of the central jet in both space and time. We will also present the first XSHOOTER observations of SS 433, which for the first time provide up to 20 pairs of jet lines simultaneously and allow to constrain the conditions and heating mechanism of the optical emitting jet gas as it travels through a dense surrounding medium. We will discuss the implications of these measurements for the accretion-ejection structure of SS 433.

E1.13-0021-18 SEARCHING FOR OUTFLOWS IN ULTRALUMINOUS X-RAY SOURCES THROUGH HIGH-RESOLUTION X-RAY SPECTROSCOPY

Peter Kosec, pk394@cam.ac.uk

University of Cambridge, Cambridge, United Kingdom Ciro Pinto, ciropinto1982@gmail.com

University of Cambridge, Cambridge, United Kingdom Andy Fabian, acf@ast.cam.ac.uk

University of Cambridge, Cambridge, United Kingdom Dominic Walton, dwalton@srl.caltech.edu

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Ultraluminous pulsars are a definite proof that persistent super-Eddington accretion occurs in nature. They support the scenario according to which most Ultraluminous X-ray Sources are super-Eddington stellar mass accretors rather than intermediate mass black holes. An important prediction of theories of supercritical accretion is the existence of powerful outflows of moderately ionized gas at relativistic speeds (0.2-0.3c). In practice, the spectral resolution of X-ray gratings such as RGS onboard XMM-Newton is required to resolve their observational signatures in ULXs. Using RGS, the outflows have been discovered in the spectra of 3 ULXs (none of which are currently known to be pulsars). We studied a sample of 10 ULXs and found one which shows evidence (3σ) for a relativistic jet with a projected speed of 0.34c, another feature widely predicted by the models of super-Eddington accretion. The rest do not have high enough data quality for a significant detection but most show signatures similar to those of ULXs with known outflows. A majority also exhibits narrow emission lines which could originate in photoionized, or shocked gas (as the potential outflow hits the surrounding medium). Most recently, the 4th ultraluminous pulsar was discovered in NGC 300. I will present the results of a rigorous, in-depth search for a relativistic wind in the spectrum of this object using all available X-ray data.

E1.13-0022-18 A NEW, CLEAN CATALOGUE OF ULXS IN NEARBY GALAXIES

Hannah Earnshaw, hpearn@caltech.edu

Caltech / IPAC, Pasadena, California, United States Tim Roberts, t.p.roberts@durham.ac.uk

Durham University, United Kingdom

Matt Middleton, m.j.middleton@soton.ac.uk

University of Southampton, Southampton, United Kingdom Dominic Walton, dwalton@ast.cam.ac.uk

Institute of Astronomy, University of Cambridge, Cambridge, United Kingdom Silvia Mateos, mateos@ifca.unican.es

Instituto de Fisica de Cantabria (CSIC-UC), Santander, Spain

Study of the wider population of super-Eddington accreting objects is facilitated by the existence of catalogues of ultraluminous X-ray sources (ULXs). We have created a new, clean catalogue of extragalactic non-nuclear X-ray sources by correlating the 3XMM-DR4 data release of the XMM-Newton Serendipitous Source Catalogue with the Third Reference Catalogue of Bright Galaxies and the Catalogue of Neighbouring Galaxies, using an improved version of the method presented in Walton et al. (2011). Our catalogue contains 1,467 sources, of which 381 are candidate ULXs. Our resulting catalogue improves upon previous catalogues in its handling of contaminants by taking into account XMM-Newton quality flags, and we estimate the contamination of ULXs by background sources to be 19%. We define a 'complete' subsample as those ULXs in galaxies for which the sensitivity limit is below 1039 erg s1 and use it to examine the hardness ratio properties between ULX and non-ULX sources, and ULXs in different classes of host galaxy. We find that ULXs have a similar hardness ratio distribution to lower-luminosity sources, consistent with previous studies. We also find that ULXs in spiral and elliptical host galaxies have similar distributions except for a hard subpopulation found in spirals, which we postulate is due to high levels of absorption within the host galaxy rather than any intrinsic difference in the spectral shape of the ULXs. Our catalogue contains further interesting subpopulations for future study, including Eddington Threshold sources and highly variable ULXs, and we give an overview of science that has been performed with these subsamples so far. We also examine the highest-luminosity ULXs in our catalogue in search of IMBH candidates, and find eight new possible candidates.

E1.13-0023-18 COMPARE SUPER-EDDINGTON ACCRETION DISKS ONTO STELLAR MASS AND SUPERMASSIVE BLACK HOLES

Yanfei Jiang, yanfei@kitp.ucsb.edu

University of California Santa Barbara, Santa Barbara, California, United States

Supper-Eddington accretion is expected to happen for both stellar mass black holes as in some ULXs and supermassive black holes as for tidal disruption events. Structures of accretion disks are normally expected to be similar for the two types of black holes. However, one important difference is the ratio between radiation pressure and gas pressure, which significantly affects the properties of MRI turbulence and disk structures. I will describe a series of 3D global radiation magneto-hydrodynamic simulations for super-Eddington accretion disks for the two types of black holes with a wide range of accretion rates. I will show the importance of density waves in the supermassive black hole case due to the strong radiation pressure. Flow structures, outflow properties, radiative efficiencies and observational properties of super-Eddington accretion disks in the two regimes will also be compared.

E1.13-0024-18 RELATIVISTIC BARYONIC JETS FROM AN ULTRALUMINOUS SUPERSOFT X-RAY SOURCE

Jifeng Liu, jfliu@nao.cas.cn

National Astronomical Observatories Of China (NAOC), Chaoyang, China

While ultraluminous supersoft X-ray sources (ULSs) bear features for intermediate mass black holes or very massive white dwarfs possibly close to Chandrasekhar mass limit, our recent discovery of processing relativistic baryonic jets from a prototype ULS in M81 demonstrate that they are not IMBHs or WDs, but black holes accreting at super-Eddington rates. This discovery strengthens the recent ideas that ULXs are stellar black holes with supercritical accretion, and provides a vivid manifestation of what happens when a black hole devours too much, that is, it will generate thick disk winds and fire out sub-relativistic baryonic jets along the funnel as predicted by recent numerical simulations.

E1.13-0025-18 THE DONOR STARS OF ULTRALUMINOUS X-RAY SOURCES

Marianne Heida, mheida@caltech.edu

Manuel Torres, manuel.perez.torres@iac.es IAC, Santa Cruz De Tenerife, Spain Kristhell Lopez, k.m.lopez@sron.nl

SRON Netherlands Institute for Space Research, Utrecht, Netherlands

Ultraluminous X-ray sources (ULXs) are the most extreme X-ray binaries in the Universe. As the large majority of ULXs are extragalactic objects and their optical emission is in most cases dominated by the accretion disc, spectroscopic identification of ULX donors is challenging. Many ULXs are believed to have high mass donor stars as they are found in or near star forming regions. This makes them possible progenitors for the black hole mergers discovered by LIGO. To learn where they fit in the picture of massive binary star evolution, knowledge of the donor stars in these systems is crucial. Detecting stellar absorption lines is also necessary to obtain dynamical mass measurements, which is the only direct way to determine the mass of any black hole accretors in ULXs.

Of the five ULX donor stars that have been identified spectroscopically, three are red supergiants discovered in our near-IR survey of nearby ULXs. The photometric part of this survey is now finished and our spectroscopic follow-up campaign, to classify the counterparts and monitor the ones that are confirmed to be stellar, is well underway. I will show the latest results of this campaign and discuss the opportunities afforded by upcoming facilities such as JWST and 30-m class telescopes.

E1.13-0026-18 A SPITZER TIME-DOMAIN INVESTIGATION OF MID-INFRARED COUNTERPARTS OF ULTRALUMINOUS X-RAY SOURCES

Ryan Lau, ryanlau@caltech.edu

California Institute of Technology, South Pasadena, California, United States Marianne Heida, mheida@caltech.edu

California Institute of Technology, Pasadena, California, United States Dominic Walton, dwalton@srl.caltech.edu

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Mansi Kasliwal, mansi@astro.caltech.edu

California Institute of Technology, Pasadena, California, United States

We present mid-infrared (IR) light curves of the Ultraluminous X-ray Sources (ULX) taken by the Spitzer Space Telescope at 3.6 and 4.5 m in the Spitzer Infrared Intensive Transients Survey. We highlight the observations of the well-studied ULX Holmberg II X-1, which exhibits variability in the mid-IR. The mid-IR emission from Holmberg II X-1 is determined to arise primarily from dust emission rather than from a jet or an accretion disk outflow. A comparison of Holmberg II X-1 with a sample of spectroscopically identified massive stars in the Large Magellanic Cloud on a mid-IR color-magnitude diagram suggests that the mass donor in X-1 is a supergiant (sg) B[e]-star. The sgB[e]-interpretation is consistent with the derived dust properties and the presence of the [Fe II] (= 1.644 m) emission line revealed from previous near-IR studies of X-1. We attribute the mid-IR variability of X-1 to the increased heating of dust located in a circumbinary torus. It is unclear what physical processes are responsible for the increased dust heating; however, it does not appear to be associated with the X-ray flux from the ULX, given the constant X-ray luminosities provided by serendipitous, nearcontemporaneous X-ray observations around the first mid-IR variability event in 2014. Our results highlight the importance of mid-IR observations of luminous X-ray sources traditionally studied at X-ray and radio wavelengths.

E1.13-0027-18 SPECTRAL PREDICTIONS FROM SUPER-EDDINGTON ACCRETION SIMULATIONS

Shane Davis, swd8g@virginia.edu

University of Virginia, Charlottesville, Virginia, United States

The study of super-Eddington accretion is essential to our understanding of the growth of supermassive black holes in the early universe, the accretion of tidally disrupted stars, and the nature of ultraluminous X-ray sources. Unfortunately, this mode of accretion is particularly difficult to model because of the multidimensionality of the flow, the importance magnetohydrodynamic turbulence, and the dominant dynamical role played by radiation forces. However, recent increases in computing power and advances in algorithms are facilitating major improvements in our ability to model radiation in numerical simulations of astrophysical plasmas. I will briefly describe our new radiation transfer modules and discuss our efforts to model super-Eddington accretion flows around stellar mass and supermassive black holes. I will focus on the predictions of the spectrum from these simulations generated using Monte Carlo radiation transfer methods to post process the numerical simulations.

E1.13-0028-18 SUPER-EDDINGTON ACCRETION IN TIDAL DISRUPTION EVENTS

Lixin Dai, phycosimo@gmail.com

Niels Bohr Institute, Copenhagen, Denmark Nathaniel Roth, nroth@astro.umd.edu

University of Maryland, College Park, College Park, Maryland, United States Jonathan McKinney, jcm@umd.edu

University of Maryland, College Park, College Park, Maryland, United States Enrico Ramirez-Ruiz, enrico@ucolick.org

University of California, Santa Cruz, Santa Cruz, California, United States Cole Miller, miller@astro.umd.edu

University of Maryland, College Park, Maryland, United States

In a tidal disruption event (TDE), a star is disrupted close to a supermassive black hole by the overpowering tidal force. Stellar debris is fed to the black hole at a rate determined by the black hole mass and spin as well as the stellar structure and orbital parameters. This rate can be as high as hundred times of the Eddington accretion rate of the black hole. As compared to the scenario in Active Galactic Nuclei or X-ray binaries, a TDE disk is formed at a much closer distance to the black hole. Therefore, TDEs likely provide the best environment to study superEddington accretion onto supermassive black holes in the local universe. I will talk about our general-relativistic radiation magnetohydrodynamics simulation of a compact super-Eddington disk resembling disks assembled in TDEs. Wide-angle, optically thick winds are produced from the radiation pressure dominated thick disk, and a relativistic jet can be produced when conditions are optimal. Emissions produced from the inner disk are reprocessed in the outflows, and the observed emissions sensitively depend on the viewing angle of the observer. I will also discuss how this leads to a unified model for TDEs, which can explain various classes of TDEs that have been observed.

E1.13-0029-18 THE EFFECTS OF RADIATION PRESSURE ON DUSTY GAS: SUPER-EDDINGTON OUTFLOWS IN NORMAL AGN

Andy Fabian, acf@ast.cam.ac.uk

University of Cambridge, Cambridge, United Kingdom Wako Ishibashi, wako@physik.uzh.ch

Switzerland

Claudio Ricci, claudio.ricci.astro@gmail.com

Pontificia Universidad Catolica de Chile, Santiago, Chile

The force due to UV radiation acting on gas with a typical Galactic dust content is about 1000 times greater than the radiation force on ionized hydrogen due to Thomson scattering of electrons. If we consider that the Eddington limit occurs when the radiation force of an object equals its gravitational attraction, then AGN which exceed 0.1% of the Eddington limit for ionized gas alone can be Super-Eddington for dusty gas. The UV absorption is rapidly absorbed however so the effective limit is a function of the column density of the gas. An outflow region is defined in the Eddington fraction - column density plane. Observational evidence for this will be presented and discussed together with modelling of the dynamics of momentum-driven outflows seen in many AGN. Much that is learned from dusty outflows should be relevant to all Super-Eddington outflows.

E1.13-0030-18 MULTI-WAVELENGTH OBSERVATIONS OF THE SUPER-EDDINGTON ACCRETION FLOW IN NARROW-LINE SEYFERT 1 GALAXIES

Chichuan Jin, jinchichuan@gmail.com

National Astronomical Observatories, CAS, Beijing, China Chris Done, chris.done@durham.ac.uk

Durham University, Durham, United Kingdom Martin Ward, m.ward

Durham University, Durham, United Kingdom Emma Gardner, elzgardner@gmail.com Durham University, 3LE, United Kingdom

The most powerful accretion and radiation processes in the Universe can be found in superEddington AGN. Among them, super-Eddington Narrow-line Seyfert 1 Galaxies (NLS1s) are the most ideal targets for observations with current instruments. This is because they are both bright and highly variable, and so can provide high-quality data for detailed investigation of the accretion flow. In this talk, I will present multi-wavelength spectral-timing properties and the broadband spectral energy distribution of unobscured super-Eddington NLS1s. I will show that these observational results can be explained in a unified accretion flow scenario, which contains a standard outer disc, a puffed-up inner disc with strong disc wind and/or advection (which suppresses the radiation efficiency), an extended soft X-ray corona region, and a compact hard X-ray corona region. By considering the inclination angle effect, such a scenario has the potential to explain the X-ray complexity of all super-Eddington NLS1s, without requiring a large spin parameter. I will also show that super-Eddington NLS1s are most likely to be the low-redshift analogies of super-Eddington quasars at high redshifts. Finally, I will mention future observations that can bring new information about the super-Eddington accretion flow in AGN.

E1.13-0031-18 WHAT'S IN THE WIND? SPECTRAL SYNTHESIS FOR BROAD ABSORPTION LINE QUASARS

Karen Leighly, leighly@ou.edu

University of Oklahoma, Norman, Oklahoma, United States

Despite years of study, physical constraints on broad absorption line quasar outflows have been obtained from only a handful of objects. We introduce SimBAL, a spectral synthesis fitting method for broad absorption line quasars (BALQSOs), which uses Bayesian model calibration to compare synthetic spectra computed from photoionization model results with observed spectra. We have found that SimBAL allows us to study BALQSOs in new ways. We present results from SDSS 0850+4451, a low-ionization BALQSO, where we were able to map the physical parameters of the outflowing gas (ionization parameter, column density, covering fraction) as a function of velocity. We present results from a sample of iron low-ionization BALQSOs, where we found that the distances of the outflows from the central engine range from sub parsec to kiloparsec scales, as well as a dearth of objects with large line widths at kiloparsec distances. We discuss future prospects, and speculate on the relationship between accretion and the power source of the outflows.

E1.13-0032-18 HOW DOES THE EDDINGTON LIMIT AFFECT THE MULTIWAVELENGTH VARIABILITY OF AGN?

Douglas Buisson, djkb2@cam.ac.uk

University of Cambridge, Cambridge, United Kingdom Andy Fabian, acf@ast.cam.ac.uk

University of Cambridge, Cambridge, United Kingdom

AGN emit a significant fraction of their power as a variable X-ray continuum, which is usually observed to correlate with variability in UV/optical emission. However, such correlations are not always observed. For example, the recent 40 day long XMM-Newton large programme on IRAS 13224-3809 showed no correlation between X-ray and W1-band variability. This source is believed to be accreting at around the Eddington limit and other discoveries in the new dataset, such as a variable Ultra-Fast Outlow, demonstrate that more than the thin accretion disc and corona structure of sub-Eddington AGN is present in this source. Other highly accreting AGN also lack correlations between the observed X-ray and optical emission, suggesting that changes to the accretion flow at around the Eddington limit may be responsible for the lack of correlation. We will present results from the IRAS 13224-3809 campaign and compare these with findings from other AGN monitoring campaigns to show what such campaigns can teach us about differences in the accretion structure between moderately and highly accreting systems.

E1.13-0033-18 LONG-TERM BEHAVIORS OF THE ULTRALUMINOUS X-RAY SOURCE NGC1313 X-1

Tessei Yoshida, yoshida.tessei@astro.phys.sci.ehime-u.ac.jp Ehime University, Ehime, Japan

Ultraluminous X-ray sources (ULXs) are known to vary X-ray luminosities with one order of magnitude. However, the behavior in just rising and decaying phases during outbursts is still unclear due mainly to the sparse data sampling. Here, we analyzed a long-term monitoring data set (since 2013 June) of NGC1313 X-1 obtained with Swift/XRT. We found that X-1 has experienced the low luminosity state (about 7 1039 erg/s, a quiescent stable phase) and two types of outbursts: One is month-scale outbursts with relatively modest brightening (to

9 1039 erg/s) and spectral softening. Contrastingly, the other type shows day-scale, remarkable brightening (to 4 1040 erg/s) with spectral hardening; such an extreme luminosity has been observed only once, with Suzaku reported by Mizuno et al. (2007). We also found a distinctive behavior just before some outbursts.

Based on best-fit parameters of each phase and the hysteresis variation of NGC1313 X-1, we suggest a super-critical accretion flow model composed of two parts: a moderately massive inner disk and a highly massive outer one. The luminosity and spectral variations of X-1 may be caused by moves of the transition radius which separates these two disk regions. In addition, we will mention a notable behavior during a more long period by many archival data sets with other satellites.

E1.13-0034-18 ASTROSAT OBSERVATIONS OF MAXI J1535-571 DURING ITS BRIGHT 2017 OUTBURST

Aru Beri, a.beri@soton.ac.uk

University of Southampton, Southampton, United Kingdom Diego Altamirano, d.altamirano@soton.ac.uk

University of Southampton, Southampton, United Kingdom Poshak Gandhi, p.gandhi@soton.ac.uk

University of Southampton, Southampton, United Kingdom Matt Middleton, m.j.middleton@soton.ac.uk

University of Southampton, Southampton, United Kingdom

MAXI J1535-571 (J1535) is a hard X-ray transient recently discovered by the Monitor of All-sky X-ray Image (MAXI) and Swift/BAT. Radio and X-ray follow up observations showed that this system is a Low-Mass X-ray binary containing a Black Hole. This source is of particular interest, as the outburst was very bright, reaching a maximum flux of 2 Crab as seen by Swift/BAT (15- 50 keV). As a part of several multi-wavelength campaigns on J1535, AstroSat observed J1535 for a total of 5 consecutive days (between 12-17 September, 2017). The observations made with the Large Area X-ray Proportional Counter (LAXPC) instrument on-board AstroSat revealed the presence of a strong and sharp Quasi Periodic Oscillation (QPO) at 2.4 Hz. Assuming a source distance of 8 kpc, we measure the source luminosity of about 6e38 ergs/s which is close to the Eddington luminosity measured for a 10 solar mass black hole. In this talk, I will present results on this 5-days observation of the brightest LMXB transient observed with Astrosat, including a detailed analysis of the powerand lag-spectrum and the interpretation of these results, in the context of the 0.5-80 keV broadband spectra as seen by the Soft X-Ray Telescope (SXT) and LAXPC.

E1.13-0035-18 NUMERICAL SIMULATIONS OF TIME-VARYING VISCOSITY INSIDE A TWO COMPONENT ADVECTIVE FLOW STUDYING CREATION AND ANNIHILATION OF KEPLERIAN DISC DURING AN OUTBURST

Abhishek Roy, skyislowerlimit@gmail.com

S.N. Bose National Centre for Basic Sciences, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

Accretion process around compact objects needs a considerable amount of viscosity to transport angular momentum and maintain the flow at a steady rate. If the viscosity is inadequate, the rates can be time dependent. X-ray outbursts are believed to be the effect of sudden rise in viscosity which transports angular momentum efficiently and increases the accretion rates causing higher X-ray flux. As the viscosity is reduced, the outburst subsides and the object returns back to its pre-outburst quiescence stage. We perform numerical simulations considering the rise and the fall of the viscosity parameter at the outer injection grid, assumed to be located at the accumulation radius where matter from the companion is piled up before being released by enhanced viscosity. Since X-ray spectra of a black hole candidate can be explained by a Keplerian disc component in presence of a post-shock region of an advective flow, we want to understand if the flow configurations required to explain spectral states of an outbursting source could be obtained by time varying viscosity. We present our simulation results to prove that low-angular momentum (sub-Keplerian) advective flows do form a Keplerian disc in the pre-shock region when the viscosity is enhanced which disappears at a much longer time scale after the viscosity is withdrawn. From the variation of the Keplerian disc inside an advective halo, we have successfully explained the two component advective flow dynamics during an entire X-ray outburst. We also claim that the hysteresis effect of an outburst is mainly due to the difference in creation and annihilation times of the Keplerian component.

E1.13-0036-18 RELATIVISTIC ACCRETION HYDRODYNAMICS AROUND ROTATING BLACK HOLES.

Soumen Mondal, soumenjuphysics@gmail.com Jadavpur University, Kolkata, India

Using this relativistic equation of state(EOS) in which the adiabatic index Gamma(=Cp/Cv), varies smoothly from 5/3 to 4/3 as a function radius, we re-investigate the issue of the formation of the shocks in accretion and wind solutions once again. We find that except for the region very nearby the compact object, Gamma does not change significant from its non-relativistic value and therefore the EOS mostly remains non-relativistic in nature. As a consequence the existence of two saddle type critical point becomes a rare possibility indicating that it is an artifact of the choice of the constant ultra-relativistic (Gamma =4/3). Therefore, the formation of shocks in the flow (which require the presence of two saddle type points) becomes unlikely.

E1.13-0037-18 EVOLUTION OF FLOW PARAMETERS OF THE PERSISTENT X-RAY SOURCE CYGNUS X-1 USING THE TWO COMPONENT ADVECTIVE FLOW SOLUTION

Indrani Banerjee, tpib@iacs.res.in

Indian Association for the Cultivation of Science, Kolkata, India Ayan Bhattacharjee, ayan12@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India Anuvab Banerjee, anuvab.banerjee@bose.res.in

S. N. Bose National Centre for Basic Sciences, Kolkata, India Dipak Debnath, dipakcsp@gmail.com

Indian Centre for Space Physics, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

Cygnus X-1 is one of the brightest persistent galactic black hole (BH) binaries. It dwells most of the time in its hard state although it also exhibits soft-states as well as 'failed-transitions'. Because of its persistence, brightness and proximity Cygnus X-1 is a very important source to study the physics of accretion processes around black holes. In this work, we investigate the spectral behavior of the persistent black hole candidate Cygnus X-1 from December 10, 1997 to May 12, 1998 when it was in its persistent hard state as well as during one of its flaring phases, between March 12, 2003 to October 7, 2003 when the object entered into the soft/intermediate state. We use the RXTE/PCA data and apply Two-Component Advective Flow (TCAF) solution for this purpose. We classify the spectral states based on the nature of the TCAF model fitted flow parameters, namely, the disk and the halo rates, the location, size and the density of the Compton cloud produced by the post-shock flow and the accretion rate ratio (the ratio between the halo rate and the disk rate). This gives us an idea of the underlying accretion flow dynamics and provides us with evolution of the aforementioned accretion flow parameters. This is the first time that explicit flow parameters of Cygnus X-1 are obtained from the spectral analysis. From the behavior of the accretion flow parameters during the flaring phase, i.e., the dynamical evolution of the Keplerian and the sub-Keplerian rates, we conclude that the free-fall time scale is comparable to the viscous time-scale which further enables us to infer that the Keplerian disk of Cygnus X-1 is possibly quite small.

E1.13-0038-18 ACCRETION TORI AROUND KERR SMBHS: CONSTRAINTS ON RETROGRADE AND PROGRADE DOUBLE ACCRETING TORI

Daniela Pugliese, dany.pugliese@gmail.com

Silesian University in Opava, Opava, Czech Republic

We provide constraints on formation and interaction of coupled coplanar accreting tori orbiting a central Kerr SMBH, independence on its dimensionless spin. This is a comparative investigation of the prograde versus retrograde tori properties. We demonstrate that two accretion tori orbit around the central Kerr attractor only under very specific conditions. These configurations could be directly linked to the current models featuring the obscuration of galactic BHs X-ray emission. The emergence of instability phases of a torus couple, consisting in a super-Eddington accretion stage, is discussed, tori collision has been also investigated. The first evaluation of the center-of-mass energy and the accretion rates proves that the collisional energy efficiency increases with the dimensionless black hole spin, being very high for near-extreme black holes. Dynamics of the unstable phases of the double tori systems becomes significant for the high energy phenomena which could be observable in the X-ray or γ-ray emission in active galactic nuclei and quasars.

E1.13-0039-18 X-RAY OBSCURERS: BRIDGING THE GAP BETWEEN WARM ABSORBERS AND ULTRA-FAST OUTFLOWS

Jelle Kaastra, j.kaastra@sron.nl

SRON Netherlands Institute for Space Research, Utrecht, Netherlands

Outflows from active galactic nuclei are found over a broad range of distances from the supermassive black hole and with a large range of velocities. The so-called "warm absorbers" cover a broad range of ionization parameters but at modest velocities of a few hundred to thousand km/s and relatively modest column densities of typically less than 1% of the Thomson depth. On the other extreme, ultra-fast outflows with speeds of order 0.1c have column densities up to a Thomson depth but are almost fully ionized.

In this contribution, we discuss a newly discovered component, the X-ray obscurers which occupy the velocity gap and likely also the distance gap between warm absorbers and ultra-fast outflows. These obscurers have been studied in detail using deep joint monitoring observations with XMM-Newton, HST, Swift and NuSTAR in for example NGC 5548 and NGC 3783. The gas is generally lowly ionized, has high column densities up to 10% of the Thomson depth and is outflowing at speeds of several thousands of km/s. They block a significant fraction of the ionizing radiation from the central regions, are likely due to a strong accretion disk wind, and occur more frequently than previously anticipated. We discuss the impact of these obscurers on their environment, their frequency and the observational challenges to study them.

E1.13-0040-18 ORBITAL RESOLVED SPECTROSCOPY OF GX 301-2: WIND DIAGNOSTICS

Nazma Islam, nislam@camk.edu.pl

Nicolaus Copernicus Astronomical Center, Warsaw, Poland Biswajit Paul, bpaul@rri.res.in

Raman Research Institute, Bangalore, India

GX 301-2, a bright high-mass X-ray binary with an orbital period of 41.5 days, exhibits stable periodic orbital intensity modulations with a strong pre-periastron X-ray flare. Several models have been proposed to explain the accretion at different orbital phases, invoking accretion via stellar wind, equatorial disc, and accretion stream from the companion star. From the orbital resolved spectroscopic study of GX 301-2 with the X-ray all sky monitor MAXI, we found a very large equivalent width of the iron line for a small value of the column density in the orbital phase range 0.1-0.3 after the periastron passage. The orbital dependence of the spectral parameters favours accretion on to the neutron star occurring via a high density accretion stream plus stellar wind of the companion. We further investigate the characteristics of the accretion stream with an ASTROSAT LAXPC and SXT observation of the system.

E1.13-0041-18 THE FULL CYCLE OF SIMULATING BLACK HOLE SHADOWS: FROM RAY TRACING TO SPECTRUM-SPECIFIC IMAGES OF AN ARBITRARILY SHAPED SCREEN

Vladimir Strokov, vnstrokov@gmail.com

Lebedev Physical Institute of Russian Academy of Sciences, Moscow, Russia Anton Popov, zalivnaja@gmail.com

Lebedev Physical Institute of Russian Academy of Sciences, Moscow, Russia

We present a bundle of codes which realize the full cycle of simulation of black hole shadows: from massive ray tracing to depicting the shadow and its spatial Fourier transform for an arbitrarily shaped luminous screen and the radiation spectrum of the latter. Unlike available public codes, which mostly deal with ray tracing alone, our code implements the entire workflow up to providing the resulting image in a digital format. The ray tracing is parallelized on graphics processing units (GPUs) which reduces the simulation time to a few seconds. This allows for exploiting the output of the code as an input in Monte Carlo routines that fit observational data to theoretical models. It is highly relevant in view of the upcoming Event Horizon Telescope data which will make it possible to constrain the geometry and physics of accretion disks by their direct images.

