We considered our model for a few different parameters of liquid and material transported by a river. For Titan we consider liquid corresponding to a Titan's rain (75% methane, 25% nitrogen), for Earth - the water. Material transported in rivers on Titan is the water ice, for Earth - quartz. Other parameters of our model are: inflow discharge, outflow level, grain size of sediments, etc. For every calculation performed for Titan's river similar calculations were performed for the corresponding terrestrial river.

Results and Conclusions

The results of our simulation show the differences in behaviour of the flow and of the sedimentation on Titan and on the Earth. Our preliminary results indicate that suspended load is the main way of transport in simulated Titan's conditions. We also indicate that braided rivers appears for larger range of slope S on Titan (e.g. S=0.01-0.04) than on Earth (e.g. S=0.004- 0.009). Also, for the same type of river, the grain size on Titan is at least 10 times larger than on Earth (1 cm for Titan versus 1 mm for the Earth). It is very interesting that on Titan the braided rivers appear even for very low discharge (e.g. Q=30 m 3 s 1) and for very large grain size (e.g. 10 cm). In the future we plan the experimental modelling in sediment basin to confirm results from computer modelling.

We investigate the surface of Titan using spectro-imaging near-infrared data from the Visual and Infrared Mapping Spectrometer (VIMS). We use a radiative transfer code to determine the contributions of atmospheric haze to the spectrum and retrieve the surface albedo [1]. We focus on the major geological units identified in [2;3;4] from SAR data: mountains, plains, labyrinths, impact craters, dune fields, and alluvial fans. We find that all the different regions classified as being the same geomorphological unit in SAR show a similar spectral response after the VIMS data analysis, thus suggesting a good correlation in the classification between SAR and VIMS. Exceptions are the undifferentiated plains, which present two different types of spectral responses. In addition, by matching the extracted albedos with candidate materials for Titan's surface [5], we find that all regions of interest fall into one of three main compositional groups of major candidate constituents: water ice-like, tholin-like, or an unknown, very dark material. More specifically, we find that part of Titan's surface appears to be dominated by a tholin-like and/or a dark unknown (most likely organic) material, and that some fraction of the surface is covered by atmospheric/organic deposits. Material with a spectral response similar to water ice is also present at a number of regions as major constituent at latitudes higher than 30ºN and 30ºS. The surface albedo differences and similarities among the various geomorphological units constrain the implications for the geological processes that govern Titan's surface and interior (e.g. aeolian, cryovolcanic, tectonic). Our results show that Titan's surface composition has a significant latitudinal dependence [6].

The Cassini mission has opened many science questions related to Saturn's atmospheric dynamics: jet-streams (including the hexagonal-shaped northern polar jet), giant convective storms, stratospheric equatorial oscillations, interhemispheric transport. This inspired our group to develop a Global Climate Model for Saturn that couples a massively-parallel icosahedral-grid hydrodynamical solver with detailed physical parameterizations (notably correlated-k radiative transfer) for Saturn's troposphere and stratosphere. Multiple test simulations led us to determine the best modeling settings to run simulations in which (amongst other requirements) the conservation of angular momentum is ensured with good accuracy. Multi-year simulations carried out with a spatial resolution of 1/2° in latitude/longitude allowed us to analyze the mechanisms accounting for jet acceleration (and possible latitudinal migration) in the troposphere and the stratosphere of Saturn, the formation of large-scale vortices and waves, and the occurrence of a zonostrophic regime. The perspectives for improvements of the reference Saturn simulations will be reviewed. We will also present simulations carried out for Jupiter (presently observed by the Juno mission) with the exact same modeling platform, to discuss comparative dynamics between both gas giants.

B5.2-0034-18 EXTENDING CASSINI SCIENCE: THE NEED FOR SATURN PROBE IN SITU MEASUREMENTS

Amy Simon, amy.simon@nasa.gov

NASA/GSFC, Greenbelt, Maryland, United States Donald Banfield, banfield@astro.cornell.edu

Cornell University, Ithaca, New York, United States David Atkinson, david.h.atkinson@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

The Cassini mission gave us 14 years of spectacular atmospheric observations. However, some quantities can only be measured through direct sampling in the atmosphere. Most important of these are the noble gas abundances, as they are non-reactive and have no spectral signature. Constraining the noble gas abundances is crucial for distinguishing between solar system formation models, including determining when and where Saturn formed in the protosolar nebula. Additionally, several methods have attempted to constrain helium through indirect means and remote sensing, but a ground truth measurement would help to validate these retrieval techniques. Although the other elements (C, N, O, S) are more easily detected by their spectral signature, remote sensing measurements may not be sensitive to their deeper well-mixed values, and also require in situ validation. In situ measurements of the noble gas and elemental (and isotopes of both) abundances form a complete picture of the role Saturn played in gas giant migration, a key component to understanding the structure of our present day solar system.

In situ measurements of wind, temperature, and pressure beneath the cloud deck also tie the cloud top motions to deeper structure, essential to providing ground truth for global circulation models. Even a single location's profiles are crucial to understanding local and global circulation and advancing our modeling capability; the Galileo probe's Jupiter profile is the initial condition for most Jupiter models despite having entered a non-representative location. Measurements of the temperature profile and cloud particles are also needed to validate remote sensing retrievals of cloud structure from imaging data. A major concern with retrievals from remote sensing is their ability to uniquely constrain the cloud layers. Further knowledge of cloud locations and local composition and dynamics, in even one location, is critical to gaining confidence in the inferences provided from remote imaging.

To improve models of Solar System formation and to provide an improved context for exoplanet systems, measurements of the atmospheric composition, structure, and processes within the atmospheres of the giant planets are essential. In particular, measurements of the abundances of noble gases and isotope ratios of hydrogen, carbon, oxygen, and nitrogen, as well as the thermal profile, cloud structure, and dynamics of Saturn are needed. The SPRITE (Saturn PRobe Interior and aTmosphere Explorer) entry probe mission concept would address these important science priorities and would provide ground truth for remote sensing to improve understanding of Saturn's interior structure and composition, and by proxy those of extrasolar giant planets.

The SPRITE mission concept comprises a Carrier Relay Spacecraft (CRSC) and an entry probe descending to at least ten bars in less than 2 hours. The primary scientific instrument payload of the SPRITE probe would include two spectrometers - a Quadrupole Mass Spectrometer and a Tunable Laser Spectrometer, and an Atmosphere Structure Instrument including both a nephelometer and a Doppler Wind Experiment for measuring and characterizing Saturn's tropospheric thermal, cloud, and dynamical structure. The Atmospheric Structure Instrument would also include accelerometers to measure entry accelerations from which the probe entry trajectory and descent location could be reconstructed and for characterization of the thermal structure of the upper atmosphere. The solar powered CRSC carries a Multi-Channel Imager for pre-entry imaging of the probe entry location, and to provide local and global context imaging for the probe measurements.

SPRITE would follow an Earth-Venus-Earth-Earth gravity assist trajectory to reach Saturn in ten years. The SPRITE probe would enter Saturn's atmosphere at a relative velocity of 27 km/s, experiencing a peak heat flux near 3000 W/cm^2 and a peak deceleration up to 45 g's. The aeroshell would be released above the tropopause, initiating the descent science sequence and permitting up to 2 hours for the probe to reach and pass through 10 bars. To ensure low risk data return, the descent probe design is fully-redundant with a dual-channel telecommunication system powered by primary batteries. After the probe science data is collected by the flyby Carrier Relay Spacecraft, the probe data and Carrier imaging data would be downlinked to Earth multiple times through the Deep Space Network

In the context of giant planet science provided by the Galileo, Juno, and Cassini missions to Jupiter and Saturn, a small, relatively shallow Saturn probe capable of measuring noble gas abundances and isotopic ratios of key atmospheric constituents, and atmospheric structure including pressures, temperatures, dynamics, and cloud locations and properties not accessible by remote sensing would serve to test competing theories of solar system and giant planet origin, and chemical and dynamical evolution.

B5.2-0036-18 PREDATOR-PREY ANALOGS FOR SATURN'S NON-LINEAR RING DYNAMICS

Larry W. Esposito, larry.esposito@lasp.colorado.edu University of Colorado, Boulder, Colorado, United States Sreenivas Madhusudhanan, srma6521@colorado.edu

Zhangye Medical College, Boulder CO, Colorado, United States Prasanna Madhusudhanan, mprasanna@colorado.edu University of Colorado at Boulder, United States

Cassini observations of straw, gaps, ghosts, kittens, propellers, solitary waves and the edge disruption of the Keeler gap by Daphnis may all indicate non-linear dynamics in Saturn's rings. This dynamical behavior cycles ring material into and out of transient aggregations: We see the rings changing before our eyes! How can we understand the structures seen by Cassini and the rapid times scales? Numerical simulations cannot yet capture all the relevant physics, the multiple spatial scales or the asymptotic behavior at long time scales. An ecological analogy of a predator-prey model provides a non-linear model, including aggregation by sweep-up, disk instability and the stochastic collisions of clumps. In this model, the aggregate mass is the prey, and the dispersion velocity is the predator, since the dispersion 'feeds' off the aggregates stirring the system. This, in turn, limits the growth of the 'prey'. In some cases, the system shows the dynamics of a driven pendulum or of the Duffing oscillator. For specificity, we adopt the 'twogroup' model of Goldreich for proto-planetary disks, with the 'groups' being the ring particles and their aggregates. This provides a simplification of the size and velocity distributions. Our analysis gives the phase plane trajectories, the equilibrium points and the size distribution of the largest aggregates. Forcing at mean motion resonances creates non-linear density waves, which increase the surface mass density and decrease the relative velocity in their crests. We use Toomre's criterion to check for disk instability. This triggers aggregation, which is out of phase with the forcing, explaining the 'straw' and associated gaps seen between density wave crests. The largest objects have a steeper size distribution, because of the difficulty of accretion in the tidally influenced regime near the Roche limit. The knee in the size distribution of F ring 'kittens' (at about 700m) may therefore be associated with the transition from adhesive growth to collisional gravity-dominated accretion. The predator-prey model thus provides an intuitive description of the non-linear dynamics that leads to the structures seen in Cassini UVIS and ISS observations.

B5.2-0037-18 STATUS OF THE POST-CASSINI SATURNIAN SATELLITE EPHEMERIDES

Robert Jacobson, robert.jacobson@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Prior to the Cassini Tour of the Saturnian system Jacobson (2004 AJ 128, 492) determined the orbits of the Saturnian satellites from Earth-based astrometry and observations acquired with the Pioneer 11 and Voyager spacecraft. We have been extending that work to include additional Earth-based astrometry, and Doppler tracking, radiometric range, very long baseline interferometry, and imaging from the Cassini mission (Jacobson et al., 2006 AJ 132, 2520). Our basic procedure is to repeat the Cassini navigation reconstructions together with reconstructions of the Pioneer 11 and Voyager encounters but with a common set of ephemerides. Data from the spacecraft trajectory reconstructions are combined with other non-spacecraft data sets to update the ephemerides. We call this our "global" solution.

Cassini entered orbit about Saturn on 2004 July 1. After touring the system for 270 orbits, it had its final flyby of Titan on 2017 April 22 and began its proximal orbits, a series of 22 orbits with periapses between the innermost D-ring and the upper layer of Saturn's atmosphere. It plunged into Saturn on 2017 September 9. During the tour there were 3 Enceladus flybys, 3 Dione flybys, 2 Rhea flybys, and 10 Titan flybys dedicated to acquiring measurements of the satellite gravity fields. Saturn's gravitational field strongly perturbed the proximal orbits; tracking through periapsis of 5 of these orbits was acquired to improve knowledge of Saturn's gravity. Accurate knowledge of the gravitation environment of the Saturnian system is crucial to our ephemeris development. In addition to the gravity flybys, Cassini had another 116 Titan flybys as well as flybys of every major satellite. Tracking of the spacecraft before and after each of these satellite encounters provided an indirect measure of the satellite position at the km level. For the determination of the satellite orbits, Cassini also contributed 5766 imaging observations to the existing set of 600 from the two encounters. The Cassini data are highly accurate and cover multiple orbits of the satellites.

The Cassini Navigation Team has completed preliminary reconstructions for all of the spacecraft orbits from the start of Saturn tour through the final Saturn plunge, and we have collected all of the data needed for our final post-Cassini determination of the satellite orbits. Our analysis of the data and its inclusion in the "global" solution is underway and is expected to be completed before the end of the year. This paper reports on the current status of the work.

B5.2-0038-18 TITAN'S POLARIZATION PHASE CURVES WITH CASSINI/ISS

CICLOPS/Space Science Institute, Boulder, Colorado, United States Panayotis Lavvas, panayotis.lavvas@univ-reims.fr

Universite Reims Champagne-Ardenne, Reime, France

The sunlight reflected by Titan's atmosphere is strongly polarized at phase angles near quadrature. This Rayleigh-like behavior has been a key clue for the understanding of the aggregate nature of Titan's ubiquitous atmospheric haze. We are preparing Titan's polarization phase curves with data collected with Cassini's Imaging Science Subsystem. The Cassini/ISS dataset covers the spectrum from the UV to the NIR, and phase angles from nearly zero degrees (full illumination) to 150 degrees, thereby extending the observations made by the Voyager and Pioneer spacecraft decades ago. The Cassini/ISS dataset confirms the older trends in Titan's polarization, but also shows new insight thanks to the relatively good phase sampling and to the availability of data at wavelengths affected by methane absorption. Since we now how spectrally-resolved phase curves in both brightness and polarization, we are investigating the optimal way to combine that information towards the optimal characterization of Titan's atmosphere. The question is also relevant to the prospective characterization of exoplanets.