E1.13-0042-18 HOW OUTFLOWS ARE COLLIMATED AND ACCELERATED? – ROLE OF TOROIDAL MAGNETIC FLUX TUBES

Arnab Deb, arnabdeb1988@gmail.com

S. N. Bose National Centre for Basic Sciences, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India Kinsuk Giri, kinsuk@nitttrkol.ac.in

National Institute of Technical Teachers' Training & Research (NITTTR), Kolkata, Kolkata, India

Observations in the two spectral regions of the electromagnetic spectrum, in the domain of the hard X-rays on one hand, and in the domain of radio wavelengths on the other hand, revealed existence of relativistic jets known as microquasars or nano-quasars. It has been shown that the relativistic jets with significant matter content and kinematic luminosity are produced when the inner part of the disk is destroyed and evacuated. Clearly, Magnetic field has to play a major role in origin, acceleration and collimation of these relativistic jets.

Due to predominantly rotating accretion flows close to the inner edge of a disk, magnetic fields advected through the flow would be toroidal. We study the trajectories of these toroidal flux tubes inside a time dependent geometrically thick flow which undergoes a centrifugal force supported shock. These flux tubes are under the influence of drag force, tension, Coriolis force and buoyancy force. We also study effects of these flux tubes on the dynamics of the inflow and the outflow specifically focussing on the outflow properties such as its collimation and the rate. It is seen that depending upon the cross sectional radius of the flux tubes which control the drag force, these field lines may move towards the central object or oscillate vertically before eventually escaping out of the funnel wall (pressure zero surface) along the vertical direction. A comparison of results obtained with and without flux tubes clearly show the role these flux tubes play in collimation and acceleration of jets and outflows.

E1.13-0047-18 SEGREGATION OF DISC, HALO AND OUTFLOW FROM A TRANSONIC FLOW AROUND A BLACK HOLE

Kinsuk Giri, kinsuk@nitttrkol.ac.in

National Institute of Technical Teachers' Training & Research (NITTTR), Kolkata, Kolkata, India

Arnab Deb, arnabdeb1988@gmail.com

S. N. Bose National Centre for Basic Sciences, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

Rigorous numerical simulations of rotating, axisymmetric, two dimensional viscous accretion flows in presence of cooling around black holes were performed using a grid based finite difference method. In our earlier works, we performed single quadrant (first quadrant) simulations for the same purpose. However, in this present work, we do not use reflection symmetry on the equatorial plane to inspect if the whole disc along with the centrifugal barrier oscillate vertically. The segregation of Keplerian disc, sub-Keplerian halo with oscillating shocks and bi-directional outflows are clearly seen in these simulations.

E1.13-0048-18 THE 2005 APPARENT OUTBURST OF XTE J1118+480: SPECTRAL STUDY WITH THE TCAF SOLUTION

Debjit Chatterjee, debjitchatterjee92@gmail.com Indian Centre for Space Physics, Kolkata, India Dipak Debnath, dipakcsp@gmail.com

S.N. Bose National Centre for Basic Sciences, Kolkata, India Arghajit Jana, argha0004@gmail.com

Indian Centre for Space Physics, Kolkata, India

We have analysed RXTE/PCA data for 2005 outburst of black hole candidate (BHC) XTE J1118+480. The spectral analysis of the source has been done with two types of model: phenomenological power-law (PL) and physical two component advective flow (TCAF) fits file in XSPEC. We notice that during the entire epoch of the outburst, accretion flow is highly dominated by the sub-Keplerian halo matters. From PL model fits, it is also evident that no signature of thermal disk black body component is found while fitting spectral with only PL model. From TCAF model fits, very low contribution from Keplerian disk component is found. From nature of the variation of the spectral fitted parameters, we defined entire period of the 2005 outburst as hard/low hard state. The entire phase of the 2005 outburst, was highly dominated by jets/outflow since high radio fluxes are observed. We also estimate the mass of the black hole and contribution of the jet X-rays from our TCAF model fitted spectral analysis.

Debnath, D., Chakrabarti, S.K., & Mondal, S., 2014, MNRAS, 440, L121 Chatterjee, D., Debnath, D., Jana, A., & Chakrabarti, S.K., 2018 (in preparation) Jana, A., Chakrabarti, S. K., & Debnath, D., 2017, ApJ, 850, 91

E1.13-0049-18 IMPLICATION OF SOFT LAG IN HIGH INCLINATION BLACK HOLE TRANSIENTS

Broja Gopal Dutta, brojadutta@gmail.com

Department of Physics, RBC College & Indian Centre for Space Physics, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

We study the time lag properties of few low and high inclination black hole sources by using the observational data of RXTE during the evolution of Quasi Periodic Oscillation (QPO). We find a positive lag for all QPO frequencies in face on sources (low inclination) while the frequency dependent time lag switches sign (positive to negative lag) at a certain crossing frequency 2-3 Hz and becomes negative for the edge on sources. We also find in both type of sources that the time lag increases when QPO frequency goes down, i.e., when the size of the Comptonizing region goes up and at around a specific QPO frequency, i.e., roughly at a specific size of the Comptonizing region, the lag changes from hard to soft (i.e., switches sign). This frequency gives rise to a characteristic length scale where the lag changes its sign. This frequency is certainly not universal as the cancellation of lags would depend on inclination angles and the mass of the black holes which determine the length scales of the Compton cloud.

E1.13-0050-18 IMPLICATIONS ON DISK DYNAMICS FROM OUTFLOWS OF TRANSIENT SOURCES

Santanu Mondal, astrophy.sm@gmail.com Universidad de Valparaiso, Valparaiso, Chile Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

The problem of origin and acceleration of jets in compact objects is still a long term unsolved problem. According to TCAF model, centrifugal pressure dominated region of the flow just outside the black hole horizon, with or without shocks, acts as the base of outflow. This region also up-scatters soft photons from the Keplerian disk, which is dependent on the accretion rate. These soft photons gain energy at each scattering in the Compton cloud and makes it cooler. Thus it creates a link between accretion, cooling and ejection. As the cooling increases, thermal pressure is reduced and the jet flow rate decreases. Specifically, the emerging spectrum is softened due to increase in cooling. Our main goal is to show spectral softening due to mass outflow in presence of Compton cooling. We also observe from our transonic solution that the softening is higher when both cooling and outflow are present as compared to the case with cooling alone. It is observed that during hard and intermediate states, the outflow rate is higher. Our theoretical findinggs agree with the observed results on outbursting candidates. We thus directly correlate the outflow rate with the spectral state of the disk.

Chakrabarti, S.K., & Titarchuk, L.G. 1995, ApJ, 455, 623

E1.13-0051-18 ENERGY DEPENDENT TIME LAGS OF PHOTONS: SIMULATION MEETS OBSERVATION

Arka Chatterjee, arka019icsp@gmail.com Indian Centre for Space Physics, Kolkata, India

Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India Himadri Ghosh, himadri.ghosh@heritageit.edu

Heritage Institute of technology, Kolkata, India

Time lags of photons originated from the accretion disk provides valuable information on the geometry of the disk. Major components that contributes to the lag variations are Comptonization, disk reflection and photon bending and are articulated in the literature. Using Monte-Carlo technique, we incorporate the aforesaid physical mechanisms considering Two Component Advective Flow (TCAF) geometry. Spectral distribution of photons emitted from TCAF are obtained. Variation of time lag with the size of Compton cloud or CENBOL, accretion rate, energy and inclination angle are reported. Finally, we compare our simulated results from TCAF with the observational results reported in the literature. We show that the the main reason for increasing time lag is the increase in size of the Compton cloud, or CENBOL.

E1.14-0001-18 THE CHERENKOV TELESCOPE ARRAY: PROJECT STATUS AND SCIENTIFIC PROGRAM

Stefano Vercellone, stefano.vercellone@brera.inaf.it

INAF - Osservatorio Astronomico di Brera, Merate, Italy CTA Consortium

See https://www.cta-observatory.org/consortium_authors/authors_2018_01.html for full author list

The Cherenkov Telescope Array (CTA) will be the next generation gamma-ray observatory, open to the scientific community, to investigate the very high-energy emission from a large variety of celestial sources in the 20 GeV - 300 TeV energy range. The full array, distributed over two sites, one in the northern and one in the southern hemisphere, will provide wholesky coverage and will improve the sensitivity with respect to the current major arrays such as H.E.S.S., MAGIC and VERITAS by a factor of five to twenty, depending on the energy. CTA will investigate a much higher number of already known classes of sources, going to much larger distances in the Universe, performing population studies, accurate variability and spatially-resolved studies. Moreover, new light will be shed on new classes of TeV sources, such as GRBs and cluster of galaxies. Furthermore, by pushing the high-energy limit to E > 100 TeV, CTA will allow a thorough exploration of the cut-off regime of the cosmic accelerators. The search for an annihilation signature of dark matter in the Galactic halo and in prominent dwarf spheroidal galaxies is one of the most important goals of CTA. We review the current status of the CTA project, introducing the highlights from the telescope prototypes and discuss the main CTA Key Science Projects, which will focus on major scientific cases, allowing us to provide legacy data-sets of high value to a wider community.

E1.14-0002-18 THE SCHWARZSCHILD-COUDER TELESCOPE: AN INNOVATIVE TECHNOLOGY FOR SCIENCE WITH THE CHERENKOV TELESCOPE ARRAY

Justin Vandenbroucke, vandenbrouck@wisc.edu

University of Wisconsin-Madison, Madison, Wisconsin, United States CTA Consortium

See https://www.cta-observatory.org/consortium_authors/authors_2018_01.html for full author list

A dual-mirror gamma-ray telescope design, called the Schwarzschild-Couder Telescope (SCT), has been proposed for imaging atmospheric Cherenkov telescopes, in particular as a type of Medium Sized Telescope providing excellent sensitivity in the core energy range (0.1 to 10 TeV) of the Cherenkov Telescope Array. The design features excellent optical resolution, enabling gamma-ray angular resolution and background rejection that are superior to the traditional single-mirror design. An international group is now constructing a prototype SCT alongside the VERITAS array at the Fred Lawrence Whipple Observatory in Arizona. The support tower, drive system, and optical support structure are in place, and primary mirror panel installation is now underway. The prototype camera, featuring silicon photomultipliers and waveform sampling digitizers, has achieved first light in the laboratory and will be installed on the telescope when the primary mirror installation is complete. I will describe the unique advantages of the SCT design as well as the status of the prototype telescope.

E1.14-0003-18 THE CHERENKOV TELESCOPE ARRAY AS A PROBE OF FUNDAMENTAL PHYSICS

Aion Viana, aion.viana@mpi-hd.mpg.de Universidade de Sao Paulo, São Carlos, Brazil CTA Consortium

See https://www.cta-observatory.org/consortium_authors/authors_2018_01.html for full author list

High-energy gamma rays can provide unique information about Particle Physics phenomena beyond the Standard Model of Particle Physics, which complements the studies performed at dedicated laboratory experiments and particle accelerators. The next generation of groundbased observatory for gamma-ray astronomy, the Cherenkov Telescope Array (CTA), will be sensitive to gamma-rays from 20 GeV to more than 300 TeV. With more than 100 telescopes located in two sites in the northern and southern hemispheres, CTA will provide full-sky coverage and will achieve an improvement by a factor of five to twenty in sensitivity with respect to the current major gamma-ray instruments. The reach of CTA encompasses considerable discovery space in the area of fundamental physics. For instance, CTA will probe the expected thermal relic cross-section for self-annihilating dark matter (DM) for a wide range of dark matter masses, including those inaccessible to the Large Hadron Collider (LHC). Besides the search for annihilation signals from dark matter, there is the exciting possibility of detecting spectral modulations in the gamma-ray emission from distant sources due to axion-like particles (ALPs), and finding evidence of Lorentz invariance violation (LIV) associated with possible quantum gravity effects on space-time at the Planck scale. In this talk, I will provide an overview of the fundamental physics topics in gamma-ray astronomy and the prospects for CTA to address them. A particular focus will be given to the CTA key science projects that relate to the studies of DM, ALPs and LIV.

E1.14-0004-18 FERMI STATUS (IN THE CONTEXT OF CTA)

Alberto Dominguez, tigudh@gmail.com

Universidad Complutense de Madrid, Madrid, Spain

The Fermi Gamma-ray Space Telescope has revolutionized our understanding of the high-energy gamma-ray Universe. Since its launch about ten years ago, its primary instrument, the Large Area Telescope (LAT), is surveying the whole sky with unique sensitivity and location accuracy. These characteristics have made possible extraordinary scientific breakthroughs and also provided fundamental support for other facilities. Furthermore, the LAT collaboration has produced different catalogs of sources for the astronomy community allowing new discoveries, follow ups, and in general, an unprecedented characterization of the GeV sky. In this contribution, we will review the latest major results from the LAT collaboration, mainly focusing on extragalactic science. There is no doubt that Fermi-LAT will be an essential instrument in the coming multi-messenger multi-energy era in which CTA will play a crucial role in the TeV range.

E1.14-0005-18 HAWC AND WIDE ANGLE GAMMA-RAY SURVEYS IN THE CTA ERA

Segev BenZvi, sybenzvi@pas.rochester.edu New York, United States

HAWC Collaboration https://www.hawc-observatory.org/collaboration/

The High-Altitude Water Cherenkov (HAWC) observatory, now completing its third full year of operations, is conducting a wide-angle survey of TeV gamma rays and cosmic rays from two-thirds of the sky. With its discoveries of extended sources in the galactic plane, its highstatistics measurements of cosmic-ray backgrounds, and its continuous long-term monitoring of galactic and extragalactic objects, HAWC is carrying out a broad science program ranging from studies of galactic particle acceleration to searches for physics beyond the Standard Model. Data from HAWC are highly complementary to the sensitive pencil-beam surveys performed by imaging air Cherenkov detectors, and provide excellent opportunities for multi-wavelength and multi-messenger studies of steady and transient objects. I will present highlights from the first three years of HAWC measurements, and discuss the many synergies between current and future wide-angle surveys and the planned CTA observatory.

E1.14-0006-18 FUTURE GAMMA-RAY MISSIONS IN THE MEV REGION AND THE CONNECTION WITH CTA

Aldo Morselli, aldo.morselli@roma2.infn.it INFN Roma Tor Vergata, Rome, Italy

The energy range between 300 KeV and 100 MeV is an experimentally very difficult range and remained uncovered since the time of COMPTEL. Future instruments like e-ASTROGAM can address all astrophysics issues left open by the current generation of instruments. In particular, a better angular resolution in the energy range 10 MeV - 1 GeV is crucial to resolve patchy and complex features of diffuse sources in the Galaxy and in the Galactic Centre as well as increasing the point source sensitivity. This instrument addresses scientific topics of great interest to the community, as matter evolution, dark matter search, antimatter generation, very energetic phenomena in compact objects and massive black holes with particular emphasis on multifrequency correlation studies involving radio, optical, IR, X-ray, soft gamma-ray and TeV emission.

E1.14-0007-18 LATTES: DESIGN AND EXPECTED PERFORMANCE FOR A HYBRID DETECTOR FOR VHE GAMMA-RAYS COMPLEMENTARY TO CTA

Ulisses Barres De Almeida, ulisses@cbpf.br

Centro Brasileiro de Pesquisas Físicas (CBPF), Rio De Janeiro, Brazil
The LATTES Team

P. Assis, U. Barres de Almeida, A. Blanco, R. Conceição, B. D'Etorre Piazzoli, A. De Angelis,

M. Doro, P. Fonte, L. Lopes, G. Matthiae, M. Pimenta, R. Shellard, B. Tome.

Current detectors for Very-High-Energy gamma-ray astrophysics are either pointing instruments with a small field of view (Cherenkov telescopes), or large field-of-view instruments with relatively large energy thresholds (extensive air shower detectors). The next generation of Cherenkov telescopes, the Cherenkov Telescope Array (CTA) will be installed in the Canary Islands and in Chile, and has already entered construction phase. Extensive air shower arrays are complementary to observatories such as CTA, as they are specially suited for detecting transient phenomena, working as a powerful trigger of extreme variable sources such as GW counterparts and gamma-ray bursts. In this talk we present the proposal for LATTES, a new hybrid extensive air shower detector, to be installed in South America, sensitive in an energy region starting from about 100 GeV. The detector combines a small water-Cherenkov detector, able to provide a calorimetric measurement of shower particles at ground, with resistive plate chambers which contribute significantly to the accurate shower geometry reconstruction. A full simulation of this detector concept shows that it is able to reach better sensitivity than any previous gamma-ray wide field-of-view experiment in the sub-TeV energy region. It is expected to detect with a 5-sigma significance a source fainter than the Crab Nebula in one year at 100GeV and, above 1TeV a source as faint as 10% of it.

E1.14-0008-18 COSMIC RAY STUDIES IN THE CTA ERA

Stefano Gabici, gabici@apc.in2p3.fr Laboratoire APC, Paris, France

More than a century after their discovery, the origin of cosmic rays is still a matter of debate. Gamma ray observations are one of the most powerful ways to test our ideas about cosmic ray origin. In this talk, I will briefly review the status of the field, with particular attention to the role of future gamma ray facilities such as the Cherenkov Telescope Array.

E1.14-0009-18 FUTURE RADIO ASTRONOMY IN THE CONTEXT OF CHERENKOV TELESCOPE ARRAY

Josep M. Paredes, jmparedes@ub.edu Universitat de Barcelona, Barcelona, Spain

In order to have a better understanding of the physics behind the non-thermal cosmic sources a multi-wavelength approach is necessary. Radio Astronomy has played a fundamental role in determining accurately the positions, structures and behaviors of many of the sources detected at gamma-rays. The synergies between radio and gamma will be strongly reinforced in the next decade thanks to the Square Kilometer Array (SKA) and the Cherenkov Telescope Array (CTA). These future new generation observatories will enable breakthrough science not possible with current facilities in radio and gamma. I will briefly report the main performances of these facilities and what kind of discoveries can we expect from the contemporaneous use of these new generation instruments.

E1.14-0010-18 X-RAY ASTRONOMY IN THE CONTEXT OF CTA

Patrick Slane, slane@cfa.harvard.edu

Harvard-Smithsonian Center for Astrophysics, Cambridge, Massachusetts, United States

The Cherenkov Telescope Array (CTA) promises to open a new frontier in very high energy gamma-ray astrophysics, with unprecedented sensitivity and angular resolution. Its broad science goals include the investigation of sites and mechanisms for particle acceleration, physical processes in the extreme environments of neutron stars and black holes, and the broad contributions of shocks, jets, and accretion to the high energy Universe. Previous observations and theoretical studies have made clear the intimate connection between gamma-ray emission in these environments and the observed properties of the associated X-ray emission. From constraints on magnetic fields and the properties of thermal gas to contemporaneous observations of variability and high-resolution studies of shocks and jets, X-ray observations provide unique insights into the environments that produce energetic gamma-rays. It is thus of crucial interest to consider the available X-ray resources for complementing gamma-ray studies in the era of CTA.

In this talk I will provide a brief summary of X-ray connections to key studies in the field of VHE gamma-ray astrophysics, and investigate future prospects for this synergy in the context of ongoing and upcoming X-ray facilities. With continued contributions from current observatories along with new capabilities provided by upcoming missions with survey capabilities, high spectral resolution, and polarimetry, the prospects for unique advances in high energy astrophysics are extremely promising.

E1.14-0011-18 COSMOLOGY IN THE CHERENKOV TELESCOPE ARRAY ERA

Daniel Mazin, mazin@icrr.u-tokyo.ac.jp University of Tokyo, Chiba, Japan

The Cherenkov Telescope Array (CTA) will be the next generation gamma-ray observatory, open to the scientific community, and with two operational sites, one each in the northern and southern hemispheres. The observatory will thus provide full-sky coverage and an energydependent improvement by a factor of five to twenty in sensitivity with respect to the current major arrays. Thanks to CTA's low energy threshold of 20 GeV and a superb flux sensitivity in the range 50 GeV to 1 TeV CTA will detect hundreds of extragalactic sources (presumably mostly blazars) both in flaring and in quiescent states in a redshift up to z=2, and even beyond in case of extraordinary flares.The resolution of CTA will allow unique identification of spectral features induced during the propagation of gamma rays in the universe, which is sensitive to the density of the Extragalactic Background Light and to the magnetic fields in voids for reprocessed gamma rays In this talk I will give prospects for CTA to perform observational cosmology by resolving the evolution of the EBL with redshift as well as measuring the intergalactic magnetic field.

E1.14-0012-18 ASTRONOMY'S NEXT: WHAT CAN WE EXPECT FROM CTA AND GRAVITATIONAL WAVES?

Szabolcs Márka, sm2375@columbia.edu

Columbia University, New York City, New York, United States

The discovery of gravitational waves and their multi-messenger fingerprint has opened tremendous opportunities for astrophysics. Instrumental breakthroughs in gravitational-wave detectors, electromagnetic and neutrino observatories shall lead to an information explosion during the coming years rapidly expanding humanity's cosmic and scientific horizon. Observations of gravitational-wave sources with the Cherenkov Telescope Array (CTA) promises opportunities that are complementary to insights with other cosmic messengers. The observation of an electromagnetic counterpart to the gravitational-wave event GW170817 by a multitude of instruments highlighted the value of multi-messenger astrophysics and indicated that short gamma-ray bursts (GRB) could arise from mergers of pairs of neutron stars, and, more generally, that binary mergers are capable of accelerating particles and producing high-energy emission. Potential GeV-scale emission from gravitational-wave events probes the environments into which the mergers are exploding, as well as the physics of particle acceleration at relativistic shocks. The Cherenkov Telescope Array, with a detection threshold of 20 GeV and rapid slewing capability, will be uniquely capable of characterizing the multi-GeV emission. The wide field of view of CTA enables it to efficiently observe the gravitational-wave localization region, allowing CTA to provide rapid source localizations for other instruments.

E1.14-0013-18 NEUTRINO ASTRONOMY AND CTA

Tyce De Young, deyoung@pa.msu.edu

Michigan State University, East Lansing, Michigan, United States

CTA will soon provide a greatly enhanced view of the very high energy gamma ray sky. Complementing the past decade's groundbreaking observations by gamma ray observatories such as HESS, MAGIC, VERITAS, Fermi and HAWC, discoveries of gravitational waves by LIGO and cosmic neutrinos by IceCube are opening the door to a new era of multi-messenger astronomy. We will review recent observations of cosmic neutrinos and the planned next steps in neutrino astronomy, and discuss the prospects from joint observations with CTA.

E1.14-0014-18 ESTIMATION OF GAMMA-RAY BURST DETECTION WITH CHERENKOV TELESCOPE ARRAY

Quentin Piel, piel@lapp.in2p3.fr

LAPP, Université de Savoie, CNRS/IN2P3, Annecy, France

Observations by Fermi-LAT have proven that GeV emission is a relatively common feature in 12-13% of the GRBs detected at low energy by the GBM instrument. However, the number of photons detected at these energies is still limited due to the poor effective area of space-based detectors. Despite the long-lasting observational efforts of the current generation of Imaging Atmospheric Cherenkov Telescopes (IACTs), GRBs are still undetected with ground facilities.

The small number of photons detected between few tens of GeV and 100 GeV together with the lack of detections above 100 GeV have left unanswered many important questions about GRB physics. The next generation Cherenkov Telescope Array (CTA) has identified the GRBs as one of its multi-year key observational programs. The improved sensitivity of CTA will allow the study of GRB emission above few tens of GeV with a sufficiently large photon statistics to discriminate between the proposed emission models.

In this work, I report about the prospects for CTA detection rate on a physically-modeled GRB population. The analysis of the simulated events have been performed by using the latest version of Ctools, one of the CTA data analysis pipeline and instrumental response functions. As an additional outcome, this work could help us to determine the best observational setup for the north and south arrays.

E1.14-0015-18 INVESTIGATING THE ORIGIN OF THE RECOMBINING PLASMA IN W49B WITH X-IFU ONBOARD ATHENA

Aytap Sezer, aytap.sezer@gmail.com Avrasya University, Trabzon, Turkey

Aya Bamba, bamba@phys.s.u-tokyo.ac.jp The University of Tokyo, Tokyo, Japan Tulun Ergin, tulun.ergin@tubitak.gov.tr

TUBITAK Space Technologies Research Institute, Ankara, Turkey Ryo Yamazaki, ryo@phys.aoyama.ac.jp

Aoyama Gakuin University, Sagamihara, Japan Satoru Katsuda, katsuda@phy.saitama-u.ac.jp Saitama University, Saitama, Japan

Yutaka Ohira, ohira@phys.aoyama.ac.jp Aoyama Gakuin University, Sagamihara, Japan

The X-ray Integral Field Unit (X-IFU) on board Athena will provide spatially resolved highresolution X-ray spectroscopy in the 0.2-12 keV energy band with a spectral resolution of 2.5 eV up to 7 keV. Observations with X-IFU, will enable us to better understand the origin of the recombining plasma (RP) in W49B. In this work, we investigate the RP in the spectra of W49B with detailed simulations for X-IFU detector and we examine the spatial distribution of the RP in this remnant. Here, we present our initial results and compare them with those obtained from other X-ray observatories.

E1.14-0017-18 A STUDY OF THE PLERIONIC COMPOSITE SUPERNOVA REMNANT MSH 15-56 WITH SUZAKU

Nergis Cesur, nergiscesur7@gmail.com

Yildiz Technical University, ISTANBUL, Turkey Aytap Sezer, aytap.sezer@gmail.com

Avrasya University, Trabzon, Turkey

The Galactic supernova remnant (SNR) MSH 15-56 is a member of the class of plerionic composite SNRs that consists of the remnant shell and a displaced pulsar wind nebula (PWN). The previous X-ray observations reported the comet-like morphology of the PWN, and also ejecta distribution of the SNR. In this work, we present a study of MSH 15-56 using the archival Suzaku data. We investigate the thermal and non-thermal nature of the emission and spectral parameters of the remnant. Our spectral analysis and initial results will be presented and discussed.

The High Energy Stereoscopic System (H.E.S.S.) is a gamma-ray instrument that operates in the broad energy range between a few 10s of GeV to more than 50 TeV. Most of the very-highenergy sources visible to H.E.S.S. emit gamma rays with energies up to 10s of TeV and the nominal analysis methods are optimised to have the best sensitivity in this core energy band. The work presented in this contribution aims at optimising analysis techniques for the gammaray detection at the highest energies to improve the sensitivity above 10 TeV. Moreover, current analysis techniques in H.E.S.S. typically allow for the reconstruction of events with offsets of up to 2.5 degrees - the field-of-view of the Cherenkov cameras. Optimisation of the reconstruction and selection tools can increase the acceptance to gamma-ray events at larger offsets and can hence increase the effective field of view up to 9 degrees. As a result, this allows for an increased photon statistics and improved the sensitivity in the high-energy domain. An improved method that is capable of reconstructing events with offsets up to 4.5 degrees will be presented in this contribution.

E1.14-0019-18 DETECTION OF THE GAMMA-RAY BINARY PSR J2032+4127/MT91 213

Ralph Bird, ralph.bird.1@gmail.com

University of California, Los Angeles, Los Angeles, California, United States

PSR J2032+4127 is a young gamma-ray pulsar located in the same direction as the extended TeV gamma-ray source TeV J2032+4130. The pulsar has recently been discovered to be in a 45- 50 year period, highly eccentric binary orbit with the Be star MT91 213. Periastron occurred in November 2017 and was accompanied by a significant enhancement in the X-ray and very-highenergy gamma-ray flux. I will present results of the intensive VERITAS observing campaign over the November 2017 periastron period, compare this system with other gamma-ray binaries and explore the relationship between this system and TeV J2032+4130.

E1.14-0020-18 STUDYING THE ELEMENTAL ABUNDANCES OF KEPLER SUPERNOVA REMNANT WITH ATHENA

Tulun Ergin, tulun.ergin@tubitak.gov.tr

TUBITAK Space Technologies Research Institute, Ankara, Turkey Aytap Sezer, aytap.sezer@gmail.com

Avrasya University, Trabzon, Turkey

Aya Bamba, bamba@phys.s.u-tokyo.ac.jp The University of Tokyo, Tokyo, Japan

The lines of Cr and Mn expected in the X-ray spectra of young supernova remnants. The X-ray Integral Field Unit (X-IFU) onboard Athena, provides spatially-resolved high resolution spectroscopy. We investigate Mn, Cr as well as Fe K lines in the spectra of Kepler to study its progenitor and the explosion mechanism of supernovae, as well as mapping the distribution of these elements. To this investigation, we make detailed simulation of Kepler performed with Athena X-IFU using XSPEC 12.9.1 and ATOMDB 3.0.9. Here, we present the preliminary results of our investigation with Athena and the comparison of these results with the published results in the literature. We also give initial interpretations of these results.