B5.2-0039-18 AN EMPIRICAL MODEL OF TITAN'S MAGNETIC ENVIRONMENT DURING THE CASSINI ERA: EVIDENCE FOR SEASONAL VARIABILITY

Sven Simon, sven.simon@eas.gatech.edu

Georgia Institute of Technology, Atlanta, Georgia, United States Slawa Kabanovic, s.kabanovic@gmail.com

Georgia Institute of Technology, Atlanta, Georgia, United States Fritz Neubauer, neubauer@geo.uni-koeln.de

University of Cologne, Cologne, Germany Zachary Meeks, zmeeks3@gatech.edu

Georgia Institute of Technology, Atlanta, Georgia, United States

Based on the magnetic field data collected during the Cassini era, we construct an empirical model of the ambient magnetospheric field conditions along the orbit of Saturn's largest moon Titan. Observations from Cassini's close Titan flybys as well as 191 non-targeted crossings of Titan's orbit are taken into account. For each of these events we apply the classification technique of Simon et al. (2010) to categorize the ambient magnetospheric field as current sheet, lobe-like, magnetosheath, or an admixture of these regimes. Independent of Saturnian season, Titan's magnetic environment around noon Saturn local time is dominated by the perturbed fields of Saturn's broad magnetodisk current sheet. Only observations from the nightside magnetosphere reveal a slow, but steady change of the background field from southern lobe-type to northern lobe-type on a time scale of several years. This behavior is consistent with a continuous change in the curvature of the bowl-shaped magnetodisk current sheet over the course of the Saturnian year. We determine the occurrence rate of each magnetic environment category along Titan's orbit as a function of Saturnian season and local time.

B5.2-0040-18 NONAXISYMMETRICAL COMPONENT OF SATURN'S MAGNETIC FIELD DERIVED FROM CASSINI RADIO AND MAGNETOMETER DATA

Patrick Galopeau, patrick.galopeau@latmos.ipsl.fr LATMOS-CNRS, Guyancourt, France

A dipole model ("birotor dipole") was proposed for Saturn's inner magnetic field: this dipole presents the particularity to have North and South poles rotating around Saturn's axis at two different angular velocities; this dipole is tilted and not centered. The spin rates and the associated rotation phases are derived from a continuous wavelet transform analysis of the intensity of the Saturnian kilometric radiation (SKR) signal received at 290 kHz between July 2004 and June 2012 by the radio and plasma wave science (RPWS) experiment on board Cassini. 57 revolutions of the spacecraft, the periapsis of which is less than 5 Saturnian radii, have been selected for this study. For each of these chosen orbits, it is possible to fit with high precision the measurements of the MAG data experiment given by the magnetometer embarked on board Cassini. A nonrotating external magnetic field completes the model. This study suggests that Saturn's inner magnetic field is neither stationary nor fully axisymmetric. These results can be used as a boundary condition for modelling and constraining the planetary dynamo and they can be a starting point for the study of Saturn's inner structure and the comparison with the interior of Jupiter. An average of the birotor dipole magnetic potential is performed on the azimuthal angle revealing an average axisymmetrical component which can be compared with the published zonal models proposed for Saturn's magnetic field. The presence of a "birotor quadrupole" is required in the present model to improve the agreement for the third order Gauss coefficient.

B5.2-0041-18 MEMORIES OF SATURN'S RADIATION BELTS: SPATIAL DISTRIBUTION OF BIT-ERRORS ON THE CASSINI SOLID STATE RECORDERS

Ralph Lorenz, ralph.lorenz@jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, United States Chris Paranicas, chris.paranicas@jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, United States Peter Kollmann, peter.kollmann@jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, United States Emma Woodfield, emmwoo@bas.ac.uk

British Antarctic Survey, Cambridge, United Kingdom Elias Roussos, roussos@mps.mpg.de

Max Planck Institute for Solar System Research, Katlenburg-Lindau, Germany Susan Adamiak, susan.m.adamiak@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Cassini's science data was accumulated in two Solid State Recorders (SSRs) before being downlinked to Earth. Each of these recorders, state of the art for their time (early 1990's) contain 2.5 Gigabits of dynamic random access memory. The DRAM devices were tested to 50 kRad dose, and are shielded by >1cm of aluminium. Additionally, an Error Detection and Correction (EDAC) routine 'washes' through the entire memory once every 9 minutes, using a Hamming code (7 code bits for every 32 data bits), allowing it to detect Double Bit Errors, and detect and correct Single Bit Errors (SBEs). The counts of SBEs DBEs every hour have been collected throughout the Cassini mission, and are highly variable, from typically a couple of dozen per hour, to thousands. These spikes in occurrence take place near periapsis, when the spacecraft passes through Saturn's radiation belts. Thus the SSR housekeeping serves as an independent measurement of Saturn's trapped particle environment, albeit with low temporal (and thus spatial) resolution. The SSR rates are compared with model predictions and data from the MIMI instrument on Cassini.

B5.2-0042-18 PROBLEMS OF RIVERS CLASSIFICATION ON THE BASIS OF RIVERS EVOLUTION ON EARTH AND ON TITAN

Katarzyna Misiura, katarzyna.misiura@fuw.edu.pl

University of Warsaw, Institute of Geophysics, Warszawa, Poland Leszek Czechowski, lczecho@op.pl

University of Warsaw, Warszawa, Poland

The present classifications of the rivers are based on the terrestrial rivers. However, mission Cassini indicates existence of river systems also on Titan. We use numerical modelling of river evolution on the Earth and Titan. We are looking for differences and similarities of evolutions on these celestial bodies. The numerical analysis is performed using the package CCHE. The package is based on the Navier-Stokes equations for depthintegrated two dimensional, turbulent flow and three dimensional convection-diffusion equation of sediment transport. More information is given in [1]-[4]. For calculation of rivers on Titan some adaptation are used.

We have found that transitional rivers are a very common type. Such rivers could be a single channel river in a part of considered domain and a multiple channel river in the rest of domain. In other simulations transitional rivers reveal the features of multiple channel river for some time but later they reveal the features of single channel river. We conclude that to solve the problem of rivers' classification one have to use for classification some time scale and some spatial scale. These scales are determined by dimensionless numbers.

B5.2-0043-18 ANALYZING THE DYNAMIC AND MORPHOLOGICAL CHARACTERISTICS OF CLOUDS ON TITAN USING THE CASSINI VIMS

John Kelland, jak374@cornell.edu

Cornell University, Ithaca, New York, United States Paul Corlies, pmc232@cornell.edu

Cornell University, Ithaca, New York, United States Alexander Hayes, hayes@astro.cornell.edu

Cornell University, Ithaca, New York, United States Sebastien Rodriguez, sebastien.rodriguez@cea.fr France

Elizabeth Turtle, elizabeth.turtle@jhuapl.edu JHU/APL, Laurel, Maryland, United States

Introduction: Titan is characterized by a complex methane cycle analogous to the Earth's hydrological cycle. In 1995, this concept was strengthened by the first observational evidence of methane clouds inferred from albedo increases in specific spectral windows. Today, using data collected by the Visible and Infrared Mapping Spectrometer (VIMS) on board the Cassini spacecraft, we are able to produce high spatial-resolution images which can be used to visually inspect for tropospheric clouds on Titan. We have executed a manual search throughout the entirety of the VIMS dataset (>20,000 applicable cubes) to document cloud occurrence and morphology, providing an opportunity to analyze the global distribution, physical size, duration, and temporal variability of cloud location and geometry.