E1.14-0021-18 THE POPULATION OF GAMMA-RAY BINARIES

Guillaume Dubus, guillaume.dubus@univ-grenoble-alpes.fr

Institut de Planétologie et d'Astrophysique de Grenoble, Grenoble, France Nicolas Guillard, nguillar@eso.org

ESO, Garching, Germany

Pierrick Martin, pierrick.martin@irap.omp.eu IRAP/CNRS, Toulouse, France

Pierre-Olivier Petrucci, pierre-olivier.petrucci@univ-grenoble-alpes.fr Institut de Planétologie et d'Astrophysique de Grenoble, Grenoble, France

Gamma-ray binaries, whose spectral energy distribution peaks above 1 MeV, are rare objects thought to be composed of a pulsar in orbit around a massive star. How many gamma-ray binaries are there in the Galaxy ? What are the prospects for detecting them ? We have carried out mock gamma-ray surveys of synthetic populations of gamma-ray binaries to answer these questions.

E1.14-0022-18 PULSAR HIGH-ENERGY MAGNETOSPHERIC AND WIND EMISSION MODELS

Jérôme Pétri, jerome.petri@astro.unistra.fr

Observatoire Astronomique de Strasbourg, Strasbourg, France

Most current pulsar emission models assume photon production and emission within the magnetosphere. Low frequency radiation is preferentially produced in the vicinity of the polar caps whereas the high-energy tail is shifted to regions closer but still inside the light-cylinder. We conducted a systematic study of the merit of several popular radiation sites like the polar cap, the outer gap and the slot gap. We computed light-curves emanating from each emission site according to a prescribed distribution function for the emitting particles made of an electron/positron mixture. Calculations are performed using a three dimensional integration of the plasma emissivity in the vacuum electromagnetic field of a rotating centred dipole. We compare newtonian electromagnetic fields to their general-relativistic counterpart. In the latter case, light bending is also taken into account. As a typical example, curvature radiation light-curves and sky maps are plotted for several power-law indices of the particle distribution function. The detailed pulse profiles strongly depend on the underlying assumption about the fluid motion subject to strong electromagnetic fields from which we deduced the photon propagation direction directly or from the aberration formula. Estimates of high and very high energy pulsed spectra are also shown.

E1.14-0023-18 TESTING THE ORIGIN OF EXCESS GAMMA RAYS COINCIDING WITH 3FHL J1907.0+0713

Tulun Ergin, tulun.ergin@tubitak.gov.tr

TUBITAK Space Technologies Research Institute, Ankara, Turkey Pooja Bhattacharjee, pooja.bhattacharjee@jcbose.ac.in

Bose Institute, KOLKATA, India Lab Saha, labsaha@ucm.es

Compultense University of Madrid, Madrid, Spain Pratik Majumdar, majumdar.mpratik@gmail.com Saha Institute Of Nuclear Physics, Kolkata, India Hidetoshi Sano, sano@a.phys.nagoya-u.ac.jp Nagoya University, Nagoya, Japan

Yasuo Fukui, fukui@a.phys.nagoya-u.ac.jp Nagoya University, Nagoya, Japan

We used the off-pulse component of 9 years of Fermi-LAT data taken from the pulsar, PSR J1906+0722, and found excess gamma rays located 0.12 deg away from the supernova remnant (SNR) 3C 397 and 0.27 deg away from the pulsar. The position of this excess emission coincides with the gamma-ray source 3FHL J1907.0+0713. The 3FHL source also overlaps with a dense molecular cloud (MC), which raises the question whether the gamma-ray emission could be due to the interaction of very high energy particles escaping from either the SNR or a possible pulsar wind nebula (PWN) associated with PSR J1906+0722. The distance of the MC is either 10.7 kpc, therefore, close to the SNR, or 2.1 kpc, in the vicinity of the pulsar. The gamma-ray spectrum is probed for the leptonic model and two hadronic models, the interacting cloud scenario and the illuminating cloud scenario, in order to understand the dominant gamma-ray emission model. The results of this analysis may reveal the existence of a PWN for PSR J1906+0722, in case leptonic model dominates. Alternatively, when the hadronic model dominates, we might be able to differentiate between the two models within the hadronic scenario.

E1.14-0024-18 XMM-NEWTON OBSERVATION OF THE WOLF-RAYET COLLIDING-WIND BINARY WR 11

Hicran Bakış, hicranbakis@akdeniz.edu.tr Akdeniz University, Antalya, Turkey Aytap Sezer, aytap.sezer@gmail.com Avrasya University, Trabzon, Turkey

We present an analysis of the Wolf-Rayet (WR) binary system WR 11 (γ2 Velorum, WC8+O7.5III) using XMM-Newton X-ray data. We investigate the plasma state and spectral parameters of WR 11. We also search for the radiative recombination continuum in this system. Finally, we will discuss our initial results.

E1.14-0025-18 GAMMA RAY BURST OBSERVATIONS WITH H.E.S.S.

Quentin Piel, piel@lapp.in2p3.fr

LAPP, Université de Savoie, CNRS/IN2P3, Annecy, France

Fermi-LAT observations have proven that GeV γ-ray emission is a relatively common feature for many GRBs. However the low effective area of space detectors implies low statistics for such high energy photons which impede any physical interpretation at such energies. The highest energy photon detected by LAT reached 95 GeV proved that γ rays coming from GRBs can reach very high energies. However, the current generation of Imaging Atmospheric Cherenkov Telescopes (IACTs) array observing above few tens of GeV has not detected any GRB yet.

The High Energy Stereoscopic System (H.E.S.S.) is an IACT belonging to the current generation of such instruments. It is the first hybrid IACT array composed of four 12 m diameter and one 28 m diameter telescopes. The large light collection area of 600 m2 of the largest telesope is perfectly suitable to observe γ rays between 50 GeV and 100 GeV with an unprecedented sensitivity. This caracteristic makes H.E.S.S. among the instruments that are most promising to constrain or probe short time scale emission of GRBs at very high energies.

This contribution will describe the H.E.S.S. GRB observation program, trigger conditions of GRB observations and analyses of several tens of GRBs. This compilation of observations represents the largest list of GRB observations with IACTs and provides numerous results for GRB modeling at very high energy.

E1.14-0026-18 NOVEL SEARCH FOR TEV-INITIATED PAIR CASCADES IN THE INTERGALACTIC MEDIUM

Wenlei Chen, wenleichen@wustl.edu

Washington University in St. Louis, St. Louis, Missouri, United States Manel Errando, errando@physics.wustl.edu

Washington University in Saint Louis, Saint Louis, Missouri, United States James Buckley, buckley@physics.wustl.edu

Washington University in St. Louis, St. Louis, Missouri, United States

The observed magnetic fields in galaxies and galaxy clusters are believed to result from the dynamo amplification of weak magnetic field seeds, whose origin remains a long-standing open question. TeV emission from blazars can be used to probe the intergalactic medium and measure the intensity, coherence length, and helicity of the intergalactic magnetic field. Intergalactic magnetic fields deflect the electron-positron pairs produced by very-high-energy gamma-rays from blazars, resulting in broadened beams of cascade gamma-rays known as pair halos. Such pair-cascades develop along the projected direction of the blazar jet, which is known from imaging radio observations. We present a joint analysis of Fermi-LAT data from 12 selected high-synchrotron-peaked (HSP) blazars with well-determined jet orientation from VLBA radio observations. Our search improves the sensitivity of previous studies by taking the asymmetry of the pair haloes into account, increasing the signal to noise. Although there is no significant detection, a hint for an offset halo with a global p-value of about 0.035 is found in the 30

300 GeV energy range, corresponding to an intergalactic magnetic field with 10−15 Gauss, consistent with the inferred field from a prior, (largely independent) study using stacked HSP

BL Lacs. Based on our findings, prospects for a detection of pair haloes using the improved sensitivity and angular resolution of the CTA observatory will be presented.

E1.14-0027-18 LARGE-SCALE DIFFUSE INTERGALACTIC MAGNETIC FIELDS CONSTRAINTS WITH THE CHERENKOV TELESCOPE ARRAY

Paramita Barai, paramita.barai@iag.usp.br

Instituto de Astronomia, Geofísica e Ciências Atmosféricas - Universidade de São Paulo (IAGUSP), São Paulo, Brazil

Stela Adduci Faria, stelinhaadduci@gmail.com

Instituto de Astronomia, Geofísica e Ciências Atmosféricas - Universidade de São Paulo (IAGUSP), São Paulo, Brazil

Magnetic fields of the order of micro-Gauss are observationally detected in galaxies and galaxy clusters, which are believed to be created by the amplification of much weaker primordial seed fields. These fields within galaxies should be carried out by strong galactic outflows over time, magnetically enriching the InterGalactic Medium (IGM) at larger cosmological distances. However direct observation of magnetic fields in the IGM is scarce. Knowing the distribution of magnetic fields within the large-scale-structures is crucial in understanding the origin of the seed fields. In this talk, I will give a review of how Intergalactic Magnetic Field (IGMF)'s strength and filling factor can be constrained using numerical simulations and gamma-ray observations.

We are performing cosmological hydrodynamical simulations containing dark matter and all relevant physical processes for the baryons: metal cooling, star-formation, supernovae (SN) feedback, Active Galactic Nuclei (AGN) accretion and feedback. We analyze the simulations following the methodology of Barai (2008, ApJ, 682, L17), and compute the magnetic field in the simulation volume IGM. Our objectives are: to explore the evolution of IGMFs through cosmic times, and to compute the contributions of galactic outflows (driven by SN versus AGN) in the advection of magnetic fields from the galaxies to the IGM.

On the observational side, high-energy TeV photons emitted by distant blazars can interact with the cosmic extragalactic infrared/optical background light, producing electron-positron pairs, and initiating electromagnetic cascades in the IGM. The charged component of these cascades is deflected and delayed by IGMFs, thereby reducing the observed point-like TeV flux, and creating an extended image in the GeV energy range. Such GeV flux extensions around TeV blazars can potentially be detected with gamma-ray telescopes (Fermi-LAT, HESS, CTA). Studies calculating the GeV flux of blazars, employing different models of the IGMF, and using Monte Carlo simulations for the cascade development [e.g., Neronov Vovk (2010, Science, 328, 73); Dolag et al. (2011, ApJ, 727, L4)] have put lower limits on the IGMF strength of the order of 10−16 10−15 G, and filling factors of 60%. I will overview such studies; and describe the constraints on the IGMF which the Cherenkov Telescope

Array sensitivity is expected to give (Acharya et al. 2017, CTA consortium science paper, submitted).

E1.14-0029-18 PROMISING CTA EXTRAGALACTIC SOURCE CANDIDATES PREVIOUSLY UNDETECTED IN FERMI-LAT CATALOGUES

Ulisses Barres De Almeida, ulisses@cbpf.br

INFN-Padova, Padova, Italy

Luca Foffano, luca.foffano@pd.infn.it INFN-Padova, Padova, Italy

In the expectation of future CTA scientific exploitation, we have conducted a detailed study of a population of 150 bright high-synchrotron-peaked blazars recently detected with Fermi-LAT as part of the 1BIGB catalog. The 1 BIGB sources are defined by the presence of excess signal in the 0.3 - 500 GeV band and stand out as promising TeV blazar candidates, which might be in reach of the forthcoming CTA observatory. Here we present the 1-100 GeV gamma–ray spectral energy distribution for the sources in this population, considering PASS8 data, and integrating over 9 years of observations with Fermi-LAT. Most of the 1BIGB sources do not appear in any previous Fermi-LAT catalogue, having been identified through selection of their lower-energy counterparts from the WHSP catalogue. Their gamma-ray spectral properties are therefore presented here for the first time. We stack the gamma-ray SEDs, normalizing them via the Synchrotron-peak parameter to extract a gamma-ray template, representative of current undetected gamma-ray blazars, attempting to identify a family of extreme blazars (EHBLs) among them. We use our results to evaluate the importance of these sources in the context of future CTA population studies, by comparing some of the derived source spectra to the published CTA sensitivity curve to estimate detectability by CTA.

E1.14-0030-18 ELECTROMAGNETIC CASCADES INSIDE AND OUTSIDE BLAZARS: IMPLICATIONS FOR CTA

Timur Dzhatdoev, timur1606@gmail.com

Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russia

Blazars are among the main targets for the forthcoming CTA gamma-ray observatory. Models describing intrinsic spectra of blazars and properties of the intergalactic medium have experienced an unprecedented progress during the last decade. In particular, it was found that:

some blazars may have very hard (γ<1.5) intrinsic spectra in the GeV-TeV energy region these hard-spectra ("extreme") blazars are often apparently non-variable or slowly variable sources 3) the absorption-only model of gamma-ray propagation, that accounts for only γγ pair production and adiabatic losses, is often insufficient to describe intergalactic gamma-ray propagation. These and other facts should be accommodated in a self-consistent model of gamma-ray production and intergalactic propagation. We argue that the account of electromagnetic (EM) cascades from primary gamma-rays is an important component of such a model. Namely, the account of the intergalactic cascade process allows to qualitatively explain all known deviations from the absorption-only model ("anomalies"). On the other hand, the possibility of the development of EM cascades from primary protons or nuclei does not modify the effective opacity of the Universe significantly for realistic models of the source and magnetic field between the source and the observer. These results are described in detail in our recent paper [AA, 603, A59 (2017)]. We predict the shape of the "flux modification factor", i.e. the ratio of the observable spectrum in the framework of the EM cascade model to the one assuming the absorption-only model, and show how this prediction could be tested with the full CTA array. We predict the existence of a new population of blazars with very hard (γ<1.5) intrinsic spectra in the GeVTeV energy region that may already have been observed with the Fermi LAT telescope and could be discovered in future by the CTA observatory. Finally, we discuss EM cascade process inside broad line regions (BLR) of flat-spectra radio quasars and its possible implications on the mechanism of gamma-ray escape from these objects. Our findings have important implications for axion-like particle searches, extragalactic magnetic field measurement and blazar population studies.

E1.14-0031-18 A METHOD OF SEPARATION CHERENKOV AND FLUORESCENT LIGHT OF EAS FOR GROUND-BASED AND AEROSPACE UHE CR DETECTORS

Direct and scattered Cherenkov light (CL) is one of the relevant contributions to the uncertainty of the measured flux of fluorescent light (FL) from extensive air showers (EAS). The impact of the backscattered CL was noted in response modelling of few detectors. The problem of a reliable CL and FL separation is relevant for the better high energy EAS registration and primary particle parameters estimation. This study is first step to solving for both theoretical approaches to the problem and possible design of electronics for ground, airborne and space detectors.

E1.15-0001-18 STATUS OF THE VIRGO COLLABORATION IN EUROPE

Johannes Van Den Brand, jo@nikhef.nl Nikhef, Hilversum, Netherlands

Last year, the European Virgo detector achieved the first detection of a gravitational wave. The Advanced Virgo detector joined LIGO in the second observation run for a period of 25 days. Several detections were made. The detected waveform of event GW170814 match the predictions of general relativity for the inspiral and merger of a pair of black holes and the ringdown of the resulting single black hole. Three days later, event GW170817 constituted the first detection of a binary neutron star merger. Our observations provide unique access to the properties of space-time at extreme curvatures: the strong-field, and high velocity regime. It allows unprecedented tests of general relativity for the nonlinear dynamics of highly disturbed compact systems such as neutron stars and black holes.

The scientific impact of the recent detections will be explained. In addition key technological aspects will be addressed.

E1.15-0002-18 SAGE: USING GEOSYNCHRONOUS CUBESATS TO DETECT GRAVITATIONAL WAVES

Sylvestre Lacour, sylvestre.lacour@obspm.fr Observatoire de Paris, Meudon, France Frédéric Vincent, frederic.vincent@obspm.fr Observatoire de Paris, LESIA, Meudon, France Aglae Kellerer, akellere@eso.org

ESO, Garching, Germany

Mathias Nowak, mathias.nowak@obspm.fr Observatoire de Paris, Meudon, France Lester David, lester.david@obspm.fr Observatoire de Paris, Meudon, France Julien Woillez, jwoillez@eso.org

ESO, Garching, Germany

Vincent Lapeyrere, vincent.lapeyrere@obspm.fr Observatoire de Paris, Meudon, France

The SAGE (SagnAc interferometer for Gravitational wavE detection) observatory is based on multiple 12-U CubeSats in geosynchronous orbit. The objective of this project is to create a Sagnac interferometer with 210.000 km circular arms. The geometry of the interferometer makes it especially sensitive to circularly polarised gravitational waves of frequency close to 1Hz. The nature of the Sagnac measurement makes it almost insensitive to position error, relaxing the need of drag free spacecrafts. The light source and recombination units of the interferometer are based on compact fibered technologies, including fibered Erbium doped amplifiers, and fibered switches. With a 10W laser source, and 10-centimetre diameter apertures, a sensitivity of 0.2 pm/sqrt(Hz) can be expected. This would allow detection of gravitation wave with a strain of 10e-21, enabling the two main science cases. The first one is the detection of black holes (e.g. GW150914) several weeks before they can be detected by LIGO, to finely test prediction of general relativity upstream the merge. The second science goal consists in detecting IMBH mergers, whose event probability would give an important constraint on galactic evolution. We will present a development plan in 5 years, leveraging on the low cost/ fast development/risk acceptance of CubeSat technology.

E1.15-0003-18 ON THE SENSITIVITY OF ATLAS AND PS1 FOLLOWUP OF O2 LIGO EVENTS

Michael Coughlin, mcoughli@caltech.edu

California Institute of Technology, Pasadena, California, United States

The potential for the joint detection of electromagnetic and gravitational-wave emissions is one of the most challenging tasks in multi-messenger astronomy. In this analysis, we report on the sensitivity of the Pan-STARRS and ATLAS followup of gravitational-wave triggers reported by LIGO during its most recent science run. We show the sensitivity of the followup campaigns to a variety of potential lightcurve models, including those from kilonovae. We discuss lessons learned with an outlook on improvements as we enter the open alert era.

E1.15-0004-18 STUDY OF PULSAR SPINDOWN USING AN ANALYTIC APPROACH

Farrukh Chishtie, farrukh.chishtie@adpc.net

Asian Disaster Preparedness Center, Phayathai, Thailand Sree Ram Valluri, vallurisr@gmail.com

University of Western Ontario, London, Canada

Direct detection of gravitational waves from pulsars will be the next landmark in the field of multi-messenger gravitational wave astronomy.In this context we develop an analytic approach to study pulsar spindown. We use the monopolar spindown model by Alvarez and Carraminana (2004), which assumes an inverse linear law of magnetic fi eld decay of the pulsar, to extract an all-order formula for the spindown parameters using the Taylor series representation of Jaranowski et al.(1998). We further extend the analytic model to incorporate the quadrupole term that accounts for the emission of gravitational radiation, and obtain expressions for the period and frequency in terms of transcendental equations. We derive the period of the pulsar evolution as an approximate fi rst order solution in the small parameter present in the full solution. We fi nd that the fi rst three spindown parameters of the Crab, PSR B1509-58, PSR B0540-69 and Vela pulsars are within their known bounds providing a consistency check on our approach.

E1.15-0005-18 WHAT CAN WE LEARN ABOUT FUNDAMENTAL PHYSICS FROM GWGRB EVENTS

Olivier Minazzoli, ominazzoli@gmail.com Observatoire de la Côte d'Azur, NICE, France

In this talk, we will present how the quasi-coincidence of the events GW170817 and GRB 170817A improved our knowledge on the fractional speed difference between gravitational and electromagnetic waves by more than 14 orders of magnitude, and what it means in various frameworks of alternative theories of gravitation.

Institute of Space Science, Magurele, Romania, Magurele, Romania

The recent discovery of gravitational waves from merging pairs of massive black holes [1-4] and even neutron stars [5] has marked the beginning of a new chapter in astronomy. The increasing sensitivity of the next generation of ground-based gravitational wave detectors and of the future space-borne ones will allow for the detection of high redshift merging black hole events, down to the realm of the first-generation black holes which is inaccessible to present and future electromagnetic observations. To better estimate the expected rates of black hole mergers and mass ratios [6], existing all-sky catalogues of black hole masses (e.g. BH-Cat [7]) needs to be further developed and refined based on current observations. In the context of Romanian participation to LISA collaboration, we will present an updated version of the massive and supermassive black hole mass catalog, BH-Cat, together with its mass function and its implication for the LISA space mission. This catalog can be used to predict the mass and space distribution of the first-generation black holes, test the feedback between the black holes and the hosting galaxy evolution activities, study the growth mechanism of the black holes and predict the black holes mass merger ratios. 1. E1.15-0007-18 BOUNDS ON THE HEIGHT OF A MOUNTAIN ON A MILLISECOND PULSAR

Sudip Bhattacharyya, sudip@tifr.res.in

Tata Institute of Fundamental Research, Mumbai, India

Spinning neutron stars with a structural ellipticity should emit continuous gravitational waves. Here, using the multiwavelength data from an accreting millisecond pulsar, I argue that its observed spin-down should be primarily due to gravitational wave emission. Consequently, the lower and upper limits of the ellipticity of this pulsar can be obtained.

E1.15-0008-18 PROBING THE ACCRETION DISK WITH THE GRAVITATIONAL WAVE.

Soumen Mondal, soumenjuphysics@gmail.com Jadavpur University, Kolkata, India

Prasad Basu, prasadcsp@gmail.com India

Gravitational wave signal characteristics from a binary black hole system in which the companion moves through the accretion disc of the primary are studied. This disk can exert non negligible hydrodynamic drag on the compact objects rotating around the central black hole. Hence, the gravitational wave signal emitted from an extreme or intermediate mass ratio binary system (EMRI/IMRI) may be modified due to the modified motion of orbiting companion by the influence of hydrodynamic drag of the disk. Thus the emitted gravitational wave signals which carries the imprint of the trajectory of the companion, contains signature of the hydrodynamic features of the accretion disk. In this work, we find that there is a significant reduction in the companions infall time due to the drag exerted by the disk. This shows that the disk indeed has non negligible effects on companions dynamics. Thus, gravitaional wave can serve as another probe for studying the hydrodynamic profiles of the accretion disk. Till now the elecromagnetic spetrum emitted by the accretion disk is routinely observed and is the only observational input to check the various properties of disk. A combination of observations in the electromagnetic wave spectrum and the gravitational wave spectrum would provide us with a large number of information about the accretion disk. Further, we plan to estimate the change of the amplitude and frequency of the GW signal due to the effect of the accretion disk on the motion of the companion and modelling the waveform accordingly

E1.15-0009-18 GRAVITATIONAL-WAVE RINGDOWN ECHOES FROM BLACK HOLES IN MASSIVE GRAVITY

Ruifeng Dong, ruifengd@buffalo.edu

State University of New York, The University at Buffalo, Buffalo, New York, United States Dejan Stojkovic, ds77@buffalo.edu

State University of New York, The University at Buffalo, Buffalo, New York, United States

LIGO's detection of the black hole quasinormal modes has proved the existence of the photosphere outside the gravitational radius. Other sub-dominant long-lived modes depend on the existence of the event horizon, as well as the black hole hairs outside. These modes may reveal themselves in future gravitational-wave detectors as echoes. In this work, we study the ringdown of a de Sitter-Schwarzschild black hole in the dRGT theory of massive gravity. We find interesting signatures of ringdown echoes as we turn on the coupling between spacetime perturbations and the background vector field outside the black hole.

E1.15-0010-18 FERMI GBM AND THE ERA OF GRAVITATIONAL-WAVE ASTRONOMY

Adam Goldstein, adam.m.goldstein@nasa.gov NASA/MSFC, Huntsville, Alabama, United States

On 2017 August 17 at 12:41:06 UTC the Fermi Gamma-ray Burst Monitor (GBM) detected and triggered on the short gamma-ray burst (GRB) 170817A. Approximately 2 s prior to this GRB, the LIGO gravitational-wave observatory detected a binary compact merger candidate associated with the GRB. This is the first unambiguous coincident observation of gravitational waves and electromagnetic radiation from a single astrophysical source and marks the start of gravitational-wave multi-messenger astronomy. We report the GBM observations and analysis of this short GRB and the joint science that results from this watershed joint discovery. We also detail the ongoing work to search for weak, sub-triggered counterparts to gravitational wave detection candidates

E1.15-0011-18 DEEP LEARNING TO STUDY THE NOISE IN GRAVITATIONAL WAVE INTERFEROMETERS

Massimiliano Razzano, massimiliano.razzano@pi.infn.it INFN and University of Pisa, Pisa, Italy

Elena Cuoco, elena.cuoco@ego-gw.it EGO, Cascina, Italy

The detection of gravitational waves has inaugurated the era of gravitational astronomy and opened new avenues for the multimessenger study of the cosmos. Thanks to their sensitivity, the Advanced LIGO and Advanced Virgo interferometers can probe a much larger volume of space and will expand the potential to discover new gravitational wave sources. The characterization of these detectors is very important in order to recognize the main sources of noise and optimize the sensitivity. In particular glitches are transient noise events that impact the data quality of the interferometers, and their classification is very important to characterize the detector. Deep learning techniques are a promising tool to recognize and classify glitches. We will discuss the potential of deep learning in studying noise in gravitational wave detectors and distinguishing it from real astrophysical signals. In particular we will present a method based on deep learning for the classification of glitches based on their time-frequency evolution represented as images. Using tests on simulated data, we show its capability of disentangling the noise from real gravitational signals, and its accuracy in classification coupled with short execution times, thus providing a promising tool for online, low-latency, detector characterization.

E1.15-0012-18 PLAUSIBLE DETECTION OF GRAVITATIONAL WAVE FROM HIGHLY MAGNETIZED WHITE DWARFS

Banibrata Mukhopadhyay, bm@iisc.ac.in Indian Institute of Science, Bangalore, India

A.R. Rao, arrao@tifr.res.in

Tata Institute of Fundamental Research, Mumbai, India

Since last 6 years or so, we have initiated exploring possible existence of highly magnetized white dwarfs (B-WDs) with a new super-Chandrasekhar mass-limit. It has many implications including observed over-luminous type Ia supernovae, white dwarf pulsars, soft gamma-ray repeaters and anomalous X-ray pulsars. In the talk, we however show that these spinning B-WDs are attractive sites for gravitational radiation. The amplitude of gravitational wave produced by a B-WD with mass of the order of 2 solar mass, polar radius 700 km, rotational period about 1 sec with oblateness parameter 1/10000 and at 100 pc away from us is within the sensitivity of the Einstein@Home search for early LIGO. If the B-WD's polar radius is 2000 km, rotational period 10 sec and other parameters intact as above, a firm confirmation of gravitational wave emission can be provided by DECIGO/BBO. Nevertheless, high magnetic field rotating white dwarfs approaching a B-WD would be common and it is possible that such white dwarfs of radius about 7000 km, period 20 sec, at a distance 10 pc will is detectable by LISA.

E1.15-0013-18 SEARCHING FOR SHORT GRBS IN SOFT GAMMA-RAYS WITH INTEGRAL/PICSIT

James Rodi, james.rodi@iaps.inaf.it INAF-IAPS, Rome, Italy

INTEGRAL Gravitational Wave Team

A. Bazzano, P. Ubertini, L. Natalucci, V. Savchenko, E. Kuulkers, C. Ferrigno, E. Bozzo, S. Brandt, J. Chenevez, T. J.-L. Courvoisier, R. Diehl, A. Domingo, L. Hanlon, E. Jourdain, A. von Kienlin, P. Laurent, F. Lebrun, A. Lutovinov, A. Martin-Carrillo, S. Mereghetti, J. Rodi, J.-P. Roques, R. Sunyaev

The first electromagnetic detections associated with a gravitational wave trigger on 17 August 2017 produced a flurry of results across the EM spectrum. A notable example at hard X-ray/soft gamma-ray energies is how extremely under luminous the short gamma-ray burst (SGRB) was compared to others with known redshifts, which suggests a population of low luminosity events. The most popular interpretation has been that the GRB was viewed off-axis, rather than that the event had an intrinsically low luminosity. Regardless, this result has spurred searches for SGRBs below instrument trigger thresholds in hopes of finding similar bursts. Here we have analyzed data from the INTEGRAL soft gamma-ray detector IBIS/PICsIT (200 keV - 10 MeV) to try to corroborate the untriggered SGRB candidates reported by Fermi/GBM. In addition, we present initial results of our real-time burst analysis with PICsIT.

E1.15-0014-18 A PECULIAR LOW-LUMINOSITY SHORT GAMMA-RAY BURST FROM A DOUBLE NEUTRON STAR MERGER PROGENITOR

Binbin Zhang, bbzhang@nju.edu.cn Nanjing University, Nanjing, China

Double neutron star (DNS) merger events are promising candidates of short Gamma-ray Burst (sGRB) progenitors as well as high-frequecy gravitational wave (GW) emitters. On August 17, 2017, such a coinciding event was detected by both the LIGO-Virgo gravitational wave detector network as GW170817 and Gamma-Ray Monitor on board NASA's Fermi Space Telescope as GRB 170817A. Here we show that the fluence and spectral peak energy of this sGRB fall into the lower portion of the distributions of known sGRBs. Its peak isotropic luminosity is abnormally low. The estimated event rate density above this luminosity is at least 190 per cubic Gpc per yr, which is close to but still below the DNS merger event rate density. This event likely originates from a structured jet viewed from a large viewing angle. There are similar faint soft GRBs in the Fermi archival data, a small fraction of which might belong to this new population of nearby, low-luminosity sGRBs.