Methods: In order to identify clouds, we generate a set of three images for each VIMS cube: an RGB image and its grayscale counterpart as well as a stratospherically-corrected tropospheric image. In order to produce the RGB images, we classified specific wavelength channels based on their observational sensitivity to either surface, tropospheric, or stratospheric features. After acknowledging the disadvantageous signal-to-noise ratio (SNR) of the five-micron window, we reduced our channel set to those classified in previous identification efforts. By assigning green to surface, blue to tropospheric, and red to stratospheric, tropospheric features appear as bright blue due to their relatively significant brightening along the wings of the methane windows (the common location of said channels). Using this color scheme, we created stratospherically corrected tropospheric images simply by subtracting the red image from the blue image.

After processing all VIMS cubes, we designed a graphical user interface (GUI) in order to simultaneously analyze the images produced for each observation. This provides greater confidence throughout the cloud selection process, as the GUI allows for both multiple method verification and reference to previous identification efforts. In addition to the displayed images, the software contains a spectral plotting tool which allows the user to compare the albedo spectra of Titan's surface and a candidate tropospheric feature as well as a five-micron toggle which allows users to view cubes in the generally excluded long wavelength channels. These tools provide for the distinction between true clouds and artifacts associated with observations of bright surface features or a consistent difference in albedo caused by proximity to the terminator. Furthermore, our stratospherically corrected images mitigate the problems of hiding and blurring linked to limb-proximal cloud observations.

Results and Discussion: Our analysis spans all VIMS observations from flybys T-A through T-126 (October 2004 to April 2017). Within this dataset, we have identified and characterized tropospheric cloud features in more than 2000 cubes representing hundreds of unique clouds. We observe notable groupings of clouds throughout the southern hemisphere as well as scattered mid-latitude clouds in the northern hemisphere and a high-frequency north polar hood spanning all longitudes. Furthermore, our observations catalogue a significant density of clouds throughout the south polar region alongside scattered clouds in the northern mid-latitudes followed by a delayed transition to dense coverage in the north polar region. These distributions both support and further constrain predictions made by current global circulation models (GCMs) of Titan.

Selecting the complete expanse of every cloud visible in the VIMS dataset regardless of prior observation generates information from which properties can be derived. The GUI employs selection indices which allow for the distinction between multiple features within a single image cube, and extracting the spatial resolution corresponding to selected pixels lets us calculate the total observable area (in km^2) of each individual cloud. We witness an exponential decrease in relative frequency with respect to increasing area. Furthermore, our repeated selection of clouds imaged in multiple cubes provides two benefits: first, it allows for an analysis of the morphologic evolution of the cloud, which can inform on formation mechanisms, and second, it allows for tracking of cloud speed through repeat observations (provided significant spatial resolution) to further constrain wind speed estimates. Using radiative transfer (RT) modelling of Titan's atmosphere, we can also obtain the altitudes of certain observations. By reporting cloud altitude as a function of displacement speed, we can construct altitudinal wind speed profiles which contribute to understanding the complex dynamics of Titan's atmosphere. Although our ability to measure cloud velocity is limited to observations in which a feature's displacement is resolved, the incorporation of ISS data allows for the determination of slower speeds due to a higher global resolution. We report velocities ranging from 1.5 to 23 m/s over the entire extent of the RT model's operable altitudes, 1.5 to 48 km. Our cloud speed data does not display a strongly discernable trend, but decomposing the values into meridional subsets will allow for the analysis of wind speeds across the entirety of Titan.

B5.2-0044-18 SATURN RINGS ORIGIN: MAGNETIC PRESSURE AND QUANTUM TRAPPING OF SUPERCONDUCTING ICED PARTICLES BY THE MAGNETIC FIELD LEAD TO THE STABLE RINGS SYSTEM

Vladimir Tchernyi (Cherrny), chernyv@list.ru

Modern Science Institute at SAIBR, MOSCOW, Russia Andrew Pospelov, chernyv@bk.ru

Modern Science Institute at SAIBR, Moscow, Russia

It is demonstrated how superconducting iced particles of the protoplanetary cloud of Saturn are coming to magnetic equator plane and create the stable enough rings disk. There are two steps. First, after appearance of the Saturn magnetic field due to Meissner phenomenon all particles orbits are moving to the magnetic equator plane. Finally they become distributed as rings and gaps like iron particles around magnet on laboratory table. And they are separated from each other by the magnetic field expelled from them. It takes up to few tens of thousands years with ten meters rings disk thickness. Second, due to their quantum trapping all particles become to be trapped within magnetic well at the magnetic equator plane due to Abrikosov vortex for superconductor. It works even when particles have small fraction of superconductor. During the rings evolution some contribution to the disk also could come from the collision-generated debris of the current moon and from the geysers like it happened due to magnetic coupling of Saturn and Enceladus. The rings are a relic of the earliest days of the magnetic field of Saturn system.

B5.3-0001-18 YEARNING TOWARD THE GLOOM WITH VENTUROUS GLEE: A SWINBURNIAN TOUR OF OCEAN WORLDS EXPLORATION

Jonathan Lunine, jlunine@astro.cornell.edu

Cornell University, Ithaca, New York, United States

Though not intended as such, A.C. Swinburne's "On the Verge" provides an abundance of metaphors for the remarkable nature of ocean worlds, as good as any a way to vignette through a subject now much too large for a COSPAR-length overview talk. Here begins the sea that ends not til the world's end: Globe-girdling oceans of liquid water have been detected beneath the surfaces of five moons, using diverse techniques that required missions to fly repeatedly past their targets. Shines and darkens, wanes and waxes: The brightness of Enceladus' plume is tied to the moon's orbital period, providing the key to the mechanism of its emission and a clue to the plausibility of the assertion that the plume composition tells of the ocean beneath. Gazing hence, we see the water that grows iron round the pole: What is the nature of the colored material that paints Europa's water ice surface? If endogenous, what might this tell us of the material Europa Clipper might find, especially if plumes at high southern latitude are present? Ere our eyes and brows be fanned round with airs of twilight: As Cassini ended its mission, northern summer solstice on Titan revealed a variety of intriguing cloud features in the wettest (with methane as liquid) part of Titan's surface. Do these provide a clue to the nature of the lake/sea interactions with the atmosphere, and the annual stability of the smaller lakes? Nor may seas declare nor skies unroll what has been from everlasting, or if aught shall always be: Is the ocean of Europa as old as the moon itself? Are the seas of Titan remnants of an ancient methane ocean, or the result of an outgassing event in the last billion years? How long has Enceladus had an ocean? These questions have important implications for the astrobiology of these targets. But here [wo] man's heart leaps, yearning toward the gloom with venturous glee, though [her] pilot eye behold nor bay nor harbor, rock nor shoal: Future exploration of the oceans and seas of the ocean worlds will require imagination, daring, scientific passion, and novel ways to reduce trip times while not escalating cost.

B5.3-0002-18 OASES FOR LIFE BENEATH ICE-COVERED OCEANS: HYDROTHERMAL EXPLORATION OF OCEAN WORLDS

Christopher German, cgerman@whoi.edu

Woods Hole Oceanographic Institution, Woods Hole Road, Massachusetts, United States

This paper will present recent research results from a NASA PSTAR program designed to help inform future exploration for life beyond Earth with a particular emphasis on seafloor fluid flow, its ability to sustain chemosynthetic ecosystems and their ability to propagate biosignatures upward from the seafloor into the overlying ocean and/or ice-shell. One particular focus of our work was centered on a field program to the Arctic Ocean in Fall 2016 in which we deployed a new proto-type underwater vehicle called NUI (Nereid Under Ice) as both a fully autonomous vehicle (AUV) and, using a single unarmored optical fiber, as a remotely operated vehicle (ROV) to conduct detailed seafloor mapping, photographic surveys and seafloor sampling. This project was nested within a larger program that also conducted extensive and ultimately successful exploration for evidence of hydrogen-rich submarine venting on the ultra-slow Gakkel Ridge. In parallel, our research has also been pursuing development of a continuous 3-D physical model that can faithfully reproduce the dispersion of a well characterized deep sea hydrothermal plume (from the Axial Seamount, Juan de Fuca Ridge) to provide a continuous digital workspace within which we can test and optimize algorithms for future robotics-based exploration for hydrothermal activity in unknown oceans. While we have already pioneered such AUV-led exploration work, successfully, in Earth's oceans, an ability to eliminate support ships from such exploration would be a massive win-win for the future of both Ocean and Ocean World Exploration. We will close with an outline of future plans, including (a) upgrades to the NUI vehicle that are in progress to enable it to reach any under-ice ocean environment on Earth and (b) future plans for a return to the Arctic to conduct detailed investigations of the newly discovered vent-sites there and test our newly developed vent-exploration search strategies.

B5.3-0003-18 EXPLORING EUROPAN ANALOGS OF THE MCMURDO SOUND AND ROSS ICE SHELF

Britney Schmidt, britneys@eas.gatech.edu

Georgia Institute of Technology, Atlanta, Georgia, United States
The RISE UP Team

J. D. Lawrence, M. R. Meister, D. J. G. Dichek, C. D. Ramey, B. C. Hurwitz, A. Spears, J. J. Lutz, J. P. Lawrence, M. Philleo, J. B. Glass, A. S. Stockton, J. S. Bowman, N. Speller, D. P. Block, L. Kassabian, A. Mullen

The NASA-funded RISE UP program (Ross Ice Shelf Europa Underwater Probe) is a threeseason project to build future exploration technologies for ocean worlds that facilitate the exploration of analogs for ice-ocean processes in Antarctica. Key focuses of this work include basal ice conditions, ice-ocean interactions, and environmental conditions from the ice to the sea floor beneath the McMurdo sound sea ice, the McMurdo Ice Shelf, and the Ross Ice Shelf. Enabling this science to be achieved is the novel and scientifically capable Icefin hybrid AUV/ROV vehicle that conducts surveys from the ice to the seafloor to provide an integrated picture of the conditions below the ice. With one field season now complete in 2017-18, the project will extend its observations in the 2018-19, and 2019-20 austral summers. In cooperation with the Antarctica New Zealand Ross Ice Shelf Programme, PI Christina Hulbe, RISE UP will also deploy Icefin through a borehole through the Ross Ice Shelf to access previously unmapped regions of the sub-shelf water column.

I will highlight the first results of RISE UP's first field season from October 2017 to early January 2018. This season includes data collection at three sea ice locations: two that allow us to swim Icefin underneath the ice shelf, and one at the Erebus Glacier Tongue. Onboard Icefin, we collected data from two sonars, two cameras, a DVL/ADCP, and sensors for conductivity temperature, depth, pH/ORP, DO, CDOM/FDOM and turbidity. In 2018, Icefin will also carry a custom built cell counter, and a microscope, water sampling and ice sampling systems are being designed. The highlights of the scientific data collected this season include the first detection of new boundary layer interactions between the ice and ocean, observations of forming marine ice beneath the MIS, and observations of ice-ocean interactions within an ice shelf rift. In addition to describing Icefin and its observations of the basal ice, oceanographic properties below the sea ice and ice shelves, and seafloor, I will describe how these new data provide information that allows us to better frame our understanding of Europa's ocean and its potential interactions with the ice shell.

This work was supported by NASA PSTAR program grant NNX16AL07G. Field work in Antarctica was supported by NASA and NSF under USAP project number B-041-M.

B5.3-0004-18 INSIGHTS INTO THE CHEMICAL EVOLUTION OF OCEAN WORLDS FROM OBSERVATIONS OF DWARF PLANET CERES WITH THE DAWN MISSION

Dawn Team Dawn Team

Ceres, the most water-rich (in volume fraction) body in the inner solar system, has recently been recognized to have astrobiological importance. Chemical and physical measurements obtained by the Dawn mission enable quantification of key parameters constraining the habitability of the inner solar system's only dwarf planet. Current knowledge indicates that Ceres once had water, energy sources, and redox gradients. Furthermore, bounds on elemental C (Prettyman et al., 2017) and direct detection (De Sanctis et al. 2017) support the possibility that organic compounds are widespread within the subsurface. The surface chemistry and internal structure of Ceres testify to a protracted history of reactions between liquid water and rock (Ammannito et al. 2016; Prettyman et al. 2017). Arguably, the most significant finding from the Dawn mission is unambiguous evidence for oceanic material exhibited on Ceres' surface, associated with recent cryovolcanic features (Zambon et al. 2017; Carrozzo et al. 2018). The degree to which prebiotic chemistry, liquid water, and other environmental factors may have combined to make Ceres a habitable world is left for future missions to explore. Dawn's observations confirmed earlier predictions for a volatile-rich shell and a warm and liquid-bearing interior, akin to icy moons. Indeed, Ceres' structure is similar to that of an icy satellite that has almost entirely frozen (Ermakov et al. 2017; Fu et al. 2017). The prospect that a relict ocean may have survived into the present led to Ceres' classification as a "candidate" ocean world in the Roadmap for Ocean Worlds (Hendrix et al. 2017). Similarities with Enceladus' plume dust composition (Postberg et al. 2011; De Sanctis et al. 2016) suggest Ceres falls in the same category of bodies that have hosted an alkaline environment for part (or all) of their history (Zolotov et al. 2007). More generally Ceres' surface chemistry is consistent with the chemical evolution expected in relatively large ice-rich bodies (McKinnon and Zolensky 2003; Neveu et al. 2017). We review the clues on chemical composition, temperature, and prospects for the present occurrence of liquid and chemical gradients in Ceres and explore how cross-pollination of knowledge between this dwarf planet and ocean worlds in the outer solar system improves our general understanding of large volatile-rich bodies.

This work is being carried out at the Jet Propulsion Laboratory, California Institute of Technology, under contract to NASA. Government sponsorship acknowledged.