E1.15-0015-18 THE SVOM MISSION.

Arnaud Claret, arnaud.claret@cea.fr

CEA Saclay, Gif-sur-Yvette Cedex, France Svom collaboration

On behalf of the Svom collaboration

The Chinese-French space mission SVOM (Space-based multiband astronomical Variable Objects Monitor) is mainly designed to detect and localize gamma-ray burst (GRB) events. The satellite, to be launched in late 2021, will carry a set of gamma-ray, X-ray, and optical imagers. Thanks to its pointing strategy, quick slew capability, and fast data connection to Earth, ground-based observations with large telescopes will allow us to measure redshifts for an unprecedented number of GRBs. While the association of long GRBs with core-collapse supernovae (SNe) is well established, short GRBs are most likely due to neutron star (NS)-NS or NS-BH (black hole) mergers and are thus expected to occur simultaneously with bursts of gravitational waves. After briefly reminding the overall science goals of the SVOM mission in the framework of the multi-wavelength and multi-messenger panorama of the next decade, we focus on the organization of the scientific ground segment, in charge of rapidly disseminating the alerts of GRB detected on board, but also organizing the ground monitoring of multi-messenger alerts from other instruments.

E1.15-0016-18 THE GRAVITATIONAL CAPTURE OF COMPACT OBJECTS BY MASSIVE BLACK HOLES

Pau Amaro Seoane, pau@ice.cat

Institute of Space Sciences ICE (CSIC) and IEEC, Cerdanyola Del Vallès, Spain

One of the most interesting sources of gravitational waves is the inspiral of compact objects on to a massive black hole (MBH), commonly referred to as an extreme-mass ratio inspiral. The small object, typically a stellar black hole, emits significant amounts of GW along each orbit in the detector bandwidth. In this talk I will summarise the science that we can do with these gravitational waves. In particular, I will review the gravitational capture of compact objects by supermassive black holes, and by intermediate-mass black holes, in globular clusters.

E1.15-0017-18 MERGER OF COMPACT BINARIES IN THE CONTEXT OF GRAVITATIONAL WAVES AND SHORT-LIVED GAMMA-RAY BURSTS

Shawqi Al Dallal, shaldallal@gmail.com Ahlia University, Manama, Bahrain Walid Azzam, wjazzam@gmail.com University of Bahrain, Sakhir, Bahrain

The discovery of gravitational waves resulting from the merger of two massive black holes (GW150914) has revolutionized our view of merging compact binaries. More recently, the Swope Supernova Survey of the optical counterpart of a gravitational wave event in the NGC 4993 galaxy, GW170817, emanating from the merger of two neutron stars, has triggered a lot of research work. Emphasis has been on comparing the existing theoretical models with the observational data, allowing for the prospect of an even more stringent test of general relativity. The afterglow of this event was observed in a wide range of wavelengths extending from radio waves to gamma rays. In this work, we first explore the evolutionary pathways of compact binary systems following the in-spiral, merger, and ring down sequence. We then proceed to discuss the processes leading to the production of gravitational waves and electromagnetic emission resulting from the merger of compact objects, particularly neutron star binaries and neutron starblack hole systems. We construct a basic inventory of the energy released during the merger of compact binaries in all bands of the electromagnetic spectrum with emphasis on gamma-ray burst emission. The constraints on certain wavelength emissions, such as gammaray bursts, are discussed in terms of orbital dynamical instabilities, energy transfer processes, and possible jet orientations with respect to the observer.

E1.15-0018-18 THE GRAVITATIONAL-WAVE OPTICAL TRANSIENT OBSERVER (GOTO)

Paul O'Brien, pto2@leicester.ac.uk

University of Leicester, Leicester, United Kingdom

Many GW sources, such as merging neutron stars, should be accompanied by an electromagnetic signal. We are currently building a new, powerful facility designed to find the first optical counterparts to GW sources - The Gravitational-wave Optical Transient Observer (GOTO).

http://goto-observatory.org/

Located on the island of La Palma, GOTO first came on-line in summer 2017 with four telescopes and will be expanded to eight telescopes within 2018 in preparation for the LIGO/VIRGO O3 run. Plans are also underway to double the facility on La Palma and add another node in Australia.

GOTO will immediately respond to GW triggers and hunt for a new optical transient source. The gravitational wave skymaps are large and the challenge is how to search such large areas of sky efficiently. GOTO is specifically designed for this task, providing an instantaneous field of view (with eight telescopes) of 36 square degrees. To provide a view of the night sky for comparison, GOTO will monitor the sky every night providing a unique, temporally-resolved view of the optical transient universe down to 21 magnitude. At these depths, GOTO data will enable a unique study of many classes of extragalactic source, including Gamma-Ray Bursts, Supernovae, Tidal Disruption Events and Active Galactic Nuclei, as well as many sources within our own galaxy.

E1.15-0019-18 THE X-RAY COUNTERPART TO THE GRAVITATIONAL WAVE EVENT GW170817

Eleonora Troja, eleonora.troja@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States

The second run of advanced LIGO led to the breakthrough discovery of the first gravitational wave (GW) signal from a neutron star merger, GW170817, coincident with a short duration gamma-ray burst, at a distance of 40 Mpc. The discovery of GW170817 and its electromagnetic counterparts marked the beginning of a new era of multi-messenger astrophysics, in which photons and gravitational waves provide complementary views of the same source.

I will present the discovery and long-term monitoring of the X-ray counterpart associated with GW170817. While the electromagnetic counterpart at optical and infrared frequencies was dominated by the radioactive glow from freshly synthesized r-process material in the merger ejecta, known as kilonova, observations at X-ray and, later, radio frequencies revealed the emergence of a relativistic, structured outflow interacting with the surrounding low-density environment. I will discuss the key results of our multi-wavelength campaign, the open questions raised by this event, and the critical role of X-ray observations in the new era of multi-messenger astrophysics.

E1.15-0020-18 NEUTRON STAR MERGERS, KILONOVAE, AND THE COSMIC ORIGIN OF THE HEAVY ELEMENTS

Daniel Siegel, dsiegel@astro.columbia.edu

Columbia University, New York, New York, United States

The recent detection of the binary neutron star merger GW170817 by LIGO and Virgo was followed by a firework of electromagnetic counterparts across the entire electromagnetic spectrum. In particular, the ultraviolet, optical, and near-infrared emission is consistent with a kilonova that provided strong evidence for the formation of heavy elements in the merger ejecta by the rapid neutron capture process (r-process). In this talk, I will discuss our current understanding of how kilonovae are produced in neutron star mergers, specifically in light of GW170817, but also with regard to future events. I will discuss possible scenarios and mass ejection mechanisms that can give rise to the observed kilonova features and demonstrate how r-process nucleosynthesis in these outflows can explain the cosmic origin of the heavy elements in the universe, which has been an enduring mystery for more than 70 years.

A wide-field ultraviolet survey mission with 6U cubesat for investiging gravitational wave sources and the other intriguing transients is presented. GW170817 showed kilonova-like IR emission which arose about 3 days after the GW detection. While in the earlier phase, the observed optical counterpart was much bluer than that of the expected kilonova models and its emission process is still unclear. To reveal the mysterious early phase blue emission just after the merging and constrain the geometrical distribution and velocity of the neutron-rich ejecta, we are developing an UV wide field telescope. To cover the large error circle of GW detectors the UV telescope was designed to have a FoV of 20 deg2. The detection limit is 20 mag for 1000 s exposure in NUV band, which is rather shallow but is sufficient to detect UV emission from NS-NS merger within 200 Mpc from the earth, assuming the intensity of GW170817. In this presentation we show the mission overview and progress report.

E1.15-0022-18 DEVELOPING AN EARLY-WARNING SEARCH FOR GRAVITATIONAL WAVE TRANSIENTS USING RANDOM MATRIX FACTORIZATION

Amit Reza, amit.reza@iitgn.ac.in

Indian Institute of Technology Gandhinagar(IITGN), Gandhinagar, India Anand Sankar Sengupta, asengupta@iitgn.ac.in

IIT Gandhinagar, Gandhinagar, India Anirban Dasgupta, anirbandg@iitgn.ac.in

Indian Institute of Technology Gandhinagar, India, Gandhinagar, India

Increased bandwidth and improved sensitivity at low frequencies in the advanced LIGO/Virgo detectors have led to a vast increase in the number of templates against which data is cross correlated. It has also resulted in longer template waveforms. Both of these effects have amplified the computational cost of the gravitational wave (GW) searches from compact binary systems by several orders of magnitude. In a seminal work, Hanna, Canon et al. have validated the use of the singular value decomposition (SVD) method to deal with a large number of templates. However, performing SVD on large matrices in situ has severe memory and logistical challenges. Random matrix factorization is an efficient technique for low-rank approximation of such large template matrices, where the templates are randomly projected into a much lower dimensional space. The basis vectors in the projected space are obtained by QR decomposition. We investigate the application of this technique to optimize the total computational and memory requirements of typical GW searches. Our approach is easily scalable and can be deployed over a distributed memory computer architecture. We further develop the idea into a early-warning hierarchical search pipeline for transient GW signals from compact binaries. Observing such transients in Earth and space based electromagnetic telescopes holds enormous potential for new discoveries. Our numerical experiments indicate that the proposed new algorithm is as accurate as the standard SVD within a fixed probabilistic error bound.

E1.15-0023-18 RADIO FOLLOW-UP OF GRAVITATIONAL WAVES IN THE ADVANCED LIGO/ VIRGO ERA

Alessandra Corsi, alessandra.corsi@ttu.edu

Texas Tech University, Lubbock, Texas, United States

During their second observing run (O2), the advanced LIGO and Virgo detectors scored their first direct observation of gravitational waves from a binary neutron star (NS) merger, GW170817. This event also gifted the astronomical community with an electromagnetic (EM) counterpart spanning all bands of the spectrum. The delayed radio afterglow of GW170817 uniquely probed the mass, velocity, and geometry of the fastest ejecta, as well as the density of the ambient ISM. The radio has also unveiled key features of the interaction between relativistic ejecta and neutron rich matter, fundamentally advancing our knowledge of jet physics, and critically informing expectations for future EM-GW searches. In this talk, I will discuss these future expectations in the context of both the upcoming run O3, and the longer-term future of advanced GW detectors and next generation radio arrays.

E1.15-0024-18 IDENTIFYING EM COUNTERPARTS TO NS-NS MERGERS: AN OPTIMIZED RADIO FOLLOW-UP STRATEGY

Dario Carbone, dario.carbone@ttu.edu

Texas Tech University, Lubbock, Texas, United States Alessandra Corsi, alessandra.corsi@ttu.edu

Texas Tech University, Lubbock, Texas, United States

Recently the first merger of two neutron stars was observed both through electromagnetic and gravitational waves. It was detected in all the electromagnetic bands, from gamma rays to radio. In the near future many more of these events will be discovered, therefore, we need to have an efficient radio follow-up plan to detect and identify them, and to be able to determine their physical parameters. In this talk, I will present a new statistical method that allows us to optimize the follow-up strategy, maximizing the accuracy in identifying binary neutron star mergers, and recovering their physical parameters.

E1.15-0025-18 INVESTIGATING SUPERMASSIVE BLACK HOLE BINARY MASS-RATIOS IN ROTATING GALAXIES

Muhammad Awais Mirza, awaismirza786@yahoo.com

Space and Upper Atmosphere Research Commission (SUPARCO), Karachi, Pakistan Fazeel Mahmood Khan, khanfazeel.ist@gmail.com

Institute of Space Technology, Islamabad, Islamabad, Pakistan Kelly Holley-Bockelmann, k.holley@vanderbilt.edu

Vanderbilt University, Nashville, Tennessee, United States

There is strong observational evidence that supermassive black holes (SMBHs)–weighing in the range between 106 and 109 times the mass of the sun–are present in the center of most of the galaxies. After two galaxies merge, their SMBHs advance towards each other, form a binary system and ultimately coalesce into each other emitting a burst of gravitational waves. SMBH binary coalescence is believed to be one of the loudest sources of gravitational waves. To understand the physics of SMBH binary coalescence, various observational, theoretical and computational efforts are being made. These studies showed that binaries with equal mass SMBHs are strongly affected by the rotation of galactic merger remnant. However, it is unclear if the mass-ratio between primary and secondary SMBHs residing in rotating galaxies affects the binary's evolution. In order to extract this dependence of binary evolution on mass-ratios, direct N-body simulations were carried out on a Graphics Processing Units (GPUs accelerated supercomputer. We employed ϕ-GPU code for performing the simulations which is based on fourth order Hermite integrator and is massively parallel to run on the GPUs based machines. SMBH binaries of several mass-ratios were investigated by placing them in both co and counter galaxy models. The results indicate a decreasing trend of binary eccentricity values from equal to small mass-ratio binaries for counter-rotating models while small and roughly equal eccentricities for co-rotating models. The time of formation of binary was also observed to follow a pattern with binary massratios. These results are vital to estimate SMBH merger events having an impact on future gravitational waves antennas such as eLISA—enhanced Laser Interferometer Space Antenna.

E1.15-0026-18 DETECTING UV GRAVITATIONAL WAVE SOURCES WITH GLUV

Brad Tucker, brad@mso.anu.edu.au

Australian National University, Weston Creek, ACT, Australia

GLUV is a 30cm ultraviolet survey telescope under development at ANU (Sharp et al. 2016) for a high altitude balloon platform. It will feature a 7deg2 field of view and a limiting magnitude in near-UV of 22. Ridden-Harper et al. (2017) explores the application of GLUV to gravitational wave source characterisation, showing that early UV observations could provide a powerful diagnostic to identify merger pathways. The system is expected to fly in 2019 and build towards a constellation of telescopes flying in observation campaigns.

E1.15-0027-18 KILOHERTZ RADIO SIGNAL BY GW OF NS-NS COLLAPSE CONVERTED BY PLANETARY,GALACTIC FIELDS: A DETECTABLE NOVEL DISCOVERY?

Daniele Fargion, daniele.fargion@roma1.infn.it

Physics Department, Rome University 1, INFN Rome 1,, Rome, Italy

The very recent Gravitational Wave detection at several hundreds Hertz by LIGO due to a few tens solar masses binary black hole collapse at 400 Mpc distance imply also a much abundant population of a few solar masses BH-NS or NS NS merging event, bounded in a more rapid collapse system. Indeed the very recent and very near GW170817 and its correlated GRB170817A did exibith such a GW kilohertz peak signatures occurring at a much nearer volumed (40 Mpc distance) and at a consequent much higher rate. The (NS-NS) merging frequency should be much higher than heavier tens Solar masses BH events, and they will be detectable within 20-80 Mpc by future LIGO-VIRGO GW advanced array detector, possibly leading to several NS-NS event each year. However their low energy graviton (tens Kilohetz) conversion into long radio ones along their flight from the source, by galactic (or even by solar or planetary) magnetic fields, may lead to sudden radio burst correlated with the same GW and or GRB burst. These very low radio bangs (and their polarization), foreseen more than twenty years ago, might be observable today at best from a screened radio array antenna located for instance on the Moon hidden and silent side. If such radio array might be sent also at solar system edges (Voyager distances) their far diluted plasma space will allow a better radio detection even at the low KHz radio waves, comparable to the recent GW-GRB 170817A event and even to the lightest BH-BH collapse. Triangulations, time correlation also with LIGO-VIRGO signals, may filter and disentangle the event from most interstellar radio noises. References: 1) D.Fargion, Prompt And Delayed Radio Bangs At Kilohertz By SN 1987A: A Test For Graviton-Photon Conversion; Grav.Cosmol. 1, 301-310, (1995).

E1.15-0028-18 GRAVITATIONAL WAVE ASTROPHYSICS IN THE MID-BAND: PROGENITORS AND PRE-MERGER LOCALIZATIONS OF ADVANCED LIGO/VIRGO BINARY-MERGER EVENTS

MAGIS team

We consider the scientific potential of gravitational wave (GW) observations in the 30 mHz to 3 Hz frequency range with the Mid-band Atomic Gravitational-wave Interferometric Sensor (MAGIS). MAGIS is a probe-class space-mission concept, using an atom-based gravitational wave detector, that will provide allsky strain sensitivities of 1E-21 sqrt(Hz) and better (1- year) in the GW-frequency mid-band between the LISA/L3 detector (planned 2034 launch) and ground-based Advanced LIGO/Virgo interferometers. Primary gravitational wave astrophysics science in the mid-band include GW observations of the binary black hole population discovered by Advanced LIGO/Virgo at higher-frequencies, prior to their merger stage. For such systems, MAGIS will observe the binaries in their inspiral phase, where system parameters such

as eccentricities are most easily constrained, and will provide pre-merger, degree-scale localizations that would enable electromagnetic observations of possible precursor emission 1-week to 1- month prior to their mergers as well as prompt post-merger transient emission. Joint GWobservations with MAGIS and Advanced LIGO/Virgo covering all stages of binary coalescence will further reduce uncertainties in the GWlocalizations and distances, and will be powerful paired with galaxy catalogs, to enable unique galaxy counterpart identifications in the case black hole binary mergers are completely absent of detectable electromagnetic precursor or transient signals. These possibilities for MAGIS extend to neutron star binary systems (black hole - neutron star, neutron star - neutron star), and mid-band prospects for such systems will also be considered. Importantly, the full sequence of binary evolution of Advanced LIGO/Virgo merger events through the GW mid-band and post-merger electromagnetic follow-up, will unfold within PhD-timescales.

The MAGIS team is a collaboration between institutes in the U.S. including Stanford, AOSense, Harvard, NASA/GSFC, NASA/JPL, NIST, NRL, and UC Berkeley, and international partners at Birmingham, Bordeaux, CNRS, Dusseldorf, Ecole Normale Superieure, Florence, Hannover, and Ulm University.

E1.15-0029-18 SCALAR AND ELECTROMAGNETIC PERTURBATIONS OF NONSINGULAR NONROTATING BLACK HOLES IN CONFORMAL GRAVITY

Bobomurat Ahmedov, bahmedov@yahoo.com

Ulugh Beg Astronomical Institute, Tashkent, Uzbekistan Bobir Toshmatov, b.a.toshmatov@gmail.com

Silesian University in Opava, Opava, Czech Republic

We study scalar and electromagnetic perturbations of a family of nonsingular nonrotating black hole spacetimes that are solutions in a large class of conformally invariant theories of gravity. The effective potential for scalar perturbations depends on the exact form of the scaling factor. Electromagnetic perturbations do not feel the scaling factor, and the corresponding quasinormal mode spectrum is the same as in the Schwarzschild metric. We find that these black hole metrics are stable under scalar and electromagnetic perturbations. Assuming that the quasinormal mode spectrum for scalar perturbations is not too different from that for gravitational perturbations, we can expect that the calculation of the quasinormal mode spectrum and the observation with gravitational wave detectors of quasinormal modes from astrophysical black holes can constrain the scaling factor and test these solutions.

E1.15-0030-18 RESULTS FROM THE NASA SPACE TECHNOLOGY 7 DISTURBANCE REDUCTION SYSTEM MISSION ON LISA PATHFINDER

John Ziemer, john.k.ziemer@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, United States

Space Technology 7 Disturbance Reduction System (ST7-DRS) is a NASA technology demonstration payload that was hosted on ESA's LISA Pathfinder mission to provide drag-free control of the spacecraft. The DRS used the inertial sensor on board ESA's LISA Technology Package (LTP) to provide feedback and keep the spacecraft following one of two free-floating test masses at noise level acceptable for a future gravitational wave (GW) observatory. The DRS includes four subsystems: (1) The Integrated Avionics Unit (IAU), a computer; (2) Colloid Micro Newton Thrusters (CMNT), two clusters of four thrusters, each; (3) Dynamic Control Software (DCS), a software subsystem which implements drag-free control algorithms and

(4) Flight Software (FSW), a software subsystem which processes commands and telemetry and hosts the DCS. LISA Pathfinder was launched on December 3, 2015, and the DRS went through IAU, FSW, and thruster commissioning in January 2016, full instrument commissioning in July to August 2016, prime mission and experiment from August to December 2016, and an extended mission and experiment from March to April 2017. Experiments included controlling the spacecraft through various drag-free control modes, observing test mass position and acceleration noise, thruster calibration and performance model validation. The DRS met all mission-level requirements for a successful demonstration of the colloid microthruster and 18 degree-of-freedom drag-free control technologies and showed good performance. Here we summarize the performance of the NASA thrusters and control laws throughout the mission.

E1.15-0031-18 AUSTRALIAN FOLLOW-UP OF GRAVITATIONAL WAVE COUTERPARTS

Bruce Gendre, bruce.gendre@gmail.com

University of Western Australia, Crawley, Australia Kendall Ackley, kendall.ackley@monash.edu Monash University, Clayton, Australia

Igor Andreoni, iandreoni@swin.edu.au

Swinburne University's Centre for Astrophysics, Melbourne, Australia Jeffrey Cooke, jeffreycooke@swin.edu.au

Swinburne University's Centre for Astrophysics, Melbourne, Australia David Coward, coward@physics.uwa.edu.au

University of Western Australia, Perth, Australia Eric Howell, eric.howell@uwa.edu.au

University of Western Australia, Perth, Australia

We will present on behalf of a large collaboration observational results on the electromagnetic follow-up of GW170817. We will in particular focus on the Australian led efforts in the optical and radio domains and discuss the implications of these observations on the nature of this event. Finally will outline our plans for the next LIGO-Virgo observational run planned for late 2018.

E1.15-0032-18 ACCURATELY RECALIBRATED WAVEFORMS FOR EXTREME-MASS-RATIO INSPIRALS IN EFFECTIVE-ONE-BODY FRAME

Wenbiao Han, wbhan@shao.ac.cn

Shanghai Astronomical Observatory of CAS, Shanghai, China

How to calculate the gravitational waves (GWs) of Extreme-mass-ratio-inspirals (EMRIs) in a highly accurate and efficient way still keeps a challenge. In this paper, we present a so-called fully recalibrated waveforms for EMRIs with high accuracy. Based on the numerical data by solving the Teukolsky equations, we recalibrate all mass-ratio independent coefficients of the factorized waveforms which are used in the effective-one-body (EOB) models. Due to these new coefficients, the precision of waveforms is improved enormously, and is much higher than the original forms and at the same time higher than other existing calibration models. We believe our model will play an important role in the waveform-template construction of the space-based GW detectors.

E1.15-0033-18 OBSERVING GRAVITATIONAL WAVE SOURCE ERROR BOXES WITH THE TAROT NETWORK OF AUTOMATED TELESCOPES

Kanthanakorn Noysena, astronu@gmail.com University of Toulouse, Toulouse, France Michel Boer, michel.boer@oca.eu

CNRS, Nice, France

Alain Klotz, alain.klotz@free.fr CESR, Toulouse, France

Siramas Komonjinda, siramas.k@cmu.ac.th Chiang Mai University, Chiang Mai, Thailand

During the previous runs (O1 and O2) of Virgo and LIGO, the TAROT network has followed the localizations that were communicated. This set of small instruments (25cm) is distributed in three locations around the globe in France, Chile and La Réunion island (F). We present the observations that were made, and the methods we have developped to process the data.

E1.15-0034-18 G-CUBE: A NOVEL NANO-SATELLITE FOR GRAVITATIONAL WAVE ELECTROMAGNETIC COUNTERPART (GW EM) DETECTION

ShuFan Wu, shufan.wu@sjtu.edu.cn Zhangye Medical College, ShangHai, China Shaolin Xiong, xiongsl@ihep.ac.cn

Institute of High Energy Physics, CAS, China, Beijing, China Zhongcheng Mu, muzhongcheng@sjtu.edu.cn

ShangHai JiaoTong University, ShangHai, China Wenxi Peng, pengwx@ihep.ac.cn

Institute of High Energy Physics, Chinese Academy of Sciences, Beijing, China

Beneficial from the nano-satellite technology exploration in the past decades and the innovative development of Silicon photomultipliers technology, in the present paper, a nano-satellite mission to detect X/gamma-ray EM counterpart of compact binary star merger GW observed by LIGO and Virgo will be proposed (G-cube project). Aiming to guarantee the reliability, the matured cubesat technology is adopted, and most platform components of nano-satellite are inherited from STU-2 cubesat mission, which was successfully launched into orbit in Sept. 2015. The payload consists of three novel and compact gamma-ray detectors sensitive from 10 keV to 1 MeV, each of which is made with a LaBr3 scintillator read out by an array of SiPM. G-cube project will verify the space application of this novel gamma-ray detector which will be used in the future space-based gamma-ray detection, and shall become the first effort internationally to demonstrate inexpensive gravitational wave EM detection technology based on the nano-satellite.

E1.15-0035-18 TIME DELAY BETWEEN SN NEUTRINO PROMPT SIGNALS BY NEARBY GALAXIES AT HYPERKAMIOKANDE: A DETECTABLE (AND GUARANTEED) ATMOSPHERIC NEUTRINO MASS.

Daniele Fargion, daniele.fargion@roma1.infn.it

Physics Department, Rome University 1, INFN Rome 1,, Rome, Italy

Ther recent LIGO-VIRGO detection of GW did show succesfully the possibility to observe nearby (40 Mpc) NS-NS collapse even with correlated GRB burst. The eventual NS-NS collapse and spherical thermal neutrino flash will be hardly detectable by ICECUBE GigaTon or Super Kamiokande SK tens KiloTons underground neutrino detectors. However the near future HyperKamiokande (HK) Megaton twin detector in Japan and possibly Corea might be able to reveal ten MeV thermal neutrino in wider distances and at more frequent and abundant Super Novae event rate. A non negligible fraction of such SN might be triggered by a NS merging with white dwarf stars leading to observable GWs and neutrino burst. Also assymmetric SN explosion may be source of GW and huge thermal neutrino burst. Their SN occurence might be hundred time more abundant than NS NS collapse. Therefore such SN triggered binary collapse and their GW might be take place within a few Mpc (at less intense metric perturbation respect NS NS event) each year and their correlated neutrino burst might be reachable by HK opening a fundamental thermal neutrino versus GW multifrequency signal. Moreover nearer (but a little more rare) SN-GW within one or two Mpc distances sites, the eventual correlated GW (by Ligo-Virgo) and its (millisecond sharp) first prompt neutrino signal (obervable in HK), its time delay (a few milliseconds later) than its GW, it might be observable (for instance from Andromeda). Such a time delay measure might disentangle even the minimal (tiny but guaranteed) atmospheric (0.05 eV) neutrino mass. That result might be therefore the first and most sophisticated astrophysical mass neutrino measure never achieved or even foreseen, by any terrestrial laboratory. References: 1) D.Fargion, Time Delay Between Gravitational Waves and Neutrino Burst From a Supernova Explosion: a Test for the Neutrino Mass Lett.Nuovo Cim. 31 (1981) 499-500. 2)D. Fargion, D. D'Armiento, Inconsistence of super-luminal Cern-Opera neutrino speed with observed SN1987A burst and neutrino mixing for any imaginary neutrino mass; J. Phys. G: Nucl. Part. Phys. 39. 085002,(2012)

E1.15-0036-18 GEOMETRIC-STOCHASTIC TEMPLATE BANKS FOR GRAVITATIONAL WAVE SEARCHES FROM COMPACT BINARIES IN ADVANCED-LIGO DATA

Soumen Roy, soumen.roy@iitgn.ac.in IIT Gandhinagar, Gandhinagar, India

Anand Sankar Sengupta, asengupta@iitgn.ac.in IIT Gandhinagar, Gandhinagar, India Parameswaran Ajith, ajith@icts.res.in

International Centre for Theoretical Sciences, Bengaluru, India

Gravitational waves from compact binary coalescence are the most promising candidate for terrestrial broadband interferometric observatories like the Advanced LIGO/Virgo detectors. Searches for compact binary sources involve matched-filtering the data with a set of possible template waveforms spanning a range of waveform parameters. Development of efficient gridding strategies for covering the search parameter space leads to computationally efficiency. This is particularly important in the era of advanced detectors, where the increased bandwidth and low-frequency sensitivity have resulted in a vast increase in template bank sizes as seen in the recently concluded O1 and O2 searches. To this end, we present a new template placement algorithm that combines the robustness of the stochastic placement method along with the efficiency afforded by the use of (A∗n) lattice to cover the volume. We show that the template placement is resilient to variations in the curvature of the parameter space and can deal with so-called “boundary effects” with no explicit fine tuning in the design. We also develop a numerical method to evaluate the metric in the space of waveform parameters, used to place these hybrid templates. We compare these hybrid banks against existing stochastic template banks to establish that while both are equally effective in capturing sources modeled by IMRPhenomD and SEOBNRv4 waveform families, the new hybrid banks are significantly smaller in size and take an order of magnitude less time for generation.

E1.16-0001-18 WFIRST: SURVEY OVERVIEW AND MISSION STATUS

Jeffrey Kruk, jeffrey.w.kruk@nasa.gov

Goddard Space Flight Center, Greenbelt, Maryland, United States

The Wide-Field InfraRed Survey Telescope (WFIRST) will be the next NASA Astrophysics flagship mission to follow JWST. The observatory payload consists of a Hubble-size telescope with a wide-field NIR instrument, and a coronagraph operating at visible wavelengths and employing state-of-the-art wavefront sensing and control. The Wide-field instrument is optimized for large area NIR imaging and spectroscopic surveys, with performance requirements driven by programs to study cosmology and exoplanet detection via gravitational microlensing. All data will be public immediately, and a substantial guest observer program will be supported.

The WFIRST Project is presently in Phase A, with a transition to Phase B expected in early to mid 2018. Candidate observing programs are under detailed study in order to inform the mission design, but the actual science investigations will not be selected until much closer to launch. We will present an overview of the present mission design, expected performance of representative surveys, and a summary of Project status.

E1.16-0002-18 UNVEILING THE DARK UNIVERSE WITH THE EUCLID SPACE MISSION

Yannick Mellier, mellier@iap.fr

Institut d'Astrophysique de Paris UMR 7095- CNRS & UPMC, Paris, France Rene Laureijs, rlaureij@rssd.esa.int

ESA/ESTEC, Noordwijk, Netherlands Giuseppe Racca, giuseppe.racca@esa.int ESA/ESTEC, Noordwijk, Netherlands The Euclid Collaboration

The Euclid Consortium and the ESA Euclid Team

The ESA Euclid mission aims to understand why the expansion of the Universe is accelerating and pin down the source responsible for the acceleration. It will uncover the very nature of dark energy and gravitation by measuring with exquisite accuracy the expansion rate of and the growth rate of structure formation in the Universe. To achieve its objectives Euclid will observe the distribution of dark matter in the Universe and its evolution over the last ten billion years by measuring the shapes of weakly distorted distant galaxies lensed by foreground cosmic structures. The shapes of lensed galaxies will be measured using the Euclid wide field imaging instrument VIS. In parallel, Euclid will analyse the properties of baryon acoustic oscillations and redshift space distortion and the distribution of clusters of galaxies by measuring the redshifts of galaxies with the NISP photometer and spectrometer instrument. The Euclid mission will observe one third of the sky (15,000 deg2) to collect data on several billion galaxies spread over the last ten billion years. In parallel to the space mission, the Euclid survey also comprises ground-based photometric and spectroscopic observations that will be used jointly with the Euclid satellite data to get photometric redshifts of billions of sources. Altogether the Euclid data set will be an exceptional gold mine for cosmology and fundamental physics but also for all fields in astrophysics. The presentation will describe the main scientific objectives and expected performances of the Euclid mission. The most recent forecasts and constraints on dark energy, gravity and dark matter will be presented as well as the expectations for the physics of inflation or neutrinos and the other domains of astronomy that will benefit from the Euclid mission data base.

E1.16-0003-18 THE EUCLID MISSION AT THE CRITICAL DESIGN REVIEW

Giuseppe Racca, giuseppe.racca@esa.int ESA/ESTEC, Noordwijk, Netherlands Rene Laureijs, rlaureij@rssd.esa.int ESA/ESTEC, Noordwijk, Netherlands Yannick Mellier, mellier@iap.fr

Institut d'Astrophysique de Paris UMR 7095- CNRS & UPMC, Paris, France

Euclid is a space-based optical/near-infrared high precision and high accuracy survey mission of the European Space Agency (ESA) to investigate the nature of dark energy, dark matter and gravity by observing the geometry of the Universe and on the formation of structures over cosmological timescales. Euclid will mainly use two probes of the signature of dark matter and energy: Weak gravitational Lensing, which requires the measurement of the shape and photometric redshifts of distant galaxies, and Galaxy Clustering, based on the measurement of the 3-dimensional distribution of galaxies through their spectroscopic redshifts. The mission is scheduled for launch in 2022 and is designed for 6 years of nominal survey operations. The Euclid Spacecraft is composed of a Service Module and a Payload Module. The Service Module comprises all the conventional spacecraft subsystems, the instruments warm electronics units, the sun shield and the solar arrays. In particular the Service Module provides the extremely challenging pointing accuracy required by the scientific objectives. The Payload Module consists of a 1.2 m three-mirror Korsch type telescope and of two instruments, the visible imager "VIS" and the near-infrared spectro-photometer "NISP" both covering a large common fieldof-view enabling to survey 15,000 sqd, more than 35% of the entire sky. All sensor data are downlinked using K-band transmission and processed by a dedicated ground segment for science data processing. The Euclid data and catalogues will be made available to the public at the ESA Science Data Centre. Euclid is currently undergoing to a Critical Design Review, a major milestone to prove the soundness of the mission design in all its aspects before manufacturing of flight hardware is fully deployed. We will also report on the expected mission performance following the latest simulations. This is based on the calculated and measured image qual- ity parameters of the optical system which shows exceptional capability of the Euclid space observatory.

E1.16-0004-18 AN OVERVIEW OF THE CHINESE SPACE STATION OPTICAL SURVEY

Hu Zhan, zhanhu@nao.cas.cn

National Astronomical Observatories Of China (NAOC), 100012, China

The Chinese Space Station Optical Survey is a major science project under the Space Application System of China Manned Space Program. It will be carried out by a 2m off-axis telescope in the same orbit as the Chinese space station, starting from early 2020s. The telescope is designed for a minimum lifetime of 10 years and can dock with the space station for service when needed. The survey plans to cover roughly 17,500 square degrees of the sky at a resolution of 0.15” in at least 6 broadband filters from 250nm to 1000nm, reaching an average depth of AB 25.5 mag (point source, 5-sigma). Low resolution slitless spectra will be taken at the same time over the same area reaching broadband depths of AB 22-23 mag. Deeper exposures will be made over selected areas across the sky. I will give a brief introduction to the project in this talk and discuss the expected performance from simulations.

E1.16-0005-18 THE LARGE SYNOPTIC SURVEY TELESCOPE (LSST)

Steven Kahn, skahn@slac.stanford.edu

Stanford University, Stanford, California, United States

LSST is a large-aperture, wide-field, ground-based telescope designed to provide a time domain imaging survey of the entire southern hemisphere in six optical colors. Over ten years of operations, LSST will acquire roughly one thousand visits of every part of the southern sky, reaching 24th magnitude in a single visit, and 27th magnitude for the co-added images. The resulting database will enable a diverse array of scientific investigations, ranging from studies of small moving bodies in the solar system, to the structure and evolution of the universe as a whole. The design of LSST incorporates an 8.4 m monolithic primary/tertiary mirror, a 3.5 m secondary, and 3.2 gigapixel camera, mounted up near the secondary. The construction is well underway, with most of the key subcomponents in the final stages of fabrication, leading to “first light” in 2020 and the onset of the survey in 2022. I will provide a brief overview of this project, and highlight some of the exciting science that is likely to emerge from LSST when it comes on line.

E1.16-0007-18 DARK ENERGY WITH EUCLID

Santiago Casas, s.casas@protonmail.com CEA Saclay, Paris-Saclay, France

Euclid is an ESA medium-class mission expected to launch in 2020 that will map the geometry of the Universe by imaging 109 galaxies and measuring 107 galaxy redshifts in 15000 square degrees of the sky. This will provide us detailed information about the accelerated expansion, the evolution of large-scale structure and the matter-energy content of the Universe up to a redshift of about z 2. In this talk, I will review how the main probes of Euclid, namely galaxy clustering and weak lensing, will be able to constrain theories beyond the standard cosmological ΛCDM model and how we will be able to pin down the equation of state of dark energy with about 1% precision. Galaxy clustering measures mainly the movement of tracers along geodesics, while weak lensing is an almost direct mapping of the gravitational potentials at large scales. Using both of these observables, we can obtain valuable information about the growth of perturbations and the geometrical quantities of the Universe and therefore constrain the properties of General Relativity. Since the measurements of Euclid will also give insights on the properties of dark matter and neutrinos at cosmological scales, I will also show how we can measure non-standard couplings between matter species and dark energy and how we can give tight constraints on many alternative theories of gravity.

E1.16-0008-18 DARK ENERGY WITH WFIRST

Shoubaneh Hemmati, shemmati@caltech.edu

Infrared Processing and Analysis Center (IPAC), Caltech, Pasadena, California, United States

The cause of the now observationally well established cosmic acceleration over the last five billion years remains one of the most fundamental questions in physics. Either Einstein's theory of gravity break down on cosmological scales or the universe is dominated by some form of Dark Energy which we still know very little of. The Wide Field Infrared Survey Telescope (WFIRST)'s primary Dark Energy science objective is to determine the expansion history of the universe and the growth history of its large-scale structure in order to test possible explanations of its accelerating expansion. This goal will be achieved through a combination of the dedicated High Latitude Survey (HLS), which will provide four bands (Y, J, H, F184) imaging and spectroscopy (1.35 - 1.95um) over 2000 square degrees, along with a three-tiered survey aimed at detecting supernova Ia. In this talk, I will discuss how WFIRST observations enable higher precision measurements of cosmological parameters using three complementary techniques (i.e. supernova Ia, weak gravitational lensing, and baryon acoustic oscillations) using forecast simulations and comparisons to other ground and space based missions.

E1.16-0009-18 SCIENCE OF THE CHINESE SPACE STATION OPTICAL SURVEY

Zuhui Fan, fanzuhui@pku.edu.cn Peking University, Beijing, China

The Chinese Space Station Optical Survey (CSS-OS) is a space-borne mission designed to have a 2m aperture and about 1.1 square degrees field of view. It will carry out both imaging and spectroscopic surveys with the wavelength coverage from 255nm to 1000nm. The primary science goal of CSS-OS is to understand the dark Universe by probing the large-scale structures via weak lensing effects and galaxy clustering. Meanwhile, its wide wavelength coverage and high imaging quality can enable a broad range of studies from the solar system to galaxy formation and evolution. In this presentation, I will discuss the scientific potential and challenges of CSS-OS with an emphasis on cosmology.

E1.16-0010-18 NEUTRINOS, MODIFIED GRAVITY AND NON-GAUSSIANITY WITH EUCLID

Eva-Maria Mueller, eva-maria.mueller@port.ac.uk University of Portsmouth, Portsmouth, United Kingdom

Upcoming spectroscopic and photometric surveys such as the Euclid mission will measure the large scale structure (LSS) of our Universe to an unprecedented level. LSS data not only contains information about dark energy but allows us to constrain the sum of neutrino masses and primordial non-Gaussianity as well as to test gravity. I will present an overview of the observational effects of these extensions to the vanilla ΛCDM model on the LSS, discuss expected constraints and provide an outlook of potential theoretical and observational challenges.

E1.16-0011-18 ASTROMETRY WITH WFIRST

Robyn Sanderson, robyn@caltech.edu

California Institute of Technology, Pasadena, California, United States WFIRST Astrometry Working Group

Robyn E. Sanderson, Andrea Bellini, Stefano Casertano, Jessica R. Lu, Peter Melchior, David Bennett, Michael Shao, Jason Rhodes, Sangeeta Malhotra, Scott Gaudi, R. Michael Fall, Ed Nelan, Puragra Guhathakurta, Jay Anderson, Shirley Ho, Mattia Libralato

The Wide-Field InfraRed Space Telescope (WFIRST) will be capable of delivering precise astrometry for faint sources over the enormous field of view of its main camera, the Wide-Field Imager (WFI). This unprecedented combination will be transformative for the many scientific questions that require precise positions, distances, and velocities of stars. I will describe the expectations for the astrometric precision of the WFIRST WFI in different scenarios, illustrate how a broad range of science cases will see significant advances with such data, and outline synergies with current and future projects such as Gaia and LSST.

E1.16-0012-18 THE STARSHADE PROBE MISSION CONCEPT

Sara Seager, seager@mit.edu

Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

The Starshade Rendezvous Mission Concept Probe is a Starshade that works with the WFIRST Mission, but is built and launched separately, with a rendezvous on orbit. A 2015 Exo-S report first detailed the mission concept. In the current study we develop a new scientific vision for WFIRST exoplanet discovery and characterization, using the complementary coronagraph and starshade to execute the most sensitive and thorough direct imaging campaign ever attempted. The overarching goal is to carry out the first “deep dive” direct imaging exploration of planetary systems orbiting the nearest sun-like stars in a search for Earth-like planets using only a fraction of the WFIRST telescope time. The study aims to improve on the Exo-S 2015 report with updated study of the key spacecraft and starshade technology development issues, as related to WFIRST design changes since 2015 that make the timely implementation of such a mission possible. Starshade mission options beyond the Rendezvous Mission Concept with WFIRST are also described.

E1.16-0013-18 MICROLENSING WITH WFIRST

Matthew Penny, penny@astronomy.ohio-state.edu Ohio State University, Columbus, Ohio, United States

Roughly a quarter of WFIRST's primary mission will be spent conducting an exoplanet microlensing survey. The survey will provide a statistical assay of the cold exoplanet population with masses greater than that of Mars and orbits beyond 1 AU, with a total planet yield comparable to Kepler's. It will also measure the mass function of free-floating planets potentially down into the mass regime of large Kuiper Belt Objects. The WFIRST microlensing survey parameter space spans critical mass and distance scales in planet formation theories, including the ice line, the isolation mass, and the critical mass for runaway gas accretion. I will give an overview of the WFIRST microlensing survey, and the highlights of its expected results. I will also describe the legacy value of the WFIRST microlensing data set of high-cadence near-infrared lightcurves of 200 million stars, which are potentially useful for asteroseismology, astrometry, transiting hot and warm Jupiters, and isolated black holes, to name but a few.

E1.16-0014-18 CASTOR: A WIDE-FIELD UV-OPTICAL IMAGING TELESCOPE

Patrick Cote, patrick.cote@nrc-cnrc.gc.ca

National Research Council/HIA, Victoria, Canada

Since 2012, the Canadian Space Agency has been developing a mission concept for a widefield, nearly diffraction limited UV/optical space telecope: the Cosmological Advanced Survey Telescope for Optical and uv Research (CASTOR). CASTOR is a 1m telescope that uses a three mirror anastigmat design to provide deep, panoramic imaging in three filters covering the 150-550nm wavelength range. In this talk, I describe the current design of the facility and highlight its extraordinary scientific potential by focusing on specific programs in cosmology and dark energy, galaxy evolution and star formation, AGNs and QSOs, near-field cosmology, Galactic structure, stellar astrophysics, exoplanets and the outer solar system.

E1.16-0015-18 SPHEREX: AN ALL-SKY SPECTRAL SURVEY

Olivier Dore, olivier.dore@caltech.edu

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

SPHEREx, a mission in NASA's Medium Explorer (MIDEX) program that was selected for Phase A in August 2017, is an all-sky survey satellite designed to address all three science goals in NASA's astrophysics division, with a single instrument, a wide-field spectral imager. We will probe the physics of inflation by measuring non-Gaussianity by studying large-scale structure, surveying a large cosmological volume at low redshifts, complementing high-z surveys optimized to constrain dark energy. The origin of water and biogenic molecules will be investigated in all phases of planetary system formation - from molecular clouds to young stellar systems with protoplanetary disks - by measuring ice absorption spectra. We will chart the origin and history of galaxy formation through a deep survey mapping large-scale spatial power in two deep fields located near the ecliptic poles. Following in the tradition of all-sky missions such as IRAS, COBE and WISE, SPHEREx will be the first all-sky near-infrared spectral survey. SPHEREx will create spectra (0.75 - 5 um at R = 40 and 135) with high sensitivity using a cooled telescope with a wide field-of-view for large mapping speed. During its two-year mission, SPHEREx will produce four complete all-sky maps that will serve as a rich archive for the astronomy community. With over a billion detected galaxies, hundreds of millions of highquality stellar and galactic spectra the archive will enable diverse scientific investigations and enable many synergistic analysis with other large scale structure surveys of the next decade.

E1.16-0016-18 THE HABITABLE EXOPLANET OBSERVATORY (HABEX)

Alina Kiessling, alina.a.kiessling@jpl.nasa.gov

Jet Propulsion Laboratory, Pasadena, California, United States Scott Gaudi, gaudi.1@osu.edu

Ohio State University, Columbus, Ohio, United States Bertrand Mennesson, bertrand.mennesson@jpl.nasa.gov

Jet Propulsion Laboratory, Pasadena, California, United States Sara Seager, seager@mit.edu

Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

The Habitable Exoplanet Observatory (HabEx) is one of four flagship mission studies currently underway in preparation for the 2020 Astrophysics Decadal Survey. HabEx is a large UV to near-IR space telescope that is being designed to optimize high contrast direct imaging and characterization of Earth-sized and larger exoplanets using starlight suppression with a coronagraph and starshade. The large aperture, ultra-stable telescope will also enable a broad range of observatory science from two dedicated instruments: a UV to near-IR camera and spectrograph and a multi-object UV spectrograph. The optical and infrared surveys of the 2020's will reveal an enormous range of exciting new discoveries and HabEx is poised to enhance on these efforts in the 2030's with its next-generation instruments and capabilities.

E1.16-0017-18 INFRARED SURVEYS WITH THE ORIGINS SPACE TELESCOPE

Douglas Scott, dscott@astro.ubc.ca

University of British Columbia, Vancouver, Canada

The Origins Space Telescope (OST) is the mission concept for a midand far-IR surveyor, one of NASA's flagship-class studies for the 2020 Decadal Survey. Operating between 5 microns and 660 microns, OST's cold (4K) telescope (5.9m) will provide a sensitivity that is orders of magnitude better than what can be currently achieved. This capability opens up a wide range of science goals, within the themes of "Are we alone?", "How did we get here?" and "How does the Universe work?" A suite of four instruments is being studied, which include broad-band imaging, spectroscopic, polarimetric, and coronagraphic capabilities. Moreover, OST will be capable of fast mapping speeds to support large-area surveys in the infrared. The satellite will used for projects such as targeted exoplanet investigations, tracking water through astrophysical environments, charting the rise of metals, and large-scale mapping of the Universe in IR continuum and lines. It will build upon the wide-area surveys of WFIRST and Euclid. Its complementarity with other facilities also offers OST the possibility of probing the end of the dark ages, as well as following up obscured gravitational wave sources and other transient phenomena, in ways that are not possible at optical wavelengths.

E1.16-0018-18 PIXEL FUSION: MODELING THE SKY WITH ALL AVAILABLE DATA

Peter Melchior, peter.m.melchior@gmail.com

Princeton University, Princeton, New Jersey, United States

The image modeling framework "scarlet" (Melchior et al. 2018) enables the joint use of multiple data sets of the same celestial scene. It can be used to improve source modeling and source separation by working on multi-band images and/or by combining low-resolution with highresolution images. It is specifically developed for joint pixel-level processing of data from LSST, WFIRST, and Euclid. I will introduce the method, discuss the statistical challenges in interpreting scenes consistently across multiple data sets, and demonstrate the improvement for precision photometry and shape measurements that are achievable with scarlet.

E1.16-0019-18 WIDE FIELD SPACE BASED SURVEYS IN THE 2020S: A PANEL DISCUSSION

Jason Rhodes, jason.d.rhodes@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

We will have a panel of scientists involved with WFIRST, Euclid, and the Chinese Space Station Optical Survey discuss planes for these ambitious surveys and take questions from the audience.

Releasing large volumes of survey data such that the scientific return can be maximized is a major challenge. This requires long term preparation, development of dedicated data processing and handling facilities, and a high degree of organization with the participation of scientific data experts. The Euclid Space Mission is no exception, and Euclid has the additional commitment to meet an agreed data release schedule. Many aspects have to be taken into account, not all of these aspects are visible to the end user, but can raise major (design) problems to make a data release happen on time. In addition, the end user must have access to supplementary information before starting the scientific exploitation. This extra information has to be transferred from the instrument development via the operational experience to the scientist. Even though Euclid's data rate will not be the most extreme (approximately 200 Gbyte per day of raw science data), Euclid is expected to generate a 24/7 data flow for 6 years to cover eventually an area of 15,000 deg2 in optical imaging, near-infrared imaging photometry and near-infrared spectroscopy, with space-based spatial resolution. These data will be combined with g, r, i and z-band ground-based optical photometry, covering the same sky as Euclid. In total the final Euclid survey will release about 100 Pbyte of images and catalogues. Key elements are the accessible archive with its data products, the scientific validations, and user support providing knowledge and, possibly, advanced remote processing facilities. We will review these key elements from a Euclid perspective - also considering experiences from and synergies with other missions - and discuss the possible choices enabling a successful science exploitation after data release.

E1.16-0022-18 MULTI-TRACER, HIGH-RESOLUTION MASS MAPPING OF WIDE FIELDS

Julian Merten, giuliano.merten@gmail.com

Osservatorio Astronomico di Bologna, Oxford, United Kingdom

To this point, the fields of cosmic shear and the lensing analysis of individual objects such as lensing clusters of galaxies or single galaxies have been largely distinct, for good reasons. On the one hand, only pencil-beam optical/NIR observations with e.g. HST or ground-based telescopes such as Subaru fulfilled the requirements on the density of background objects and image quality/resolution to allow detailed mass reconstruction of deflectors in the field of interest. On the other hand, earlier wide-field optical surveys such as SDSS and on-going surveys such DES, KiDS or HSC deliver weak lensing observations over large portions of the sky but have to compromise in terms of weak lensing background galaxy density or the identification of additional tracers such as strong lensing features. This picture will change dramatically with the advent of ground -and space-based lensing surveys such as LSST, Euclid or WFIRST. Detailed mass reconstructions of large fractions of the sky will become possible, given the development of methods that can produce mass maps on such scales. Two qualities are key for the success of such methods: a) an adaptive resolution of the resulting mass map which is based on multiple lensing and other tracers at varying spatial scales and b) numerical efficiency and parallelism which enables almost all-sky reconstructions at potentially sub-arcminute resolution at acceptable runtimes. We have recently developed a framework which fufills these requirements. The method derives from combined weak -and strong-lenging reconstructions of galaxy clusters and it recovers the lensing potential in the so-called mesh-free domain. This means that the spatial distribution of output nodes does not have to follow any regular pattern and can hence optimally follow the distribution of input constraints. Such constrains can be either weak lensing measurements in the field, different kinds of strong lensing tracers at halo centres, baryonic tracers such as tSZ or X-ray measurements or local kinematic information as derived from galaxy spectroscopy. Secondly, the method was fully encapsulated into a three-stage parallelisation hierarchy, meaning a model that employs MPI for inter-node communication and OpenMP within individual nodes spawning threads to call multiple GPUs on each node, depending on the specific configuration of the production machine. Currently, using a single node with two NVIDIA GeForce Titan Xp GPUs we achieve runtimes of less than one second per square degree at sub-arcminute resolution. This renders future reconstructions of thousands of square degrees possible even on moderate hardware, including a full error analysis via resampling of the input catalogues.

E1.16-0023-18 A FIRST TRANSIENTS SURVEY WITH JWST: FLARE

Eniko Regos, regos@konkoly.hu

Konkoly Observatory, Research Centre for Astronomy and Earth Sciences, Hungarian Academy of Sciences, Budapest, Hungary

JWST will answer empirically how the Universe made its first stars. Instead of classical stare mode and still photography of objects of unknown spectra we quest the epoch of reionization in the time domain and target what happened to these first stars. We will observe the most luminous events: supernovae and accretion on to black holes from primordial gas. These transients provide direct constraints on star formation rates and the truly initial mass function. This will explore the physics of these events at ultra-low metallicity. These very rare events at the dawn of cosmic structure formation can be reached by JWST at 27 mag AB in 2 micron and 4.4 micron over a field of 0.1 square degree visited multiple times each year. This survey may detect massive Pop III SNe at redshifts up to 10, pinpointing the redshift of first stars, also large scale structure as the trademark of reionization; all key scientific goals of JWST.

E1.16-0024-18 THE INTEGRATED CRYOGENIC SYSTEM FOR THE SURVEY CAMERA OF THE CHINESE SPACE STATION TELESCOPE

Baoyu Yang, byyang@mail.sitp.ac.cn

Shanghai Institute of Technical Physics, CAS, Shanghai, China Yinong Wu, wyn@mail.sitp.ac.cn

Shanghai Institute of Technical Physics, CAS, Shanghai, China

The integrated cryogenic system for the Survey Camera of the Chinese Space Station Telescope includes three parallel arrangement 40W/170K low-vibration cryocoolers for the UV-Optical Focal Plane, a 6W/70K low-vibration cryocooler for the NIR Focal Plane, and flexible heat transfer device based on the low temperature heat pipe technology as well. These cryogenic elements were integrated together in order to meet the Temperature requirements of Focal Plane. This paper summarizes the cryogenic integration design, technical challenges, and the results of performance testing.

The NISP (Near Infrared Spectrometer and Photometer) is one of the two instrument onboard the ESA Euclid satellite. It operates as a slitless spectrograph in the 900-2000 nm wavelength range and as Y, J, H photometer. The instrument is composed of: - a cold (135K) optomechanical subsystem consisting of a Silicon carbide structure, an optical assembly, a filter wheel mechanism, a grism wheel mechanism, a calibration unit and a thermal control system; - a detection system based on a mosaic of 16 Teledyne H2RG sensors, with their front-end readout electronic; - a warm electronic system (280K) composed of a powerful data processing / detector control unit and of an instrument control unit; this last is connected to the spacecraft via a 1553 bus for command and control and via dedicated Spacewire links for science data transfer. NISP will provide photometric redshifts for sources imaged by the other Euclid instrument, the VISible imager, and more than 30 million accurate redshifts from slitless spectroscopy using H-alpha emission lines. This paper, presented on behalf of the NISP Team of the Euclid Consortium, describes: - the final architecture of the instrument following the Critical Design Review, - the subsystems hardware and software qualification or flight models, - the expected performances, - the development and the test plan.

E1.16-0026-18 EVALUATING AGE OF UNIVERSE BY PHOTO-METRIC ANALYSIS OF GLOBULAR CLUSTERS.

Robin Singh, robinsingh841997@gmail.com

University of Petroleum & Energy Studies, Dehradun, India Kirti Vishwakarma, gpmaruti@gmail.com

University of Petroleum & Energy Studies, Gurgaon, India Vipul Mani, mani.vipul14@stu.upes.ac.in

University of Petroleum & Energy Studies, Dehradun, India

The atoms of mankind exist from the "début de l'Univers" (beginning of Universe) encapsulated with its several other life forms. The keen drive for knowing more has always been the igniter of every thumping discovery ever made. The biggest pig in a poke where Genesis is concerned is that of the whole universe which can be unveiled by two broad methods, either by the study of the expansion of Universe or performing the same on Globular clusters containing numerous Stars because all the evidence seems to indicate that the Universe has not existed forever but that it had a beginning. Several studies have been conducted on various missions to NGC 2420 and other clusters such as NGC 4472 and NGC 2419. Futurology of this paper lies in the study of globular cluster NGC5466, which is approximately 51,800 light years away from us. As the entire information of genome is known by the DNA, likewise the age of the universe will be evaluated by the photo-metric analysis of different globular clusters in different colour bands by various methods commanded by DAOFIND, TVMARK, PHOT, PSTSELECT, etcetera. The ages of these old clusters will be compared by contrasting the estimated ages of the universe from Hubble constant and other cosmological models. Globular clusters like M2, M15, M68, M92 and NGC5466 which consists of Population III stars (extremely metal-poor stars that are theorised to have been the 'first-born' stars created in the universe) will be analysed together for evaluation of the approximate age of the universe. In addition, colour magnitude diagram(CMD) and Hertzsprung-Russel(HR) diagram evaluated from obtained data will be compared by the classical model like Benchmark, Einstein and de Sitter model for a better age estimation. Additionally, if we extrapolate back infinitely lingering around these stars, we will be able to understand if the classical age13.772 Billion years accepted so far based on the nomology is correct or not. Also, the demeanour of Universe will assist in manifesting the veracious spaciotemporal phenomenon that happened then.

E1.16-0027-18 GALAXY ELLIPTICITY MEASUREMENTS FOR WEAK LENSING USING NIR IMAGES

Bomee Lee, bomee@ipac.caltech.edu

IPAC Infrared Processing and Analysis Center, Pasadena, California, United States Ranga Ram Chary, rchary@caltech.edu

California Institute of Technology, Pasadena, California, United States Edward L. Wright, wright@astro.ucla.edu

University of California, Los Angeles, Los Angeles, California, United States

One of the primary science goals of Euclid is to constrain cosmological parameters through weak gravitational lensing. For the weak lensing shape measurement, the Euclid survey will detect galaxies in a broad optical R+i+z band (VIS), which reaches a 10 sigma depth of 24.5 AB magnitude. In this study, we demonstrate that co-added J+H-band near-infrared (NIR) images at Euclid's resolution and depth can yield better ellipticities of galaxies at redshifts $0.5<z<3$ than such optical images. There are several reasons for this better performance: Due to the morphological k-correction, galaxies have an intrinsically smoother shape distribution in the NIR bands than in the VIS, the latter mostly tracing the rest-frame UV light which follows the clumpy distribution of star-forming regions. Also, near-IR (J+H) images of galaxies have a higher surface brightness with more than three times the number of source photons per pixel and are less affected by dust extinction. Another benefit of using the near-IR bands is that they are sensitive to more than a factor of 2 more galaxies at $z>1.5$. We select galaxies at $0.5<z<3$ satisfying the Euclid sensitivity limit from CANDELS GOODS-S and GOODS-N fields and use F606w(V), F814w(I), F125w(J) and F160w(H) HST images of them. We then simulate Euclid VIS and near-IR images by degrading the co-added CANDELS/HST V+I and J+H images to the Euclid resolution, respectively, and compare the ellipticities estimated from CANDELS (I or and Euclid (V+I or J+H) images. By doing so, we find 20% better ellipticity measurement in J+H than in VIS. Despite the worse spatial sampling of the Euclid imaging data in the NIR compared to VIS (0.3" vs. 0.1"), we can extract a robust ellipticity measurement from the NIR bands. Our study motivates the careful assessment of NIR shape systematics for future weak gravitational lensing surveys, such as with Euclid and WFIRST.