B5.3-0005-18 IMPLEMENTABLE PROGRAM FOR EFFICIENT OCEAN-WORLD EXPLORATION

Brent Sherwood, brent.sherwood@jpl.nasa.gov

Jet Propulsion Laboratory, Pasadena, California, United States Jonathan Lunine, jlunine@astro.cornell.edu

Cornell University, Ithaca, New York, United States Christophe Sotin, christophe.sotin@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Tom Cwik, cwik@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

The next US planetary Decadal Survey's mission priorities will emerge in 2022-23. Current US law requires NASA to implement a "virtual" Ocean Worlds Exploration Program (OWEP) using a mix of mission classes. NASA and ESA are currently developing large missions to explore Europa and Ganymede, respectively; NASA is also formulating concepts for a potential large mission to search for biosignatures on the Europa surface. Small-class mission concepts for Titan and Enceladus were proposed in 2010 and 2014, but not selected; NASA awarded

$25M in 16 technology-development projects pertinent to Europa and other ocean worlds; recently NASA evaluated four medium-class OWEP mission in the New Frontiers program and has advanced one to Phase A. OWEP technical challenges are formidable: 1) almost a dozen diverse ocean worlds of varying priority, with key pieces of the ocean-world scientific puzzle are distributed among them; 2) power limitations at the Jovian and Saturnian ocean worlds;

3) standard launch and in-space propulsion impose half-decade (to Jupiter) or decade-long (to Saturn) transfers; and 4) the oceans are beneath kilometers of cryogenic ice. A virtual program of disparate initiatives is unlikely to cohere into an efficient OWEP. First, OWEP technologies outside the framework of individual missions have uncertain funding; the $25M allocated in FY17 is but a small down-payment, and enhanced investment would compete against many other solar system objectives. Second, the medium-class OWEP mission concepts compete against unrelated science objectives in a selection process whose outcome cannot be predicted. The MEP (Mars Exploration Program) offers one successful exemplar for a strategic program. Yet none of six key conditions underpinning the MEP over the past 15 years apply to a virtual OWEP. In particular, NASA has no mission-opportunity class comparable to the MEP backbone of MGS, Odyssey, and MRO: directed, medium-class missions supporting broader strategic objectives. Progress would be fastest if NASA could adapt three MEP program characteristics: 1) major technology investments separate from mission projects; 2) directed medium-class missions that conduct pivotal investigations on a sustained roadmap; and 3) multi-mission technical infrastructure that "lowers the bar" for individual missions. The most important OWEP example is space transportation, e.g., heavy-lift launch, and high-power solar-electric propulsion, to minimize trip times into Saturn and Jupiter orbit. This analysis treats the governing programmatic constraints, technical uncertainties, and policy gaps for an OWEP, then lays out multiple options for maximizing progress on the highest priority science objectives.

B5.3-0006-18 TRITON'S PLUMES - INSIGHTS INTO TRITON'S OCEAN WORLD STATUS

Candice Hansen, cjhansen@psi.edu

Planetary Science Institute, Tucson, United States Karl Mitchell, karl.l.mitchell@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasdena, California, United States

Lynnae Quick, quickl@si.edu

Smithsonian Institution, Washington DC, District of Columbia, United States

Introduction: Triton's young surface with relatively few craters stands out among moons in the solar system and puts it in a class with geologically active Io, Europa, Titan and Enceladus. Particulate plumes rising 8 km above the surface were imaged by Voyager in 1989, in Triton's southern spring [1]. Dark fans deposited on the surface were attributed to deposits from similar, no-longer-active plumes. The plumes were modeled as insolation-driven expulsions of nitrogen carrying particles entrained from the surface [2, 3].

Triton's warm interior: Triton's surface age of <10 MY is derived from the lack of craters on its surface [4], likely erased by surface yielding, deformation and viscous relaxation. A new model of Triton's interior suggests that the combination of radiogenic heating with ongoing tidal heating due to Triton's obliquity could sustain a long-lived subsurface ocean even without invoking substantial ammonia; thus remnant heat from Triton's capture into orbit around Neptune is not required to sustain endogenic geological activity [5].

Source of the plumes: Are Triton's plumes solar-driven or do they come from a subsurface ocean? Are they more like the endogenic eruptions at Enceladus or the seasonal gas jets of Mars? Solar-driven activity - the Mars analogy. Triton's nitrogen atmosphere is in vapor pressure equilibrium with surface ices, and will form polar caps in the winter. The solar-driven model for Triton's plumes relies on a solid state greenhouse forming in/below a seasonal layer of nitrogen ice. A 4 K rise in temperature causes a 10x increase in vapor pressure, and this temperature difference is easily achieved [3]. The discovery of the fans and modeling of the plumes on Triton inspired the solar-driven model for the origin of the fan-shaped deposits imaged on Mars' sea-sonal CO_2 polar caps from seasonal CO_2 gas jets [6]. Mars Reconnaissance Orbiter High Resolution Imaging Science Experiment (HiRISE) images have largely substantiated this model [7]. The combination of HiRISE images and updated models of the jets have allowed us to quantify parameters such as gas exit speeds (20-300 m/sec), mass flux (30-150 gm/sec), height achieved (50-100m), volatile storage requirements, and lifetimes < 2 hr [8]. Eruption from the interior - the Enceladus analogy. We now have another possible comparison, with the Cas-sini discovery that Saturn's moon Enceladus spews water vapor and ice particles from fissures across its south pole [9, 10, 11]. Enceladus showed that it is possible to have regionally confined geophysical activity, driven by tidal energy [12]. Observations indicate vapor exiting at speeds up to 1-2 km/sec in collimated jets [13]. Vapor mass flux is on the order of 200- 300 kg/sec [7]. Solid particle flux is 50 kg/sec [14]. Pluto comparison. Pluto has an N_2 atmosphere in vapor pressure equilibrium with surface frost, similar to Tri-ton. Although the New Horizons flyby of Pluto was at a season in which solar-driven fans could have been active none were imaged [15].

Summary: The solar-driven model has been the accepted explanation for many years for Triton's plumes. The distribution of fans is consistent with that model, the timing of the eruptions coincided with southern spring, and it is eminently plausible in terms of energetics. Challenges with gas storage and the required layered surface structure were considered surmountable [3]. More recent data and models however motivate a re-examination of the source of Triton's plumes. The age esti-mate for Triton's surface and recent tidal models incorporating obliquity were not available in the Voyager era. Study of Mars' jets has allowed us to characterize and quantify solar-driven processes on that planet. The discovery of tidally-driven eruptions confined geographically on Enceladus and measurements such as vapor mass flux and exit speeds have expanded possible scenarios for Triton. The possibility that Triton's plumes could be endogenic and sourced from sub-surface liquid is deserving of further investigation and would solidify Triton's identity as an ocean world.

B5.3-0007-18 GEOLOGIC ACTIVITY AND LIQUID WATER WITHIN THE ICE SHELLS OF OCEAN WORLDS

Alyssa Rhoden, alyssa.rhoden@asu.edu

Southwest Research Institute, Boulder, Colorado, United States

The outer solar system may be brimming with oceans, making it a high priority target for exploration and the search for extant life. Europa and Enceladus, in particular, are thought to have global, subsurface oceans under their geologically active icy shells. Such activity may enable material transport within the shell that can help supply nutrients to a biosphere within the ocean. However, much is unknown about how geologic features on the surfaces of Europa and Enceladus form and what those features imply about the presence of liquid water and material transport within their ice shells. Furthermore, despite having many similarities, geologic activity on Europa and Enceladus manifest in different ways. Understanding what has caused these differences is critical to understanding the long-term geophysics and habitability of all icy, ocean worlds.

Europa's young surface displays globally-distributed geologic activity of two main types. Tectonic features alter the surface through the formation of fractures and subsequent modification of those fractures to create double ridges, dilational bands, and zones of convergence. Tidal stresses caused by Europa's eccentric orbit have been implicated in the formation of fractures, particularly arcuate fractures called cycloids, but modification of fractures may be more related to processes within the shell. Endogenic features disrupt the surface from beneath and display a variety of sizes and morphologies; such features include large-scale chaos (100-200 km across) and microfeatures such as pits and domes that are typically less than 10 km across. Both tectonic and endogenic features have been linked to shallow liquid water within the ice shell. In addition, recently reported evidence of plumes in different regions of Europa also implies liquid water near the surface. However, moving water from the ocean into the shell is challenging due to the lower density of ice compared with liquid water.

Enceladus also displays recent tectonic activity, but it is highly localized near the south pole; tectonic activity becomes older and sparser with distance from the south pole and is concentrated at certain longitudes. The activity at the south pole is complex, with many generations of overlapping fractures. The most prominent set, dubbed Tiger Stripes (TSFs), are associated with high heat flows and appear to be the sources of Enceladus' large, active plumes. The timing of plume eruptions has been linked to tidal stresses, which change in magnitude and direction throughout Enceladus' eccentric orbit. Material within the plumes strongly suggests that the source fractures tap a reservoir of liquid water, and that the water is in contact with rock (i.e. an ocean). If correct, the TSFs represent the most direct example of ice-ocean interactions yet discovered. Curiously, Enceladus does not display any of the endogenic features observed on Europa (i.e. chaos). Fractures at the south pole do have double ridges, but no dilational bands, convergence bands, or cycloids have been identified. This suggests that these two ice shells interact very differently with the oceans beneath them, although the causes are unknown.

In this talk, I will review the models that invoke shallow liquid water to form Europa's surface features, describe the limitations and implications of those models, and discuss the role that thermal-orbital evolution has played in modifying Europa's surface and ice shell. I will also discuss how these processes may have operated differently on Enceladus in order to produce the very different styles of activity from what is observed on Europa. This work benefitted from thoughtful discussions with members of the Ocean Worlds Collaborative, attendees of the Europa Deep Dive workshop, and numerous colleagues.

B5.3-0008-18 TECTONIC MATERIAL TRANSPORT WITHIN THE OUTER ICE SHELLS OF ICY SATELLITES

Samuel Howell, samuel.m.howell@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Robert Pappalardo, robert.pappalardo@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

On Europa and Ganymede, the scars of tectonic activity are imprinted in water ice shells tens of kilometers thick that are inferred to overlay water oceans about an order of magnitude deeper. The origin and formation of tectonic terrains on icy satellites is tied to processes that link the ice shell and the ocean, such as spreading, rifting, subduction, and cryovolcanism, causing the ice shell to evolve through time. Understanding the tectonic material exchange mechanisms between the surface and the ocean is critical to understanding the potential habitability of these ocean worlds. Some of the most prevalent tectonic terrains on Europa and Ganymede are inferred to occur from extension in the ice shell, commonly producing long, linear "bands," an umbrella term we use to include both bands on Europa and groove lanes (sulci) on Ganymede. These bands have been proposed as ice-analogues to mid-ocean ridge spreading on Earth. Further, evidence for subduction-like convergent tectonics has raised the possibility of a buoyantly driven cycle of tectonic resurfacing and lithosphere recycling on Europa and Enceladus. In this study, we present 2D numerical models of band formation with the outer ice shells of Europa and Ganymede, and track "fossil ocean," ocean material frozen into the ice shell and deformed through geologic time. We predict which band morphologies are most likely to expose fossil ocean material, and the conditions under which those bands form. In addition, to understand whether a plate-tectonics-like cycle of resurfacing and recycling could facilitate band formation and material transport from the surface back into the interior ocean, we perform a basic feasibility test for buoyantly driven subduction and spreading on Europa, Ganymede, and Enceladus. Overall, we find that ocean material can be transported upward into the ice shell through convection and advection, and fossil ocean may be exposed at smooth bands on Europa, but not at highly tectonized bands or groove lanes on Ganymede. We also find that buoyancy forces are unlikely to contribute to subduction or spreading in the outer ice shells of these icy satellites. Thus, we find that the convergent tectonics that might recycle surface material into the ice shell interior, and eventually the ocean, require large exogenic forces.

B5.3-0009-18 TIDAL DISSIPATION IN EUROPA'S SILICATE MANTLE: IMPLICATIONS FOR SEAFLOOR ACTIVITIES AND POTENTIAL OBSERVATIONS BY EUROPA CLIPPER.

Jet Propulsion Laboratory, Pasadena, California, United States

The level of endogenic activities possibly occurring at Europa's seafloor at present day is conditioned by the amount of energy produced in the silicate mantle by tidal dissipation. In the present study, we model the viscoelastic deformation of Europa's mantle using an Andrade rheology and testing various bulk compositions consistent with available geophysical constraints. We show that, for viscosity values consistent with the expected range near the melting point of peridotite, the heat production by viscous tidal friction exceeds the present-day radiogenic heating. Maximal tidal heating rate is obtained at the base of the mantle, with an increase in the polar region and maximal values exceeding locally ten times the typical volumetric radiogenic heating rates expected assuming chondritic rocks. As a consequence, preliminary analysis based on scaling laws indicates that significant partial melting should occur at present in Europa's mantle. In order to further test the impact of tidal heating on the thermal state of Europa's mantle, we perform 3D simulations of thermal convection including heat production by tidal friction, melt production and extraction. We will discuss the implications of these model results in terms of seafloor activities and potential detection from gravity, topography and compositional data by NASA's planned Europa clipper mission.

B5.3-0010-18 GEOTHERMAL ENERGY IN PLANETARY ICY LARGE OBJECTS VIA COSMIC RAYS MUON-CATALYZED FUSION

Antonio De Morais Mendonca Teles, antonioamore@yahoo.com
Brazilian Center of Physics Research, Rio De Janeiro, Brazil