E1.16-0028-18 LARGE-SCALE STRUCTURE STUDIES WITH THE OPTICAL AND INFRARED SURVEYS BY EUCLID AND WFIRST

Simona Mei, simona.mei@obspm.fr Observatore de Paris-Meudon, Paris, France

We will discuss how the Euclid and WFIRST space surveys will revoluzionize our understanding of large-scale structure during the epoch when the knots of the cosmic web first start forming. Our predictions are based on recent results from current optical and infrared surveys with the Hubble Space Telescope (HST). Imaging and grism spectroscopy obtained by the HST CANDELS (Grogin et al. 2011; Koekemoer et al. 2011) and CARLA (Wylezalek et al. 2013) surveys are giving us our first glimpse of large-scale structure formation at $z>1.5$ from these small samples. We are able to study the formation of clusters and proto-clusters and of the progenitors of the most massive galaxies in the Universe. These new observations enable us to optimize the study of large-scale structure at these high redshifts with Euclid and WFIRST.

E1.16-0029-18 ORIGINS SPACE TELESCOPE CONCEPT-2 SCIENCE TRACEABILITY MATRIX

Kimberly Ennico, kimberly.ennico@nasa.gov

NASA Ames Research Center, Mountain View, California, United States David Leisawitz, david.t.leisawitz@nasa.gov

NASA GSFC, Greenbelt, Maryland, United States Asantha Cooray, acooray@uci.edu

University of California, Irvine, Irvine, California, United States Margaret Meixner, meixner@stsci.edu

Space Telescope Science Institute, Baltimore, United States Johannes Staguhn, johannes.g.staguhn@nasa.gov NASA/GSFC, Greenbelt, Maryland, United States

Presented on behalf of the Origins Space Telescope (OST) study team, with engineering support at Goddard Space Flight Center. OST is one of four potential flagship studies supported by NASA Headquarters to prepare for the 2020 Decadal Survey. As a large cold mid-to-far infrared telescope OST will provide a sensitivity that is orders of magnitude more powerful than Spitzer and Webb. OST's key scientific goals are to (1) To characterize exoplanet atmospheres looking for bio-signatures in transiting planets and directly imaging thermal emission in Jupiterand Saturnexoplanet analogs; (2) To measure water across cosmic time from the first galaxies to proto-planetary disks to hundreds of comets in the solar system to solve the mystery of the origin of water on Earth; (3) To study proto-galaxies before the epoch of reionization in the cosmic dark ages and map the evolution of metals and chemistry over all cosmic time. In the evolution of the mission study, Concept 2 has been designed to have minimal deployments to mitigate risk and reduce integration costs and fit within a 7m fairing. Concept 2 is a cold (4K) telescope with 25 sq-meter collecting area, diffraction limited at 30 microns, with four instruments providing imaging and spectroscopy covering 5 to 660 microns. This paper will address the Science Traceability Matrix for the OST Concept 2.

E1.16-0030-18 EUCLID QUICK LOOK ANALYSIS SOFTWARE

Luca Conversi, luca.conversi@esa.int ESA/ESAC, Villanueva De La Cañada, Spain Matteo Miluzio, matteo.miluzio@sciops.esa.int ESA/ESAC, Villanueva De La Cañada, Spain

Euclid is an ESA mission due to launch in 2021 and aim at mapping the geometry of the dark Universe in the optical/near-infrared domain, investigating the distance-redshift relationship and the evolution of cosmic structure out to redshifts 2. It will use mainly two cosmological probes: the Weak Gravitational Lensing and the Baryon Acoustic Oscillations. Euclid will map the entire extragalactic sky with two instruments, VIS (VISible imager) and NISP (NearInfrared Spectro-Photometer), providing a huge amount of data: 850 Gbit per day of raw data, 1 Pbit per year of higher processed data.

The Science Operations Centre (SOC), located at the European Space Astronomy Centre (ESAC), Villanueva de la Cañada, Spain, is responsible for implementing the survey strategy, its operation and monitoring its performance. It is also responsible to develop and run the Quick Look Analysis (QLA) software, the system in charge of pre-assessing - within 48 hours of data reception - the quality of the data in order to react as soon as possible in case of instrumental problems (mis-configurations, abnormal data, etc.). The system is based on a pass/fail structure given a set of quality flags and raising alerts accordingly.

It consists of two main parts:

the QLA Processing Framework (QPF), developed in Qtk/C++, provides the processing framework to execute system functionalities, a human-machine interface (HMI) to control all its tasks, access to a local and Euclid archives, interaction with VO-Space and an alerting system via email the QLA Diagnostic Tools (QDT), developed in Python, implements different algorithms and diagnostic functions to check the quality of all the data: VIS, NISP but also housekeeping and Attitude and Orbit Control System (AOCS) product.

QLA will analyse all level 1 data: this is uncompressed, reordered raw data with tagged metadata associated. All the checks will be executed automatically due to the large amount of data. QLA shall be capable to:

Check the correctness of instrument commanding sequence

Assess the science data content against e.g. anomalies, mainly at pixel and instrumental level. However, QLA will not asses data quality from the scientific point of view

Implement quick feed-back on survey execution and image quality

Version 2.0 was released in the first quarter of 2018: it includes most of the envisaged checks for VIS and AOCS; the code for

NISP is under development in collaboration with NASA/IPAC and currently includes the backbone architecture and a couple of diagnostics.

E1.17-0001-18 MULTI-MESSENGER OBSERVATIONS OF BLACK HOLES - AN OVERVIEW

Roger Blandford, rdb3@stanford.edu

Stanford University, Stanford, California, United States

A steady growth in observational capability, throughout the electromagnetic spectrum and beyond, has led to a corresponding steady growth in our understanding of the underlying physical processes at work around black holes. This is especially true of those holes observed in the nuclei of galaxies, in X-ray binaries and being formed in Gamma Ray Bursts and gravitational radiation sources. Powerful accretion disks, jets and winds show a rich variety of behaviors. The case will be made that much of the transient activity is mediated by strong magnetic field. The strong prospect of future discovery from recently commissioned and soon to be operational facilities will be emphasized.

E1.17-0002-18 FERMI TRANSIENT J1544-0649: A FLARING RADIO-WEAK BL LAC

Gabriele Bruni, gabriele.bruni@iaps.inaf.it INAF-IAPS, Rome, Italy

Francesca Panessa, francesca.panessa@inaf.it INAF - IAPS Rome, Rome, Italy

On May 15th, 2017, the FERMI/LAT γ-ray telescope observed a transient source not present in any previous high-energy catalogue: J1544-0649. It was visible for two consecutive weeks, with a flux peak on May 21st. Subsequently observed by a Swift/XRT follow-up starting on May 26, the X-ray counterpart position was coincident with the optical transient ASASSN17gs = AT2017egv, detected on May 25, with a potential host galaxy at z=0.171. We conducted a 4-months follow-up in radio (Effelsberg-100m) and optical (San Pedro Martir, 2.1m) bands, in order to build the overall Spectral Energy Distribution (SED) of this object. The radio data from 5 to 15 GHz confirmed the flat spectrum of the source, favoring a line of sight close to jet axis, not showing significant variability in the explored post-burst time-window. The Rx ratio, common indicator of radio loudness, gives a value at the border between the radio-loud and radio-quiet AGN populations. The CaII H&K break value (0.29±0.05) is compatible with the range expected for the long-sought intermediate population between BL Lacs and FRI radio galaxies. An overall SED fitting from Radio to γ-ray band shows properties typical of a low-power BL Lac. As a whole, these results suggest that this transient could well be a new example of the recently discovered class of radio-weak BL Lac, showing for the first time a flare in the γ/X-ray bands.

E1.17-0003-18 A UNIFIED MODEL FOR GRB PROMPT EMISSION FROM OPTICAL TO GAMMA-RAYS: EXPLORING GRBS AS STANDARD CANDLES

Sylvain Guiriec, sylvain.guiriec@gmail.com

The George Washington University / NASA Goddard Space Flight Center, Greenbelt, District of Columbia, United States

The Band function traditionally used for Gamma Ray Bursts (GRB) often fails to fit their prompt emission spectra. Our new model composed of three separate components provides an excellent description of the time-resolved prompt emission: a thermal-like and two non-thermal components. For the first time, analysis of GRBs with correlated optical and gamma-ray prompt emission show that our new model describes very accurately the whole broadband spectrum from the optical regime to higher energy gamma rays. In addition, this new model enables a new luminosity/hardness relation intrinsic to one of the non-thermal components showing that GRBs may be standard candles. If statistically confirmed, this relation will be used to (i) constrain the mechanisms powering GRB jets, (ii) estimate GRB distances, (iii) probe the early Universe, and (iv) constrain the cosmological parameters. I will present this new unified model using analysis of GRBs detected with various observatories and instruments such as Fermi, CGRO/BATSE and the combination of the three instruments on board Swift and Suzaku/WAM. I will discuss here the striking similarities of GRB spectral shapes, whose components inform on the nature of the prompt emission, as well as the possible universality of the proposed luminosity/hardness relation in the context of our new model.

E1.17-0004-18 SYNTHETIC SPECTRA FOR AN OFF-AXIS AFTERGLOW FROM A SHORT GAMMA-RAY BURST

Ioana Dutan, idutan@spacescience.ro

Institute of Space Science, Magurele, Romania Nishikawa et al.

Ken-Ichi Nishikawa, Yosuke Mizuno, Jose L. Gomez, Athina Meli, Jacek Niemciec, Oleh Kobzar, Martin Pohl, Asaf Pe'er, Jacob Trier Frederiksen, Aake Nordlund, Helene Sol, & Dieter H. Hartmann

The simultaneous detection of gravitational waves by the LIGO and Virgo detectors from a binary neutron star (BNS) merge, GW 170817, is the first gravitational wave event that has electromagnetic (EM) follow-up observations, from gamma-rays to millimeter wavelengths. The data from these EM counterparts lead to the idea that the GW 170817 might be the first offaxis afterglow observed from a short gamma-ray burst (sGRB), and they would provide the first direct observational evidence for the launching of relativistic jets in BNS mergers. The properties of the jets, as well as their interaction with the environment, can be studied at the microscopic level by using particle-in-cell (PIC) numerical simulations. We study the evolution of relativistic plasma jets containing helical magnetic fields and examine how these helical magnetic fields affect (i) kinetic instabilities (such as the Weibel instability, the kinetic KelvinHelmholtz instability, and the Mushroom instability) and (ii) magnetic reconnection in the jets. We also calculate synthetic spectra and spectral evolution for the off-axis radiation emitted by the particles accelerated in such sGRB jets and compare them with observations. Nevertheless, simulations using very large systems are required in order to thoroughly follow the evolution of global jets containing helical magnetic fields.

E1.17-0005-18 ANALYSIS OF RECENT SHORT GRB AFTERGLOW LIGHT CURVES

Nidhal Guessoum, nguessoum@aus.edu

American University of Sharjah, Sharjah, United Arab Emirates Omar Alaryani, b00054003@alumni.aus.edu

American University of Sharjah, Sharjah, United Arab Emirates Khalid Alqassimi, b00065464@aus.edu

American University of Sharjah, Sharjah, United Arab Emirates Nidal Sherif, b00062890@aus.edu

American University of Sharjah, Sharjah, United Arab Emirates Showq Sama, u14121849@sharjah.ac.ae

University of Shajah, Sharjah, United Arab Emirates

Since the historic Aug. 17, 2017 simultaneous detection of gravitational and electromagnetic waves produced by the merger of two neutron stars, the GW-GRB 170817 event, interest in short gamma-ray bursts (SGRBs) has increased exponentially. SGRBs (bursts with durations less than 2.0 seconds) represent only about 10 % of all bursts, and unlike long GRBs, there was until this recent event no complete consensus on the (merger) physical mechanism responsible for SGRBs. This combined fact had kept interest toward short bursts relatively low. But in the few years before the GW-GRB connection, which fully cemented the merger model as the physical process behind SGRBs, the detection of kilonovae/ macronovae associated with three SGRBs had already started to raise the interest in this class of bursts.

Fong et al. (2015) collected and analyzed afterglow observations of SGRBs from 2005 to 2014, covering their broadband emission from X-rays to radio. Using the widely adopted theoretical prescription of Panaitescu Kumar (2000) for calculating afterglow fluxes, Fong et al. (2015) extracted individual and statistical values for the bursts' and afterglows' physical parameters: kinetic energy, medium density, electron and magnetic energy fractions, and jet opening angles.

We have extended that work to the last 3 years (Jan. 2015 to Dec. 2017), using Swift events (29 short bursts recorded during that period) and Fermi events (116 events). We have searched the literature (GCN reports and published papers) to collect afterglow observations, whether positive or negative (upper limits), limiting ourselves to optical and near-infrared data, the bands where kilonova detections can be successful.

Our aim is to fit or constrain the afterglow light curves with physical parameters, to the extent possible, and to try to identify cases that most resemble those that have had a kilonova detection. We present the most interesting cases that we have uncovered, along with the physical results from the sample.

E1.17-0006-18 GRB JET IN NS-NS COLLAPSE FEEDING NARROW JET AND WIDER ORTHOGONAL GAMMA DISK.

Daniele Fargion, daniele.fargion@roma1.infn.it

Physics Department, Rome University 1, INFN Rome 1,, Rome, Italy

The short GRB 170817A observed by Fermi and Integral correlated with LIGO-VIRGO GW 170817 posed several key questions. The associated Optical transient OT source in NGC4993 implied a very rare nearest source, a consequent averaged large rate for such events (almost) compatible with the expected NS NS merging rate, if the GRB signal was nearly spherical. However the expected GRB (or Short GRB) must be beamed, mostly aligned at a different direction than our one. Therefore even soft GRB photons, more spread than hard ones, might be hardly be able to shine and shower to us in the very first GW by NS-NS collapse. We therefore suggested that in GRB jet there is a new Ultra-relativistic spiraling electron "skin" (surrounding the jet itself) ruled by synchrotron radiation electron rings contained by external magnetic fields, born at the birth of the NS-NS collapse. Such a new synchrotron equatorial radiation might shine by its tangential gamma photons in a much spread way into a 360 degree gamma disk, orthogonal to the much collimated (advancing forward) narrow jet. The consequent solid angle of view for such a prompt, soft, wide disk gamma radiation may be wider than within any common (cosmic) thinner gamma jet, offering a solid angle large enough to be more probably observed (at a much weaker apparent luminosity), as it has been indeed observed. In the context of pulsar studies we have developed a tool for pulsar gating at radio and gammaray energies, in order to disentangle the pulsar signal from that of its pulsar wind nebula (PWN), using the technique of the subtraction of the pulsed component. In the case of the future Imaging X-ray Polarimetry Explorer (IXPE), which will be launched in 2021 and will be able to perform spectral-polarimetry together with spectral timing, the same approach can be applied to obtain phase-resolved polarimetry for the pulsar-PWN systems (one of its key science objectives) where the instrument resolution does not easily allow the separation of the two sources.

In parallel, we are developing a tool to search for pulsars and fast radio bursts (FRBs), with a technique alternative to the Fourier transform (FT), which uses the Karhunen-Loève transform (KLT). The KLT is a mathematical algorithm which has not been fully explored yet, due to its high computational demand, but which is potentially more powerful than the FT when applied to a generic signal buried in noise. The same approach can be applied to the search of fast transients of yet unknown nature, or for the search of the same transients, at other wavelengths than radio, if enough statistics is available.

The combination of these tools provides the starting point for a pipeline for the detection of new fast transients and their time-resolved and polarimetric studies. We present the application of the tools to the multi-wavelength analysis of real and simulated data of a sample of pulsars and their PWNe, for which we determine the

spectral timing and polarimetry properties from radio to gamma-rays and discuss how the new generation of telescopes can help constrain the geometrical structure and emission mechanisms of fast transients.

Jets/outflows are important feature in black holes. The ejection mechanism depends on the accretion flow and spectral states. Compact jets are generally observed in low/hard states. Blobby jets or discrete ejection generally observed in the intermediate states. Jets are quenched in the soft states. Jets are observed in multiwave bands, form radio to high energy X-rays and gamma-rays. In case of compact jet, radio and X-ray fluxes are correlated. However, for blobby jets, the correlation is not trivial. We have developed a new method to calculate jet X-ray flux from spectral analysis with two component advective flow (TCAF) model fits file in XSPEC. We use the fact that normalization must remain constant throughout the outburst since it is a function of intrinsic source parameters such as, mass, distance and inclination angle of the system. If jet is present, constancy of the model normalization breaks, and higher values of normalization may require to fit the spectra. This allowed us to assume on the minimum normalization day, jet contribution is also minimum. On the basis of this assumption, we developed a new method to separate X-ray contribution from inflowing / accretion disk matter and from jets / outflowing matter. Using this newly developed method, we have calculated X-ray contributions of jets/ outflow for Swift J1753.5-0127 during its 2005 outburst and MAXI J1836-194 during its 2011 outburst. We find jet contributes in the X-ray is upto 44% and 86% for Swift J1753.5-0127 and MAXI J1836-194 respectively. We also find correlation between radio (FR) and jet (Fout) X-ray fluxes, as FR F 0.6, which is similar to the standard correlation. From the correlation plot, we conclude that in the intermediate state Swift J1753.5-0127 showed blobby jet while MAXI J1836-194 showed compact jet throughout the outburst.

Recently after the inclusion of two component advective flow (TCAF) model into HEASARC's spectral analysis software package XSPEC as an additive table model, accretion flow dynamics around black holes are more clearly understandable from physical point of views. The TCAF model fitted spectral parameters i.e., two component (Keplerian disk and sub-Keplerian halo) accretion rates, shock (location, i.e., the size of the Compton cloud, and the compression ratio) parameters are quite capable of describing evolutions of various spectral and temporal properties/ phenomena during active phases of black hole sources. Spectral analysis with the TCAF model is also allowed us to estimate masses of black hole objects, since in the current version of the TCAF model fits file mass is an important input parameter. So, one can obtain one best-fitted mass value from each best-fitted spectrum. Unlike other phenomenological or theoretical models, TCAF model normalization should not change for one object on daily basis, since it depends on intrinsic source parameters such as, distance and disk inclination angle and mass of the black hole. So, using the method of constant normalization until now, we have been able to estimate probable mass ranges for more than half a dozen of black hole objects quite successfully. We have also verified our estimated masses with that of other methods, and found that our estimated masses are consistent with sometimes even better accuracy.

E1.17-0010-18 NON-EQUILIBRIUM IONISATION IN MHD SIMULATIONS

Gao-Yuan Zhang, gao-yuan.zhang@cfa.harvard.edu

Harvard-Smithsonian Center for Astrophysics, Cambridge, Massachusetts, United States

Although with a Magnetohydrodynamic (MHD) simulation we can reproduce many astrophysical scenarios, the plasmas in the simulations are often assumed to be CIE. If radiative cooling from heavy elements is significant in the MHD simulation or a detected spectrum is one of the results of the simulation, the CIE assumption should be removed and an NEI calculation should be done along with the simulation.

An eigenvalue method NEI calculation is added into FLASH code MHD simulation with an updated atomic database. The updated database and the eigenvalue method are compared with the original ones separately. With the eigenvalue method the calculation efficiency is improved on a large scale, and the radiative cooling can be calculated simultaneously. Some common ways to measure ionization states are investigated with an example simulation. The ion average charge difference from the equilibrium is shown to be a better method.

E1.17-0011-18 FINDING MULTI-MESSENGER TRANSIENTS WITH SWIFT: LESSONS LEARNED FROM SEARCHING FOR MAXI, ICECUBE AND LIGO/VIRGO TRANSIENTS

Jamie Kennea, kennea@astro.psu.edu

Pennsylvania State University, University Park, Pennsylvania, United States

We present results and lessons learned from multi-messenger and multi-telescope searches for X-ray and UV counterparts of transients, utilizing the Neil Gehrels Swift Observatory. Swift is unique in many ways, firstly it is a multi-wavelength observatory, observing in 0.5-150 keV in X-rays, and visible to UV in optical, utilizing the it's three instruments, the Burst Alert Telescope (BAT), X-ray telescope (XRT) and UV/Optical Telescope (UVOT). Secondly, Swift is a robotic telescope, capable of responding rapidly (minutes to hours) to transient triggers from a variety of sources. Thirdly it's rapid slewing capability allows it to perform unique tasks, such as very low-overhead tiling of large error regions to search for transients. Here we discuss lessons learned and recent results from Swift's search for transients discovered by the Japanese "Monitor of the All Sky X-ray Image" (MAXI) near-all-sky X-ray survey instrument. We show how we applied lessons learned from 8 years of collaborating with MAXI, and show results from recent searches for optical/UV and X-ray counterparts of possible astrophysical neutrino sources, as triggered by the IceCube Neutrino Observatory. Finally we discuss searches for EM counterparts of LIGO sources with Swift, as we prepare for O3.

E1.17-0012-18 GRAVITATIONAL-WAVE ASTRONOMY WITH ADVANCED LIGO

Alessandra Corsi, alessandra.corsi@ttu.edu

Texas Tech University, Lubbock, Texas, United States

On 2017 August 17, the field of gravitational-wave (GW) astronomy made the big leagues with a dazzling discovery. After several GW detections of black hole (BH)-BH mergers with no convincing EM counterparts, advanced LIGO and Virgo scored their first direct detection of GWs from a binary neutron star (NS) merger, an event dubbed GW170817. Soon after the GW discovery, GW170817 started gifting the astronomical community with an electromagnetic (EM) counterpart spanning all bands of the spectrum. In this talk, I will review what we have learned from GW170817, what questions remain open, and what are the prospects for future EM-GW studies of the transient sky.

E1.17-0013-18 FERMI OBSERVATIONS FOR GRAVITATIONAL WAVE COUNTERPARTS

Judith Racusin, judith.racusin@nasa.gov

Goddard Space Flight Center, Greenbelt, Maryland, United States

Fermi-GBM/LIGO-Virgo Working Group and the Fermi-LAT Collaboration on behalf of the Fermi-GBM/LIGO-Virgo Working Group and the Fermi-LAT Collaboration

The Fermi Gamma-ray Space Telescope monitors the sky for gamma-ray transients, making it an ideal facility for detecting counterparts to gravitational wave sources. As demonstrated with the detection of GRB 170817A, 1.7 seconds after the LIGO-Virgo detection of the binary neutron star merger, GW170817, the Fermi Gamma-ray Burst Monitor (GBM) began the expansive multi-wavelength campaign. These observations led to important insights into the physics of compact object mergers and their emission components. I will describe both the GBM and Large Area Telescope (LAT) capabilities and pipelines for gravitational wave counterpart searches. The observations of gravitational wave counterparts provide unique insights into the physics of neutron stars and gamma-ray bursts, and implications for fundamental physics.

The INTErnational Gamma RAy Laboratory (INTEGRAL) has carried out a search for gammaray signals temporally and/or spatially coincident with gravitational-wave (GW) triggers distributed by the LIGO and Virgo collaboration (LVC). Its high duty cycle (90%) ensures an ideal coverage; the omni-directional and high sensitivity of the SPI Anti Coincidence shield yield the most stringent constraints on any impulsive gamma-ray signal between 75 keV and 2 MeV, for almost the full sky. The other INTEGRAL instruments, in particular the imager IBIS and its Veto system, provide complementary coverage in the regions with reduced sensitivity for the SPI-ACS.

The relative large field of view of the INTEGRAL coded-mask instruments allows us to place stringent limits from 3 keV to 2 MeV for a large part of a GW localization region of a blackhole binary merger, when it is serendipitously covered by planned observations. Moreover, we performed follow-up observations for the most favorable GW triggers, in order to investigate any after-glow-like associated emission.

We will report on INTEGRAL gamma-ray observations related to the detection of the neutronstar binary merger GW170817, as well as the non-detections related to the various GW signals from the binary black-hole mergers, and discuss the implications of our findings.

E1.17-0015-18 THE X-RAY COUNTERPART TO THE GRAVITATIONAL WAVE EVENT GW170817

Eleonora Troja, eleonora.troja@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States on behalf of a larger collaboration AFFILIATION: UMD/GSFC

The second run of advanced LIGO led to the breakthrough discovery of the first gravitational wave (GW) signal from a neutron star merger, GW170817, coincident with a short duration gamma-ray burst, at a distance of 40 Mpc. The discovery of GW170817 and its electromagnetic counterparts marked the beginning of a new era of multi-messenger astrophysics, in which photons and gravitational waves provide complementary views of the same source.

I will present the discovery and long-term monitoring of the X-ray counterpart associated with GW170817. While the electromagnetic counterpart at optical and infrared frequencies was dominated by the radioactive glow from freshly synthesized r-process material in the merger ejecta, known as kilonova, observations at X-ray and, later, radio frequencies revealed the emergence of a relativistic, structured outflow interacting with the surrounding low-density environment. I will discuss the key results of our multi-wavelength campaign, the open questions raised by this event, and future prospects for observations with the Athena X-ray Observatory.

E1.17-0016-18 X-RAY OBSERVATIONS OF GW170817

Raffaella Margutti, rafmargutti@gmail.com

Northwestern University, EVANSTON, Illinois, United States

I present the current status of the X-ray observations of GW170817 in the context of collimated ultra-relativistic outflows and spherical outflows.

E1.17-0017-18 HUNTING GRAVITATIONAL WAVE COUNTERPARTS WITH SWIFT.

Phil Evans, pae9@leicester.ac.uk

University of Leicester, Leicester, United Kingdom

GW 170817/GRB 170817 was the first event definitively detected both by gravitational wave observatories and via their EM emission. In this talk I will present the results of observations of X-ray and UV observations of GW 170817 with the Neil Gehrels Swift Observatory, discuss their scientific interpretation, and consider the lessons we can learn from this object to inform follow-up of events detected by future LIGO-Virgo observing runs.

E1.17-0018-18 OBSERVATION OF X-RAY COUTERPARTS OF GW SOURCES WITH MAXI

Nobuyuki Kawai, nkawai@phys.titech.ac.jp Tokyo Institute of Technology, Tokyo, Japan

We present the results and prospects of the search for X-ray counterparts of gravitational wave sources by the Monitor of All-sky X-ray Image (MAXI), an all-sky X-ray monitor onboard the International Space Station (ISS). With the orbital revolution of the ISS, MAXI scans most of the sky in the 2-25 keV band every 92 minutes with a typical transit duration of 60 seconds. Thus MAXI has chance to obtain the early X-ray observation of gravitational wave events without planned pointing based on GW localization alerts. At the epoch of GW170817, MAXI was not operational due to its orbital position with high charged particle background. Even worse, with an unfortunate coincidence of the orbital geometry and phase with respect to the source location in the sky, the source was not observed for the subsequent few orbits. Still MAXI provided the earliest X-ray upper limit for GW180817 albeit not sufficiently constraining. With the more opportunities of GW events in the coming LIGO/Virgo O3, MAXI should be able to provide early X-ray observations, with which we can test various hypothesis on the X-ray emission from the neutron star merger events, and compare the known X-ray signatures of short GRBs such as extended emission and afterglows.

E1.17-0019-18 THE HUNT FOR FAINT SHORT GRBS WITH INTEGRAL/PICSIT

James Rodi, james.rodi@iaps.inaf.it INAF-IAPS, Rome, Italy

INTEGRAL Gravitational Wave Team

A. Bazzano, P. Ubertini, L. Natalucci, V. Savchenko, E. Kuulkers, C. Ferrigno, E. Bozzo, S. Brandt, J. Chenevez, T. J.-L. Courvoisier, R. Diehl, A. Domingo, L. Hanlon, E. Jourdain, A. von Kienlin, P. Laurent, F. Lebrun, A. Lutovinov, A. Martin-Carrillo, S. Mereghetti, J. Rodi, J.-P. Roques, R. Sunyaev

The short gamma-ray burst (SGRB) associated with the gravitational wave trigger GW170817 showed timing and spectral characteristics consistent with previously observed SGRBs. Yet its isotropic luminosity was found to be several orders of magnitude lower than other SGRBs with known red-shift. This result has motivated searches for similar events below on-board instrument trigger thresholds. Here we have analyzed data from the INTEGRAL soft gamma-ray detector IBIS/PICsIT (200 keV - 10 MeV) to look for the untriggered SGRB candidates reported by Fermi/GBM. Also, we present initial results from real-time analysis to independently search for similar events.

E1.17-0020-18 SEARCHING FOR GAMMA-RAY COUNTERPARTS TO GRAVITATIONAL WAVES FROM MERGING BINARY NEUTRON STARS WITH THE CHERENKOV TELESCOPE ARRAY

Barbara Patricelli, barbara.patricelli@pi.infn.it Scuola Normale Superiore, Pisa, Italy

The recent detection of gravitational waves (GWs) from a binary neutron star (BNS) merger by Advanced LIGO and Advanced Virgo (GW 170817), in coincidence with a weak short GRB observed by Fermi-GBM and INTEGRAL (GRB 170817A), opened the era of multi-messenger astronomy and provided the first direct evidence that at least a fraction of BNSs are progenitors of short GRBs. One of the challenges for future multi-messenger observations will be the detection of short GRBs at very-high energies (VHE, > 20 GeV) in association with GW signals, that will allow us to better understand the physics of the GRB outflow and the radiation mechanisms.

The Cherenkov Telescope Array (CTA), an advanced, next generation ground-based facility, will be fundamental for the EM follow-up of transient GW events at VHE, owing to its unprecedented sensitivity, rapid response (few tens of seconds) and capability to monitor large sky areas via survey-mode operation; furthermore, it will have a coincident observational schedule with GW detectors at design sensitivity, when many GW triggers are expected to be shared with the astronomical community.

We present a comprehensive study on the prospects for joint GW and VHE EM observations of merging BNSs with Advanced LIGO, Advanced Virgo and CTA, based on detailed simulations of the multi-messenger emission and detection. We propose a new observational strategy optimized on the prior assumptions about the EM emission and we show how this novel method can improve the coverage of the GW skymaps and then the probability of detecting the EM counterparts with repect to the commonly used strategies. We explore different assumptions about the EM emission and we estimate the expected joint GW and VHE EM detection rates.

E1.17-0021-18 CALET GAMMA-RAY BURST MONITOR OBSERVATIONS

S. Yanagita, A. Yoshida, K. Yoshida

The CALET Gamma-ray Burst Monitor (CGBM) is the secondary scientific instrument of the CALET mission, continuously operating on board of the International Space Station (ISS) since October 2015.

The CGBM consists of 2 Hard X-ray Monitors (HXMs) and one Soft Gamma-ray Monitor (SGM), utilizing different scintillators, LaBr3(Ce) and BGO respectively. The primary goal of CGBM is to observe a wide variety of gamma-ray bursts and other X/gamma-ray transients with fine temporal resolution (up to 62.5 us around triggers), broad spectral range (7 keV

20 MeV) and wide field of view. By combining the data of CGBM and CALET primary instrument, Calorimeter (CAL), the energy coverage is extended to the GeV - TeV range.

The CGBM has been detecting GRBs with an average rate of 3 per month, as expected from pre-launch estimation. CALET also takes

part in the electromagnetic follow-up of gravitational wave (GW) observations made by LVC collaboration, by investigating the existence of possible X-ray and gamma-ray counterparts.

We will report on CGBM in-orbit operation, performances, observations of GRBs and search for GW counterparts.

E1.17-0022-18 SEARCH FOR GAMMA-RAY COUNTERPARTS OF GRAVITATIONAL WAVE EVENTS BY CALET

Masaki Mori, morim@fc.ritsumei.ac.jp Ritsumeikan University, Kusatsu, Japan Yoichi Asaoka, yoichi.asaoka@aoni.waseda.jp Waseda University, Shinjuku, Japan

We present results of searches for gamma-ray counterparts of the LIGO/VIRGO gravitationalwave events from the CALorimetric Electron Telescope (CALET). The main instrument of CALET, the CALorimeter (CAL), observes gamma-rays from 1 GeV up to 10 TeV with a field of view of 2 sr. The CALET Gamma-ray Burst Monitor (CGBM) views 3 sr in the 7 keV - 1 MeV and the 40 keV - 20 MeV bands using a lanthanum bromide and a bismuth germanate scintillator, respectively. CALET observation on the International Space Station started in October 2015, and here we report analysis of events associated with the gravitational wave event GW151226 and successive events reported by LIGO/VIRGO. We also discuss the CALET sensitivity for detecting high-energy gamma-ray emission associated with future gravitational wave observations.

E1.17-0023-18 THE UNITED NATIONS OPEN UNIVERSE INITIATIVE FOR DATA IN SPACE SCIENCE

Ulisses Barres De Almeida, ulisses@cbpf.br

Centro Brasileiro de Pesquisas Físicas (CBPF), Rio De Janeiro, Brazil
Paolo Giommi, paolo.giommi@asdc.asi.it

ASDC, Roma, Italy

Andy Pollock, a.m.pollock@shef.ac.uk

University of Sheffield, Sheffield, United Kingdom Massimo De Angelis, massimo.deangelis@asi.it ASI Italian Space Agency, Rome, Italy

Daniel García-Yárnoz, daniel.garciayarnoz@un.org

United Nations Office for Outer Space Affairs (UNOOSA), Vienna, Austria

"Open Universe" is an initiative under the auspices of the Committee on the Peaceful Uses of Outer Space (COPUOS) that aims at stimulating a dramatic increase in the availability and usability of space science data, extending the potential of scientific discovery to new participants in all parts of the world, especially for developing and underdeveloped Countries. The initiative is carried out under the coordination of the United Nations Office of Outer Space affairs (UNOOSA) as part of the activities in preparation for UNISPACE+50 and the United Nations Space2030 agenda. Open Universe seeks to trigger a major evolution of current space science data availability fostering the publication of all existing open space science data in a way that is easily discoverable and immediately usable, thus responding to the global demand for transparency. A number of technical activities are currently in development towards the launch of the initiative, which include a prototype, multi-discipline (astrophysics, planetary sciences, cosmicray and atmospheric physics) and multi-messenger Open Universe Portal at the Italian Space Agency (ASI), available at openuniverse.asi.it. The purpose of the Open Universe actions is to integrate and render as interoperable as possible a large number of space science data sets, analysis tools, and general information services, provided by many online space science data archives, based on VO-technology. The Open Universe is designed to answer the needs of professional scientists and common citizens alike, offering services and data products,which can be used to learn about space science or perform scientific analyses. This presentation will briefly illustrate the principles behind the Open Universe initiative and provide a description of the main features currently under development, specially for science in the multi-messenger era.

E1.17-0024-18 RESULTS FROM MULTI-MESSENGER SEARCHES FOR THE SOURCES OF HIGH-ENERGY ASTROPHYSICAL NEUTRINOS

Marcos Santander, jmsantander@ua.edu

University of Alabama, Tuscaloosa, Alabama, United States

The IceCube observatory announced in 2013 the detection of a cosmic flux of high-energy neutrinos in the TeV to PeV range. This breakthrough discovery has prompted a wide-ranging observational effort aimed at identifying the sources of the neutrino flux by combining IceCube measurements with observations spanning the entire electromagnetic spectrum. The detection of these sources would represent a major step forward for high-energy astrophysics, which could reveal the acceleration sites of cosmic rays and provide a unique probe into the extreme environments in which these particles are produced. This talk will summarize recent IceCube observations, present an update on results from the multi-messenger search for neutrino sources concentrating on gamma-ray counterparts, and outline how future instruments may help pinpoint and characterize these objects.

E1.17-0025-18 OVERVIEW OF ANTARES NEUTRINO TELESCOPE RESULTS

Maurizio Spurio, spurio@bo.infn.it

University of Bologna and INFN, Bologna, Italy

The ANTARES underwater neutrino telescope has been taking data continuously since 2007. Its primary goal is the search for astrophysical neutrinos in the TeV-PeV range. The transparency of the water allows for a very good angular resolution in the reconstruction of interactions from neutrinos of all flavors. This results in unprecedented sensitivity for searches for neutrino sources located in the Southern Sky. Thus, valuable complementary observations have been performed and constraints have been set on the origin of the cosmic neutrino flux discovered by the IceCube detector. ANTARES is actively developing a manifold multi-messenger program: latest experimental results from searches for neutrinos correlated with the recently discovered gravitational wave signals and FRB events will be reported. Other physics topics are addressed as well, that include e.g. setting constraints on dark matter from a search of neutrinos from potential dark matter annihilation in massive objects like the Sun and the Galactic Center. The high quality of the data provided by ANTARES and the competitiveness of the results achieved demonstrate the tremendous potential of the new, much larger array, KM3NeT, now under construction in the Mediterranean Sea.

E1.17-0026-18 NEUTRINOS AND OTHER HIGH ENERGY TRANSIENTS

Kael Hanson, kael.hanson@icecube.wisc.edu

University of Wisconsin - Madison, Madison, Wisconsin, United States

Seven years after the last optical sensor was lowered into the deep ice at the South Pole, IceCube remains the only kilometer-scale neutrino telescope in the world. The observatory was constructed with the principal goal of identifying sources of high-energy neutrinos in the Universe: natural gravity-powered particle accelerators that give rise to cosmic rays spanning an enormous range of energies. The charged cosmic rays are deflected by galactic and extragalactic magnetic fields and diffuse in propagating over vast distances, the neutrinos that must accompany them at the production sites travel without interaction and are the only known particles capable of mapping the ultrahigh-energy sky at cosmological distances. In 2013, IceCube reported the observation of a flux of high energy astrophysical neutrinos consistent with isotropic sources: a breakthrough discovery. Four years later the identities of sources of these high energy neutrinos and the consequent cosmic rays remain a mystery. However, the Observatory has expanded its public, real-time alerting capabilities as interest in multimessenger astrophysics grows with the hopes of correlating neutrinos, high energy gammas, and potentially even gravitational waves with sources identified by optical observatories. Even a singular such occurrence would constitute again a scientific breakthrough. This talk will discuss IceCube in the new age of multimessenger astronomy and will briefly highlight other science results from this unique telescope in the ice.

E1.17-0027-18 FALLBACK AND CIRCULARIZATION OF TIDAL DISRUPTION EVENTS DEBRIS

Giuseppe Lodato, giuseppe.lodato@unimi.it University of Milano, Milano, Italy

While early investigations of the hydrodynamics of tidal disruption events has mostly focussed on the proper disruption phase, it has been progressively realized that an equally important process is that of the subsequent circularization of the stellar debris. Currently, it is not clear whether circularization is efficient or not, not whether the discs or torii formed in this way remain in stable circular configurations. From the observational point of view, while the accretion process is expected to provide the soft X-ray emission from TDE, the optical/UV emission appears to be produced by a relatively cold component, with an almost constant temperature throughout the flare. Such emission is most naturally explained in terms of the energy released during the circulariztion process. In this talk, I will discuss recent theoretical efforts to model the circularization and early evolution of the debris in tidal disruption events.

E1.17-0028-18 X-RAY OBSERVATIONS OF TIDAL DISRUPTION EVENTS

Erin Kara, ekara@astro.umd.edu

University of Maryland, College Park, College Park, United States

The disruption of a star from the strong tidal forces of a supermassive black hole can cause the stellar debris to fall back towards the black hole at super Eddington rates. Efficient circularization of the debris can lead to the formation of an accretion disc with luminosities close to or potentially exceeding Eddington limit. Most super-Eddington accretion flow models (including recent magnetohydrodynamic simulations) predict large scale height, optically thick equatorial winds at relativistic velocities. In this talk, I will give an overview of X-ray observations of tidal disruption events. In particular, I will present observational results from two of the most well-observed X-ray emitting TDEs, Swift J1644+57 and ASASSN-14li. Both of these objects show evidence for massive outflows at tens of percent of the speed of light. The outflow in Swift J1644+57 was detected via blue shifted emission and reverberation of the iron K alpha line, and ASASSN-14li shows a potential P Cygni profile of the OVIII line. I will discuss how these and other X-ray observations are putting constraints on super-Eddington accretion flows of TDEs.

E1.17-0029-18 FAST RADIO BURSTS - AN OVERVIEW

Marta Burgay, burgay@oa-cagliari.inaf.it INAF, Selargius (CA), Italy

I will review the main characteristics of Fast Radio Burst, describe how they could be used as cosmological probes, and present some of the recent efforts to localize them through multiwavelength studies.

E1.17-0030-18 COUNTERPART EMISSION OF FAST RADIO BURSTS

Kohta Murase, murase@psu.edu

Penn State University, University Park, Pennsylvania, United States

Fast radio bursts are intense radio transients with a millisecond duration, which are widely thought to come from extragalactic objects. Their sources and radiation mechanisms have been unknown since the discovery, and many attempts to search for the counterpart emissions have been made. Many theoretical models including ones involving magnetars and double neutron star mergers have been suggested, and we discuss their multi-wavelength signatures at radio waves, X rays, and gamma rays. In particular, in certain types of pulsar and magnetar models, one can expect bright quasi-steady emission from their wind nebulae as well as possible radio afterglows. We also discuss implications of the persistent radio emission associated with FRB 121102.

E1.17-0031-18 COORDINATED X-RAY AND RADIO OBSERVATIONS OF THE REPEATING FAST RADIO BURST

Slavko Bogdanov, slavko@astro.columbia.edu

Columbia University, New York, New York, United States The FRB121102 Gang

P. Scholz, J. W. T. Hessels, R. S. Lynch, L. G. Spitler, C. G. Bassa, G. C. Bower, S. BurkeSpolaor, B. J. Butler, S. Chatterjee, J. M. Cordes, K. Gourdji, V. M. Kaspi, C. J. Law, B. Marcote, M. A. McLaughlin, D. Michilli, Z. Paragi, S. M. Ransom, A. Seymour, S. P. Tendulkar, R. S. Wharton

FRB 121102, discovered with the Arecibo radio telescope, is the only known repeating fast radio burst source. Its extragalactic nature was unambiguously established via sub-arcsecond localization using the VLA along with Gemini and Hubble optical observations, which identified the host as a faint, low-metallicity, star-forming dwarf galaxy at redshift z=0.193. Recent radio polarimetry revealed that the FRB source resides in an extreme magneto-ionic environment. In an attempt to constrain the nature of the underlying source, we have undertaken X-ray observing campaigns with Chandra, XMM-Newton, and NuSTAR in coordination with radio observations of FRB 121102 to search for X-ray burst as well as persistent counterparts. I will present the results of these observations and discuss them in the context of the host environment of this FRB and of possible sources of fast radio bursts in general. I will conclude with a review of future prospects for high energy studies of FRBs using existing and future facilities.

E1.17-0032-18 SPECTRAL PROPERTIES OF BURSTS FROM FRB 121102: FIRST DETECTION AT 5-8 GHZ FROM BREAKTHROUGH LISTEN

Vishal Gajjar, vishalg@berkeley.edu

University of California, Berkeley, Berkeley, California, United States

We report the first detections of the repeating Fast Radio Burst FRB 121102 above 5 GHz. Observations were performed using the 4-8 GHz receiver of the Robert C. Byrd Green Bank Telescope with the Breakthrough Listen digital backend. We detail spectral, temporal and polarization properties of 21 bursts detected over a period of 60 minutes. These observations comprise the highest burst density yet reported in the literature, with 18 bursts being detected in 30 minutes. A few bursts also clearly show temporal sub-structures with distinct spectral properties. Broad features occur in 1 - GHz wide subbands that typically differ between bursts within the total 4 to 8 GHz observation. Finer scale structure within these bursts are consistent with Galactic interstellar scintillation. The bursts exhibit nearly 100% linear polarization with a large average rotation measure of 93559pm101 rad m−2. We measure a constant polarization position angle in 14 of the brightest bursts. The average flux density for all bursts, 0.2pm0.1 Jy, is consistent with lower frequency (<3 GHz) measurements, suggesting a spectrally flat intrinsic emission or extrinsic transmission process.

E1.17-0033-18 WHERE NEXT FOR FRB SCIENCE?

Evan Keane, evan.keane@gmail.com

SKA Organisation, Macclesfield, United Kingdom

After the first decade of fast radio burst (FRB) science much has been achieved. Many astrophysical and cosmological applications of FRBs have been identified, progress is being made into identifying their progenitors, and discovery rates are accelerating. But where next for FRB science? A huge number of unknowns remain and the field is full of open questions. Here I will summarise the science questions that can be addressed by instruments such as ASKAP (imminently joined by CHIME) which has a large and growing haul of bright and/or nearby FRB detections. Separately I will consider the complementary work that can be done with a smaller crop of much higher redshift FRBs as can be detected by instruments such as Parkes (imminently joined by MeerKAT). I will finish by proposing several strategies for maximising the scientific output of FRB science in the next decade.

E1.17-0034-18 THE HERMES PROJECT (HIGH ENERGY RAPID MODULAR ENSEMBLE OF SATELLITES): PROBING SPACE-TIME QUANTUM FOAM AND HUNTING FOR GRAVITATIONAL WAVE ELECTROMAGNETIC COUNTERPART

Luciano Burderi, burderi@dsf.unica.it University of Cagliari, Cagliari, Italy Tiziana Di Salvo, tiziana.disalvo@unipa.it University of Palermo, Palermo, Italy Fabrizio Fiore, fiore@oa-roma.inaf.it INAF-OAR, Rome, Rome, Italy

Universita degli Studi di Cagliari, Monserrato (CA), Italy Andrea Sanna, andrea.sanna@dsf.unica.it

Universita degli Studi di Cagliari, Monserrato, Italy

I discuss how several of the proposed models for space-time quantization predict an energy dependent speed for photons. Although the predicted discrepancies with the general speed of light are minuscule, I discuss how it is possible to detect this intriguing signature of space-time granularity with a new concept of modular observatory for photons in the energy band 10 keV

30 MeV. This observatory may consist of a swarm of micro/nano-satellites on low orbits. Sub-microsecond time resolution and wide energy band allows to probe tiny energy dependent delays, expected to be the signature of the granular structure of space-time in several of the proposed theories of Quantum Gravity. Moreover this kind of experiment allows to perform temporal triangulation of high signal to noise impulsive events with positional accuracies of few arcseconds, making an observatory like that a promising hunter for the elusive electromagnetic counterparts of Gravitational Waves.

The X-ray Integral Field Unit (X-IFU) on board the Advanced Telescope for High ENergy Astrophysics (Athena) is the second large mission of the ESA Cosmic Vision science program. X-IFU will provide spatially resolved high resolution spectroscopy from 0.2 to 12 keV with 5 arc second pixels over a field of view of 5 arc minute equivalent diameter and a spectral resolution of 2.5 eV up to 7 keV. We will present how the core scientific objectives of Athena drive the instrument performance requirements, the key system issues, and the instrument baseline design in view of the Instrument Preliminary Requirement Review planned end of 2018. A special emphasis will be put on the X-IFU spectroscopic capabilities in the context of the fast reaction time of the Target of Opportunity observation mode of Athena. The X-IFU will be provided by an international consortium led by France, The Netherlands and Italy, with ESA member state contributions from Belgium, Finland, Germany, Poland, Spain, Switzerland, with additional contributions from the United States and Japan.

E1.17-0036-18 SCIENTIFIC AND SYSTEM PERFORMANCE ANALYSIS OF THE ECLAIRS INSTRUMENT WITHIN THE SVOM MISSION

Henri Emmanuel Triou, htriou@cea.fr CEA Saclay, Gif Sur Yvette, France

Olivier Godet, olivier.godet@irap.omp.eu

IRAP - Institute of Research in Astrophysics and Planetology, Toulouse, France Jean-Luc Atteia, jean-luc.atteia@irap.omp.eu

IRAP - Institute of Research in Astrophysics and Planetology, Toulouse, France

SVOM is a French-Chinese space mission to be launched in 2021, which goal is to perform multi-wavelength analysis of transient events in the sky, among which Gamma-Ray Bursts, the most powerful stellar explosions in the Universe. SVOM aims to be the next Gamma-Ray Bursts multi wavelength space observatory.

The ECLAIRs space telescope is part of the French contribution on the SVOM mission. By detecting the very first lights (prompt emission) of the Gamma Ray Bursts in the [4 keV

150 keV] energy range, ECLAIRs will be the initiator of the follow-up (multivawelength observations) based on a complementary network of space and ground instruments.

The scientific performance of the ECLAIRs instrument and its design are deduced from the scientific objectives allocated to ECLAIRs within the SVOM mission. The architecture is based on a combination of 3 key solutions: the coded mask imaging associated with advanced imaging software, a compact ASIC-CdTe hybrid detector with low noise/low energy level threshold (4 keV) as well as high sensitivity and an onboard powerful processor along with its associated trigger algorithms for gamma ray bursts detection.

Each of ECLAIRs subsystems have therefore needed specific system performance analysis and simulators developments in order to reach optimized solutions allowing the ECLAIRs system to meet the expected scientific performances.

We present the performance system analysis at mission and instrument levels. We also detail the main scientific performance (sensitivity, localization accuracy, energy resolution .) of the ECLAIRs instrument together with the tools developed to validate these performances at system and subsystem levels.

E1.17-0037-18 THE GAMMA-RAY BURST TRIGGER ECLAIRS ON-BOARD SVOM

The Space-based multi-band astronomical Variable Objects Monitor (SVOM) is a FrenchChinese satellite mission dedicated to Gamma-Ray Burst (GRB) studies. The project was adopted in 2017 and started its detailed definition (phase C), before construction and launch foreseen in late 2021. With its set of 4 on-board instruments observing the sky in the X-ray, gamma-ray and visible-band, as well as a set of dedicated prompt-observation and follow-up ground-based visible-band telescopes, SVOM will study GBRs in great details, including their temporal and spectral properties of the prompt and afterglow emission from visible to gammarays. The start of every GRB observation sequence is given by the coded-mask telescope ECLAIRs on-board SVOM. Its on-board electronics system equipped with a real-time GRBtriggering software, continuously analyzes the 2 sr-wide field-of-view of the telescope in the 4-120 keV energy range, repeatedly performing coded-mask deconvolutions in order to detect and localize the GRBs for SVOM. Thanks to its low-energy threshold, ECLAIRs is particularly sensitive to X-ray rich and redshifted GRBs, but care has to be taken to handle known sources and variable background on-board. After detection, ECLAIRs requests the spacecraft to slew autonomously, to perform GRB follow-up observations with the on-board narrow field-of-view telescopes MXT in X-rays and VT in the visible-band. SVOM also alerts the worldwide community of follow-up observers via a dedicated VHF network placed under the satellite track. This paper presents the status of the ECLAIRs on-board GRB-trigger system.

At 3:00 AM(GMT) on Jun 15, 2017 the China Space Agency launched space observation HXMT(Hard X ray Modulation Telescope,also nanme “Insight”),which is a first X ray space explorer of China. Telescope operated in a circular orbit of 550Km altitude and 43°inclination. HXMT will detect X ray from universe which possible erupted from black hole or pulsar(neutron star) between 1-250KeV with high sensitivity and angular resolution(batter than 1 arcmin.) ,besides this, HXMT is also with a powerful capability for receiving the gamma-ray burst, which its energy coverage of 200 keV - 3 MeV and the largest detection area. During the first three month in orbit, 26 GBR and X93 solar flare event were detected by HXMT. Several signals of neutron star were also received. This paper present an overview of HXMT project, including mission and highlights of technical design ,flight results from first 6 months of this mission.

As an approved mission in the space science programme of the Chinese Academy of Sciences, the Einstein Probe (EP) is a small astronomical satellite to monitor the soft X-ray sky. EP will carry out systematic surveys of high-energy transients with unprecedented sensitivity, Grasp and monitoring cadence. Its wide-field (3600 sq. deg.) imaging capability is enabled by using lobster-eye MPO X-ray focusing optics. It also carries a Wolter-I X-ray telescope for deep follow-up observations of newly discovered transients. Transient alerts will be issued in nearly real time to trigger quick follow-up observations at multi-wavelengths. The scientific goals of EP are to discover and characterise the X-ray sources of new transient phenomena to be explored in the upcoming era of multi-wavelength and multi-messenger time-domain astrophysics. The mission is scheduled for launch by the end of 2022.

E1.17-0041-18 GRID FOR STUDENTS: A NETWORK TO MONITOR THE GAMMA-RAY SKY FOR MULTI-MESSENGER ASTRONOMY

In the near future, ground based gravitational wave (GW) detectors will routinely detect neutron star mergers in the local universe. An all-sky monitor in the gamma-ray band is important to understand the gamma-ray bursts (GRBs) associated with the mergers and may help obtain a better localization accuracy needed for follow-ups at longer wavelengths. We propose to deploy at least 10 identical scintillation detectors, named the gamma-ray integrated detectors or GRID, distributed in low earth orbits using CubeSats to monitor the whole gamma-ray sky from 10 keV to 10 MeV. In combination with different techniques (interplanetary network and flux modulation), GRID is capable of localizing a GRB within 200 Mpc in synergy with GW detections (with a horizon of 200 Mpc around 2020) with an accuracy of around 1 degree for an on-axis event or about 10-15 degrees for a GRB170817A like event. GRID is a student project. As a platform to train students how to organize a large science project, it was proposed and developed mainly by undergraduate students, and will be operated by students in the future. The current GRID collaboration involves 12 institutes and keeps growing. New members from all over the world are welcome. Here we will introduce the science with GRID, the detectors, current progresses, and future perspectives.

The CALorimetric Electron Telescope (CALET) has been successfully taking scientific data on the ISS since October 2015. We present the instrument performance for GeV gammaray observations based on high statistics EPICS/Cosmos simulations with the reconstruction algorithms used in the flight data analysis. A comparison of the Monte Carlo results with the first two years of flight data is made and the sensitivity of the CALET calorimeter to GeV energy gamma-ray sources is discussed.

E1.17-0043-18 GAMERA: A GAMMA-RAY TELESCOPE FOR THE GRAVITATIONAL WAVE ASTROPHYSICS ERA

J Eric Grove, eric.grove@nrl.navy.mil

Naval Research Laboratory, Washington, District of Columbia, United States

C. C. Teddy Cheung, teddy.cheung@nrl.navy.mil

Naval Research Laboratory, Washington, District of Columbia, United States Matthew Kerr, matthew.kerr@nrl.navy.mil

Naval Research Laboratory, Washington, District of Columbia, United States

We describe GAMERA, a SmallSat concept for a single, large, broad-band (20 keV - 2 MeV), wide field-of-view (>2π sr) instrument that would serve as the prime γ-ray telescope for gravitational wave (GW) astrophysics in the Advanced/LIGO-Virgo era. GAMERA can be built today using components currently at TRL 6 or higher, thus can be quickly developed for an existing SmallSat-class spacecraft bus, assembled, tested, and launched by the time Advanced/ LIGOVirgo reach their design sensitivities in the ~2023+ timeframe.

The instrument consists of an array of scintillator detectors with effective area 5 times greater than Fermi GBM and more than half that of Compton BATSE. It will detect short GRBs (SGRBs) like the low-luminosity GRB170817A, coincident with the binary neutron star merger event GW170817, at 3x greater distances (120 Mpc). Moreover, with its excellent time resolution and large area, it will perform detailed spectral analyses of such bursts to characterize the prompt γ-ray emission component in detail. To enable joint GRB and sub-threshold GW signal searches seeded on the γ-ray detection, GAMERA will provide typical degree-scale localizations. This could potentially uncover GW emission signals beyond the nominal horizon distances achievable by the ground-based interferometers alone.

GAMERA will provide the most detailed GRB physics measurements achievable within the lowcost SmallSat envelope (<$35M). This includes detections, localizations, and spectral characterizations that will be markedly improved over currently deployed γ-ray monitors. In addition to forefront GRB physics, GAMERA will provide continuous monitoring of other types of γ-ray transients, addressing the physics of accreting pulsars, magnetars, and Galactic binary systems.

Acknowledgment: Work at NRL was supported by the Chief of Naval Research. We thank Dr. William Purcell of Ball Aerospace for valuable discussions and input.

E1.17-0044-18 HARD GAMMA GEV PHOTON SHOWERING ALONG TANGENTIAL AIR ATMOSPHERE SPACE TRACED BY THEIR SKIMMING SECONDARIES LOW ENERGY GAMMA X RAYS SHINING ON ORBIT SATELLITE

Daniele Fargion, daniele.fargion@roma1.infn.it

Physics Department, Rome University 1, INFN Rome 1,, Rome, Italy

Hard tens-GeV up to TeV gamma sources, as AGN active flare or SGR blazars, may airshower in high altitude terrestrial atmosphere leading to beamed and skimming secondaries photons at XMeV lower energy band. The terrestrial cilindrical envelope of such secondaries X-gamma flares may shine at Earth atmosphere horizons. Their terrestrial X-gamma flash of such skimming airshower may be revealed in GRB detector in orbit while crossing the correlated cilindrical blazing X-gamma cone. These relevant signatures, often tagged by the satellite Keplerian period, might, and possibly already had, been already observed.

E1.17-0045-18 A LOW ENERGY COMPTON IMAGER FOR GRB POLARIZATION STUDIES

University College Dublin, Dublin, Ireland Lorraine Hanlon, lorraine.hanlon@ucd.ie University College Dublin, Dublin, Ireland Alexei Uliyanov, alexey.uliyanov@ucd.ie University College Dublin, Dublin, Ireland

The Gamma Ray Polarimeter Experiment (GRAPE) is designed to investigate one of the most exotic phenomena in the universe - gamma-ray bursts (GRB). There has been intense observational and theoretical research in recent years, but research in this area has been largely focused on studies of time histories, spectra, and spatial distributions. Theoretical models show that a more complete understanding of the inner structure of GRBs, including the geometry and physical processes close to the central engine, requires the exploitation of gamma-ray polarimetry. Over the past several years, we have developed the GRAPE instrument to measure the polarization of gamma-rays from GRBs over the energy range of 50 to 500 keV. GRAPE is a large FoV instrument with a sensitive energy range covering the peak energy distribution of GRBs. The design is based on an array of independent modules, each of which consists of an array of (high-Z and low-Z) scintillator elements read out by a multi-anode PMT (MAPMT). Our eventual goal is to fly GRAPE on a long duration balloon (LDB) platform to collect data on a significant sample of GRBs. Our experience with two balloon flights (in 2011 and 2014), coupled with further design efforts focused on orbital payloads, has led to an improved polarimeter concept that represents a natural evolution of the current design. The new concept employs a large number of small (1 cm), optically-isolated scintillator cubes, each of which is read out by its own silicon photomultiplier (SiPM). These cubes are stacked in a three-dimensional arrangement that allows the determination of event interaction locations in three dimensions within the sensitive volume. The resulting three-dimensional location data provides a moderate level of Compton imaging capability (1 sigma angular resolution of 10-15°). Even this level of imaging can be used to significantly reduce the instrumental background by limiting the influence of the cosmic diffuse flux, resulting in an improved polarization sensitivity. Here we shall describe this concept and the expected performance for GRB polarization measurements. We will also describe our efforts to develop a working prototype, which is initially focused on the testing of various scintillators (both organic and inorganic) with SiPM readouts.

E1.17-0046-18 DETECTION CAPABILITY OF ULTRA-LONG GAMMA-RAY BURSTS WITH THE ECLAIRS TELESCOPE ABOARD THE SVOM MISSION UNDER DEVELOPMENT

Nicolas Dagoneau, nicolas.dagoneau@cea.fr CEA Saclay, Gif Sur Yvette, France Stéphane Schanne, s.schanne@cea.fr

CEA Saclay, Gif Sur Yvette, France Aleksandra Gros, aleksandra.gros@cea.fr CEA Saclay, Gif Sur Yvette, France Bertrand Cordier, b.cordier@cea.fr

CEA Saclay, Gif Sur Yvette, France

It has recently been pointed out that ultra-long gamma-ray bursts (ULGRBs), with very atypical durations of more than 1000 seconds, could form a new class of GRBs (Levan+13). ULGRBs could have a different progenitor than standard GRBs and be produced by the core collapse of a low metallicity supergiant blue star (Gendre+13) or the birth of a magnetar following the collapse of a massive star (Greiner+14). However ULGRBs could also just represent the tail of the standard long GRB distribution (Virgili+13). In any case, it is clear that the dura- tion of these bursts make them peculiar. To progress, the sample the few ULGRBs detected so far by the Swift Burst Alert Telescope and some other instruments has to be increased. SVOM (Space-based multi-band astronomical Variable Objects Monitor, Wei, Cordier+16) is a French-Chinese mission dedicated to GRBs and transient events, currently under development and scheduled for launch after 2020. SVOM will help understanding ULGRBs, since its orbit and pointing strategy will permit to image the same portion of the sky continuously during nearly one day with the onboard coded-mask telescope ECLAIRs. Thanks to the image trigger foreseen onboard (Schanne+15), we expect to increase the sample of ULGRBs with SVOM. In this paper we present methods developed to clean detector images from X-ray background and known X-ray source contributions in the onboard imaging process, and we show the capability of the image trigger to detect the currently available ULGRBs sample as well as a synthetic population of fainter and more distant ones.

E1.17-0047-18 ANALYSIS OF GRS 1915+105 IN THE 'HARD' PHASE: ACCRETION AND OUTFLOW IN THE TCAF PARADIGM

Anuvab Banerjee, anuvab.banerjee@bose.res.in

S. N. Bose National Centre for Basic Sciences, Kolkata, India Ayan Bhattacharjee, ayan12@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

The class variable source GRS 1915+105 is at variance with the transient sources in the sense that it exhibits peculiar time variabilities in the range of a few seconds to days. Depending on cts/s in different energy bands and the color-color diagram, the variability was first grouped into twelve classes and later, the χ class (where the variability is minimum) was classified into four sub-classes χ1, χ2, χ3, χ4. These classes were sequenced in ascending order based on the quantity Comptonization Efficiency (ratio of power-law photon and blackbody photon), and it shows that χ class is relatively harder with respect to other classes. The χ1,3 classes are associated with outflow. However, since all such exotic features ultimately should be associated with the variation of accretion rates with which TCAF solution is concerned of, it should treat all such apparently different classes in the same framework. This motivated us to study this object in the TCAF paradigm. The χ2,4 states are different only in the peak count, and could be fitted with different normalizations for the TCAF solution. It was shown by Rao et al. (2000) that the χ3 class data could be fitted using diskbb+CompST+Power-law model in the 3-190 keV energy range. Since the Compton cloud is self consistently addressed in the TCAF solution, here in the χ1,3 state, the spectra could be fitted using Cutoff power-law model associated with TCAF solution to take care of the outflow. The exponential roll-off factor agrees with the respective slopes in the spectra, and also TCAF+Cutoff power-law model upto high energy domain.

E1.17-0048-18 ANALYSIS OF FERMI GRB DURATIONS IN THE OBSERVED AND INTRINSIC REFERENCE FRAMES

Zitouni Hannachi, zitouni.hannachi@univ-medea.dz University Dr Yahia Fares, Medea, Algeria, Médéa, Algeria Nidhal Guessoum, nguessoum@aus.edu

American University of Sharjah, Sharjah, United Arab Emirates

Gamma-ray bursts (GRBs) are usually classified into two populations, according to their durations, denoted by T90: long bursts (T90 > 2.0 s) and short bursts (T90 < 2.0 s). Recent work has suggested the existence of an intermediate population in the bursts observed by the Swift satellite (Bromberg et al. 2013, Zitouni et al. 2015, Horváth & Tóth 2016). Moreover, a number of researchers have questioned the universality of the 2.0-second dividing line between short and long bursts: some bursts may be short but actually result from collapsars, the physical mechanism behind normally long bursts.

In this work, we focus on GRBs detected by the Fermi satellite and study the distribution of their durations measured in the observer's reference frame and, to the extent possible, in the bursts' reference frames. However, bursts with measured redshifts are limited, and this makes a statistical study difficult. We thus proceed in two ways. First, following Zhang & Wang (2017), we determine pseudo-redshifts from the correlation relation between the luminosity Lp and the energy Ep both calculated at the peak of the flux. Interestingly, we find that the uncertainties over the quantities used in the determination of pseudo-redshifts affect the precision of the results significantly, although they remain within acceptable limits. We thus present the advantages and disadvantages of using these correlation relations as cosmological candles. Secondly, we compare the results obtained with the pseudo-redshifts with those obtained from a sample of 43 GRBs with actual redshifts given by Heussaff (2013).

A chi-square statistical test shows that the distribution of the durations of Fermi bursts, both observed and intrinsic, are composed of two peaks, not three, as we had found for the BATSE bursts. We propose an explanation for the presence of an intermediate class of bursts in the Swift data, based on a selection effect related to the Swift/BAT energy band.

E1.17-0049-18 TIDAL EFFECT ON ACCRETION FLOWS IN COMPACT BINARY SYSTEMS

Arindam Ghosh, arindam.ghosh@bose.res.in

Satyendra Nath Bose National Centre for Basic Sciences, KOLKATA, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

Black hole binary orbits are expected to have some eccentricity, albeit small. Stellar companion of a black hole orbiting in an eccentric orbit will experience modulating tidal force with a periodicity same as that of the orbital period which will result in a modulation of accretion rates, seed photon flux, and flux of inverse Comptonized harder photons as well. Timing analysis of long-term X-ray data (1.5 to 12 keV) of RXTE/ASM and all sky survey data (15 to 50 keV) of Swift/BAT satellites reveal aforesaid periodicity in several black hole candidates. If this modulation is assumed to be solely due to tidal effects (without taking other effects, such as eclipses, reflection from winds, super-hump phenomena etc. into account), the RMS-value of the peak in Fourier spectrum gives us a notion of eccentricities of these orbits as well as the sizes of the Keplerian disk in two important classes of black hole binary systems. We present these very interesting results. We show that our results generally agree with independent studies of these parameters. Unknown orbital period of a binary system may also be obtained by our simple method.

E1.17-0050-18 IMPLICATION OF ACCRETION GEOMETRY ON VARIABILITY PROPERTIES IN GALACTIC BLACK HOLE SOURCES

Broja Gopal Dutta, brojadutta@gmail.com

Department of Physics, RBC College & Indian Centre for Space Physics, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

The evolution of the low frequency quasi-periodic oscillations (LFQPOs) in outbursting black hole sources can be explained by the systematic variation of the Compton cloud size in propagatory oscillating shock (POS) solution. In this solution, each of observed QPO frequency implies the location of shock i.e., the size of the Comptonizing region and the frequency drifting implies the Geometrical variation of Comptonizing region, i.e., the steady radial movement of the shock front, which is triggered by the cooling of the post-shock region. As the shock moves in with increase in disk accretion rate, the density and optical depth also generally increases. We study the X-ray variability properties of a set of low and high inclination black hole source. We find the dependence of variability properties, such as time lag, and rms power with the inclination of the source and time lag becomes negative for high inclination source after a certain QPO frequency (i.e., particular size of Comptonizing region). We discuss the effects of accretion geometry on the variability properties.

E1.17-0051-18 FROM METEORS TO GRBS - DETECTION OF OPTICAL TRANSIENTS WITH MINI-MEGATORTORA

We present the summary of some results obtained by a novel 9-channel wide-field optical monitoring system with sub-second temporal resolution named Mini-MegaTORTORA (MMT-9). This multi-element telescope can observe the sky in wide (900 square degrees) or narrow (100 square degrees) field of view with exposure time ranging from 0.1 to hundreds of seconds. Observations can be performed in white light or using arbitrary combination of the filters (Johnson-Cousins B, V and R). Observations in polarized light are also possible. The data analysis pipeline operates in real time and detects automatically rapid moving or motionless transient events. Faint meteors, satellites, variable stars, optical counterparts of X-ray sources and GRBs are routinely detected and investigated by MMT. We present statistical and physical parameters for some of them.

E1.17-0052-18 OBSERVATION OF COSMIC GAMMA RAY BURSTS IN LOMONOSOV SPACE MISSION

Vitaly Bogomolov, bogovit@rambler.ru

Moscow State University, Skobeltsyn Institute of Nuclear Physics, Moscow, Russia Lomonosov-GRB

Mikhail Panasyuk, Sergey Svertilov, Vitaly Bogomolov, Alexander Amelushkin, Vera Barinova, Andrey Bogomolov, Anatoly Iyudin, Vladimir Kalegaev, Irina Myagkova, Alaxander Minaev, Anna Shustova, Min Nguyen, Vasily Petrov, Ivan Yashin,Vladimir Lipunov, Evgeny Gorbovskoy, Viktor Kornilov, Il H. Park, H.M. Jeong, Soomin Jeong, Minbin Kim, Alberto Castro-Tirado

GRB study is one of the main goals of the Lomonosov space mission launched on 28-04-2016 from Vostochny cosmodrome to solar synchronous orbit with 490 km altitude and 98o inclination. The mission payload includes the BDRG gamma-ray spectrometer designed for spectral measurements and timing in 10-3000 keV energy range as well as for GRB triggering. Two wide-field optical cameras SHOK are placed within fields of view of the gamma-monitor. This allows the simultaneous GRB observations in gammas and optics in all-time scale of event evolution including obtaining optical light curves of prompt emission as well as of precursors. About 20 GRBs were detected by BDRG/Lomonosov during observational period from 05.2016 to 01.2017, as well as several bursts from SGR and a number of solar flares. No triggered GRB sources appeared in the FOV of on-board optical cameras but the joint observations of BDRG/Lomonosov with MASTER net of robotic telescopes allowed one to compare optical and gamma-ray light curve of some of detected GRBs at different phases of their activity. A new space project of M.V. Lomonosov Moscow State University named Universat-SOCRAT will include advanced gamma-ray instrument for GRB triggering, wide-field optical cameras and a fast-pointing optical telescope with moving mirror. The set of instruments for monitoring of space radiation and for studying of atmospheric phenomena in the optical range will also be included. The proposed gamma-ray spectrometer will be based on the considerably simple wide field-of-view coded mask telescope with 300 pixel PSD allowing to check the presence of a point gamma-ray source on the sky and to obtain its coordinates with accuracy of 1-2 degrees so one can identify GRBs on the background of various reading increases mostly caused by the electron precipitation. Immediate transfer of the GRB notice to the ground global net will be realized.

E1.17-0053-18 OBSERVATIONS OF GAMMA-RAY BURSTS (GRB) AND GRAVITATIONAL WAVE ELECTROMAGNETIC COUNTERPARTS (GW EM) BY INSIGHT-HXMT

Jinyuan Liao, liaojinyuan@ihep.ac.cn

Institute of High Energy Physics (IHEP), Beijing, China

The High Energy X-ray telescope (HE) onboard Insight-HXMT (Hard X-ray Modulation Telescope), which is the first Chinese X-ray space telescope launched on June 15, 2017, is primarily designed to observe the hard X-ray sky with a Field of View of 1x6 deg. An advanced capability was developed for HE is to use its anticoincidence detector CsI to monitor GRBs and observe the GW EM counterparts. Hence in the so-called GRB mode, HE turns out to be a unique all-sky monitor, characterized by an effective area over than 1000 cm^2, a moderate angular resolution of 10 deg, an excellent time resolution of microseconds, and a broad energy coverage of 0.2-5 MeV. So far, Insight-HXMT has observed dozens of GRBs, including a few that were firstly detected by HE with a short duration and a hard spectrum. During the observation of the first binary neutron star merger (GW170817), Insight-HXMT/HE monitored the entire GW localization area throughout the trigger time. Although Insight-HXMT did not detect any significant high energy (0.2-5 MeV) radiation from GW170817, its observation helped to confirm the unexpected weak and soft nature of GRB 170817A. Meanwhile, Insight-HXMT/HE provides one of the most stringent constraints (10-7 to 10-6 erg/cm^2/s) for both GRB170817A and any other possible precursor or extended emissions in 0.2-5 MeV, which help us to better understand the properties of EM radiation from this BNS merger.

RESEARCH IN ASTROPHYSICS FROM SPACE (E)

INFRARED ASTRONOMY: STAR FORMATION AND INTERSTELLAR PROCESSES OVER MANY SCALES (E1.18)

E1.18-0001-18 INTERSTELLAR FILAMENTS AND STAR FORMATION

Philippe André, pandre@cea.fr CEA Saclay, Gif-sur-Yvette, France

I will review recent progress in our observational understanding of the link between the structure of molecular clouds and the formation of solar-type stars. In particular, I will describe the filamentary paradigm favored by Herschel studies of the nearest molecular clouds of the Galaxy which point to the key role of the quasi-universal filamentary structure pervading the cold ISM. I will also discuss observational constraints on the formation and evolution of molecular filaments, coming from Planck polarization data and ground-based mm line studies. Overall, the available observations support a picture in which interstellar filaments and prestellar cores represent two fundamental steps in the star formation process: First, large-scale compression of interstellar material in supersonic MHD flows generates a cobweb of filaments in the ISM; second, the densest filaments fragment into prestellar cores (and subsequently protostars) by gravitational instability, while simultaneously growing in mass and complexity through accretion of background cloud material. I will end by emphasizing the need for high-resolution polarimetric imaging at far-infrared wavelengths to clarify the role of magnetic fields in the formation and evolution of star-forming filaments.

E1.18-0002-18 SOFIA OBSERVATIONS OF INTERMEDIATE LUMINOSITY PROTOSTARS IN ORION AND THEIR OUTFLOWS

Tom Megeath, tommegeath@gmail.com University of Toledo, Toledo, Ohio, United States

Observations of protostars probe the transition of interstellar matter into stars and shape our understanding of how infall, accretion and outflow determine the masses of stars, the properties of nascent planetary systems, and the rate and efficiency of star formation. While the protostellar luminosity function peaks around 1 solar luminosity, 10% of protostars have luminosities from 20-1000 solar luminosities. These intermediate luminosity protostars include precursors of intermediate mass stars as well lower mass protostars undergoing large accretion driven outbursts. Their study is important for understanding the origin of the IMF, the role of episodic accretion in low mass star formation, and the impact of feedback from protostars on the surrounding cloud. We present SOFIA observations made with FORCAST and GREAT of five intermediate mass protostars. These were identified in the Herschel Orion Protostar Survey (HOPS) using 2-870 micron SEDs from 2MASS, Spitzer, Hershel and APEX photometry. SOFIA/FORCAST 9-14 micron spectra are combined with the HOPS photometry of these sources to refine our measurements of their luminosities and envelope properties. SOFIA/GREAT observations trace the outflow from the most luminous of the protostars, HOPS 370 or OMC2 FIR3, in far-IR lines of CO and [OI]. By combining the line profiles from GREAT with line maps from PACS/Herschel, we find both far-IR emission from the jet launched by the protostar and from the gas swept up by the jet. By comparing the far-IR maps and line profiles with ground-based sub-mm data from the APEX telescope and centimeter wave continuum from the VLA, we build a detailed portrait of the mass flow in the outflow and its impact on the surrounding dense gas.

E1.18-0003-18 THE SERPENS SOUTH PROTOCLUSTER: THE POWER OF SOFIA/FORCAST IN STUDIES OF PROTOSTARS

Tracy Huard, thuard@astro.umd.edu

University of Maryland, College Park, Maryland, United States Marc Pound, mpound@astro.umd.edu

University of Maryland, College Park, Maryland, United States Lee Mundy, lgm@astro.umd.edu

University of Maryland, College Park, Maryland, United States Susan Terebey, sterebe@calstatela.edu

California State University at Los Angeles, Los Angeles, California, United States

The Serpens South protocluster is among the youngest known cluster of protostars. Using SOFIA, we observed the core of this cluster with FORCAST, detecting more than two dozen protostars within a single field of view. Including observations from the Spitzer Space Telescope and the Herschel Space Observatory, infrared spectral energy distributions are constructed for cluster members and the content of the cluster illuminated. We demonstrate a technique to estimate, using only FORCAST observations, the internal luminosities of protostars reliable to within 30–40% for 67% of protostars and to within a factor of 2.3–2.6 for 99% of protostars, comparable to the reliability achieved with Spitzer and Herschel observations that probe a greater fraction of the emission. FORCAST is a powerful instrument for luminosity studies of protostars. Its dynamic range and greater angular resolution enable FORCAST to discover and characterize protostars that were either saturated or merged with other sources in previous surveys.

E1.18-0004-18 SOFIA/FORCAST OBSERVATIONS OF THE GALACTIC CENTER

M. E. Ressler, michael.e.ressler@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

In this talk I will summarize and discuss the results from our SOFIA/FORCAST GTO program on mid-infrared (19 - 37 µm) imaging of our Galactic Center. Our observations revealed the detailed "clumpy" morphology of the circumnuclear ring, the warm dusty torus around Sgr A*, and implicate its transient nature. We also imaged the most recent confirmed event of massive star formation in the inner 10 parsecs of the Galactic center as well as the HII region around the young massive Quintuplet cluster. Lastly, I will discuss the synergies between SOFIA and JWST for investigating massive star formation and the interstellar medium.

E1.18-0005-18 THE FORMATION OF MASSIVE CLUSTERS FROM HIGH REDSHIFT TO THE PRESENT DAY UNIVERSE

Richard Klein, rklein@astron.berkeley.edu

University of California, Berkeley, Berkeley, California, United States

Massive stars lie at the center of the web of physical processes that has shaped the universe as we know it, governing the evolution of the interstellar medium of galaxies, producing a majority of the heavy elements, and thereby determining the evolution of galaxies. A significant fraction of all stars form in massive clusters, which will be observable throughout the visible universe with JWST. In this talk, I shall present first results of the formation of clusters of stars across cosmic time, both of moderate mass, such as the Orion Nebula Cluster (ONC), and of high mass, such as the super star clusters (SSC) seen in starburst galaxies, starting with high mass cluster formation in our present day universe. These simulations are carried out using newly developed advanced techniques in our radiation-magneto-hydrodynamic AMR code ORION, for radiative transfer with both ionizing and non-ionizing radiation that accurately handles both the direct radiation from stars and the diffuse infrared radiation field that builds up when direct radiation is reprocessed by dust grains. Our simulations include relevant feedback effects such as radiative heating, radiation pressure, photodissociation and photoionization, protostellar outflows, magnetic fields and turbulence. The challenge in simulating the formation of massive stars and massive clusters is to include all these feedback effects self-consistently as they occur collectively. I will first present our recent results on cluster formation on moderate scales over the dynamic range of 5pc down to 28 au for a period of 3.5x105 yr, including magnetic fields, turbulence and both radiative and outflow feedback from the protostars. At the end of the simulation, the star formation efficiency in the cluster is 4.3% and the star formation rate per free-fall time is εff =0.04, within the range of observed values. The total stellar mass increases as t2, whereas the number of protostars in the cluster increases as t1.5. We find that the density profile around most of the simulated protostars is ρ r–1.5. At the end of the simulation, the protostellar mass function approaches the Chabrier stellar initial mass function. We infer that the time to form a star of median mass 0.2 Msun in the cluster is about 1.4 × 105 yr from the median mass accretion rate. We find excellent agreement in our simulations with the protostellar luminosities observed in recent large cluster samples and a theoretical estimate, and we conclude that the classical protostellar luminosity problem is resolved. The multiplicity of the stellar systems in the cluster simulation agrees, to within a factor of 2, with observations of Class I young stellar objects; most of the simulated multiple systems are unbound. Bipolar protostellar outflows are launched using a subgrid model, and extend up to 1 pc from their host star. The mass-velocity relation of the simulated cluster outflows is consistent with both observation and theory. I shall then present our first results on massive cluster formation starting at scales 100 pc. and forming massive SSC clusters of 106 Msun using multiple zoom-in refinements with AMR and including all of the

above mentioned coupled physics. I shall discuss preliminary results of the properties of the massive SSC clusters and ONC type clusters that form. Key questions we are addressing include how effectively is radiation trapped within the cluster and how does stellar feedback affect the formation of Orion-scale clusters and SSC.

E1.18-0006-18 STAR FORMATION RATE CALIBRATIONS WITH INFRARED DATA OF YOUNG STAR-FORMING REGIONS IN NGC6946 AND M100: THE EFFECT OF METALLICITY AND IMF UPPER MASS CUTOFF

Ikechukwu Obii, iaobi@sissa.it

National Space Research and Developemnt Agency-CBSS,Nsukka, Nigeria, Nsukka, Nigeria Alessandro Bressan, sbressan@sissa.it

SISSA/ISAS Trieste, Trieste, Italy Francesca Perrotta, perotta(at) sissa.it Italy

Bonaventure Okere, bona.okere@gmail.com

Center for Basic Space Science,National Space Deve, Nsukka, Nigeria

By means of the state-of-the-art radiative transfer code GRASIL (GRAphites and SILicates) in which the recently updated database of PARSEC's (PAdova TRieste Stellar Evolutionary Code) evolutionary tracks of massive stars has been implemented, we predict the panchromatic spectral energy distribution (including halpha emission lines) of star forming regions in the nearby and well studied starburst galaxy NGC6946 and that of the normal star-forming galaxy M100.

We carry out a critical investigation of the effect of metallicity, IMF upper mass limit and star formation regime (star bursting versus normal star forming) on star formation rate (SFR) and dust attenuation properties of star forming galaxies. This allowed for the provision, from our best fit models, of a consistent set of SFR calibrations, that are explicitly dependent on metallicity and IMF upper mass limit and also on the age of the starburst, at wavelengths ranging from 3um to 1000um. We complement these with similar calibrations at radio wavelengths which do not suffer dust attenuation.

We show that the upper mass limit can be well constrained by combining information from the observed far infrared, 24um, 33 GHz and Halpha luminosities. Another interesting property derived from the fits is that, while in normal galaxies the attenuation in the lines is significantly higher than that in the nearby continuum, in individual star bursting regions they are similar, supporting the notion that this effect is due to an age selective extinction. Since in these conditions the Balmer decrement method may not be accurate, we provide relations to estimate the attenuation from the observed 24um or 33GHz fluxes. These relations can be useful for the analysis of young high redshift galaxies.

E1.18-0007-18 [CII] EMISSION FROM NGC 4258 WITH SOFIA/FIFI-LS

Philip Appleton, apple@ipac.caltech.edu

IPAC Infrared Processing and Analysis Center, Pasadena, California, United States Dario Fadda, darioflute@gmail.com

SOFIA/USRA, Mountain View, California, United States Tanio Diaz-Santos, tanio.diaz@mail.udp.cl

Universidad Diego Portales, Santiago, Chile Aditya Togi, aditya.togi@utsa.edu

University of Texas at San Antonio, San Antonio, Texas, United States Patrick Ogle, pogle@stsci.edu

Space Telescope Science Institute, Baltimore, Maryland, United States

NGC 4258 is a Seyfert 1.9 galaxy known to contain a warped inner (0.3 pc) rotating disk of water-vapor masers which allowed for the first high accuracy measurements of the mass of a supermassive black hole in any galaxy. A relativistic jet is thought to be responsible for anomalous radio-continuum spiral arms, which appear several kpc from the center, and extend outwards through the outer disk. These arms do not correlate with the galaxy's underlying stellar spiral structure, and their presence suggest that in the past, the jet has strongly interacted with the galaxy's outer disk, exciting synchrotron radiation. Since that time, a new burst of activity seems to have occurred, creating a compact (VLBI) jet at the core of the galaxy, and two radio hotspots further out associated with optical "bow-shocks". The position angle of this new "active" jet is different from that needed to excited the outer radio arms, presumably because the jet has precessed, perhaps as a result of precession of the axis of the inner warped accretion disk.

We used the FIFI-LS integral-field spectrometer onboard the Stratospheric Observatory for Infrared Astronomy (SOFIA) to explore, for the first time, the distribution and large-scale kinematics of diffuse gas emitting in the [CII]157.7μm fine-structure line along the length of the "active" jet. Our observations reveal three main condensations of [CII] emission: two associated with large regions of gas at the ends of the active jet, and a third minor axis filament associated with linear clumps of star formation and dust seen in HST images offset from the nucleus. We combine the SOFIA observations with previous Spitzer mid-IR, Chandra X-ray and VLA radio observations to explore the nature of the detected [CII] emission. In regions along the northern active jet, we see a significant deficiency in the [CII]/FIR ratio, and higher ratios near the ends of the jet. this implies that the jet has changed the conditions of the gas along its length. In several places near the jet, the [CII] emission shows very broad lines, suggestive of enhanced turbulence. Additionally, the minor-axis filament we discovered may represent gas in-falling towards the nucleus perpendicular to the jet. The results provide clues about how radio jets in active galaxies can influence the star formation properties of their host galaxies.

E1.18-0008-18 UNRAVELING THE EVOLUTION OF THE INTERSTELLAR MEDIUM AND STAR FORMATION IN THE M51 GRAND-DESING SPIRAL GALAXY WITH SOFIA.

Jorge Pineda, jorge.pineda@jpl.nasa.gov JPL, Pasadena, United States

We present results on a joint impact project to map the entire extent of the M51 grand-design spiral galaxy in the [CII] 158um line with the upGREAT and FIFI-LS instruments on SOFIA. Spiral density waves play a fundamental role in the conversion of atomic gas to molecular gas, which is followed by gravitational contraction leading to star formation. Understanding the impact of spiral density waves on the life cycle of the interstellar medium (ISM) and on star formation is a critical step for understanding galaxy evolution, and requires having a complete picture of all constituents of the ISM in galaxies. The [CII] 158m line is an important tool to diagnose the physical state of the ISM as it can reveal the distribution of the gas that is in the transition between atomic and molecular phases, including the CO–dark H2 gas (hydrogen is molecular, but carbon is not, resulting in this gas being traced neither by CO nor by HI. In this talk we present preliminary results on the distribution of [CII] across M51 and on the relationship between the different constituents of the ISM traced by FUV, Halpha, CO, HI, and [CII] emission both spatially and spectrally in the arms and interarm regions of M51.

E1.18-0009-18 HERSCHEL AND SOFIA SYNERGIES

Bernhard Schulz, bernhardjschulz@gmail.com University of Stuttgart, Stuttgart, Germany Harold Yorke, hyorke@usra.edu

SOFIA/USRA, Moffett Field, California, United States