In this brief paper, we propose the possibility that p+-d+ and d+-d+ fusions intermediated and catalyzed by the elementary particles muons (μ-), produced by cosmic rays, might hypothetically add energy to geothermal reservoirs in the interior of planetary icy large objects of the Solar System, and of other extra-solar planetary systems, interesting for astrobiological considerations. Well, it is known, since the discoveries in the planetary Solar System by the NASA's Voyagers 1 and 2 spacecraft in the l980's decade, that the four gaseous giant Jovian planets - Jupiter, Saturn, Uranus and Neptune, possess natural satellites displaying on their surfaces (mostly icy ones) recent geologic activity [17]. These moons include Jupiter's Io, Europa and Ganymede, respectively with its active volcanoes, its internal saline seas, and its rugged surface indicating a possible internal ocean of liquid water. Other moons are Saturn's Titan and Enceladus, respectively with its liquid CH4 and C2H5 seas and with its water vapor geysers and global internal ocean of liquid water. Uranus' Miranda, which displays on its icy surface a complex geology, and Neptune's Triton which shows present-state geological activity as geysers expelling dark material from its subsurface. A major heat source for icy satellites of the giant planets is tidal dissipation via orbital resonances [14] [17]. And heat within these objects is also generated by the radioactive decay of internal elements left over from the time of their initial formation. In July 14, 2015, the John Hopkins University's Applied Physics Laboratory - Southwestern Research Institute - NASA's New Horizons spacecraft made the first close flyby over Pluto and its system of 5 moons, being Charon the largest one. Initial data from New Horizons flyby were analyzed by the mission team, and first results were completely intriguing. We are learning that Pluto (and to a lesser extent, Charon) show complex, dynamical, present geologic activity [17]. Models involving tidal dissipation, which would indicate geologically "quiet" worlds, do not account for such present geological activity at Pluto, as for the existence of tidal dissipation is necessary orbital eccentricity, which is practically zero in the Pluto-Charon system. Besides such forms of geothermal energy sources as tidal and radiogenic heating, there is another one, fusion of protons in planetary interiors which was mentioned in the literature [9] [10] [13] [27]. It is usually assumed that such nuclear reactions occur only in the stars interiors, but there is an elementary particle, muon (μ-), that can intermediate such reactions in the low-temperature planetary conditions (as compared as to temperatures inside stars) [16]. This natural phenomenon is known as muon-catalyzed fusion (MCF). MCF was first theoretically proposed in the 1940-50's decades [6] [28], and experimentally observed since the 1950's decade [2] [3] [12] [22]. When a muon (μ-), which lifetime is 2 x 10-6 s, interacts with a proton (p+) and/or a deuteron (d+) (forming a p+-μ–p+, a p+-μ–d+ or a d+-μ–d+ molecule, during 10-11 s), it approximates them to a distance about 207 times smaller than in a H2 molecule with electrons, a catalysis sufficient for their fusion. The reaction ddμ → 3He + n + μ yields a Q = 3.3 MeV, with a reaction rate r (ddμ) 3.5 x 1010 s-1. The reaction pdμ → 3He + + μ yields a Q = 5.5 MeV, with a reaction rate r (pdμ) 1.8 x 105 s-1 [8]. The number of reactions one muon can catalyze was experimentally observed to be about 150, due to the alpha-particle sticking problem [8], but this can be overcome by multiple collisions, which occur normally in icy worlds temperatures. Thus, for just one muon it can yields a minimum of Q

= 500 MeV during its multiple reactions until it disintegrates. But where can we find so many muons for their reactions to give some thermal energy inside icy worlds? The most abundant source for muons is cosmic rays, which origins are solar, galactic and extra-galactic. Daily on planet Earth, an enormous quantity of high (102 MeV) to extremely high (> 100 TeV), and higher energy (1019 eV) protons and nuclei strike nuclei of atoms in the atmosphere, producing cascades of pions (other elementary particle) which decay into muons. Such muons arrive at the Earth surface with energies ranging typically from 10 GeV to 100 TeV and, depending on their energies and on the material, they can penetrate most deeply into liquid and ices than into rocks. For instance, for Eμ = 10 GeV it can penetrate 0.05 Km, and for Eμ = 10 TeV it can penetrate 6.09 Km into rocks [19]. Inside the ices of Antarctica it was measured many muons as deep as 7 km [5], and inside the Baikal lake it was measured muons at 6 Km deep [4], and at the Mediterranean sea it was measured muons at > 10 Km deep [20]. Muons also lose energy by ionization and by radiative processes which adds energy throughout their trajectories. Thus, at a depth of 1 km of rocks their flux is 10-6 than at the Earth's surface. About data on cosmic rays in the Solar System, we are fortunate because the two Voyagers are in operational status. The Voyagers' cosmic ray subsystem measured a somewhat spatial steady flux of cosmic rays throughout their trajectories in the Solar System, but varying in time and anti-correlated with sunspots activity [18]. The measured fluxes began to rise in the outer regions of the heliosphere, where the Sun's magnetosphere is weaker due to the distance

[11] [18] [21]. For objects in the outer Solar System, an enormous quantity of muons are daily produced by an enormous quantity of cosmic rays striking the icy surfaces of the Jovian moons, and of the Trans-Neptunian Objects (TNOs) as the dwarf planet Pluto. During the flybys of the Jupiter and Saturnian systems by the Voyagers, they collected data on the energy and flux of high-energy cosmic rays protons trapped into the Jovian magnetospheres, fed constantly [23] [25]. The trapped protons energies of 102 Mev to 1 GeV in the leading and trailing sides of both planets [24] [26] bombards constantly their moons, creating continuous showers of muons into their interiors. As for planet Mars, cosmic rays measurements by space-craft [17] indicate the production of muons at a similar to or higher rate than on Earth's surface [15] due to the lack of a Martian global shielding magnetic field, thus many muons go into the interior of Mars. For more MCF to occur it is necessary the existence of a large quantity of deuterons. Due to equilibrium and kinetic dynamical factors, it is modeled that icy ob-jects that formed farther out in the Solar System (and other extra-solar planetary systems [17]) should generally have higher

deuterium content in their ice than objects that formed closer to the Sun, and objects that formed in the same source regions and at similar times should have accreted ice with similar hydrogen isotopic compositions [1]. The observed D/H ratio in the inner Solar System is 10-4 [7], which are believed to be higher in the outer Solar System [1], perhaps with D/H 10-3. These ratios are small, but due to the fact the icy bodies are so abundant in the Solar System, the quantity of deuterons might be sufficient for regular MCF to occur via cosmic rays muons. So, integrating time over 4 Gyrs, there was enough time for many muons to have intermediated catalyzed fusion via pdμ and ddμ reactions, yielding regular energy for the interiors of large icy objects in the Solar System. Even being so small in geological energy terms (1 GeV = 1.6 x 10- 10 J) such MCF energy might have being significant for the energy balance inside the primitive Earth, Mars, the Jovian icy moons, the icy TNOs, and icy worlds of extra-solar planetary systems. Such deposited fusion energy might hypothetically be significant for geological activities observed on the surfaces of the Jovian moons and Pluto, with <Ts> 110 K and <Ts> 44 K, respectively [17], and other icy TNOs. In such low temperatures, a small quantity of fusion energy might appear on the surface as geological activity. And we also propose that MCF might also be significant for the energy balance in the formation of geothermal reservoirs (with liquid water) inside those icy large objects (hydrated minerals, ponds, small lakes and seas), long enough in time for the maintenance of internal chemistries interesting for astrobiology. B5.3-0011-18 MODELING THERMAL EVOLUTION OF OCEAN WORLDS WITH CONVECTIVE ICE SHELLS

Shunichi Kamata, kamata@sci.hokudai.ac.jp Hokkaido University, Sapporo, Japan

Heat transportation inside a planet is the most fundamental process in planetary evolution. Previous numerical calculation methods for the thermal evolution considering thermal convection, however, are either time consuming or less accurate.

This study provides a calculation method of the convective temperature profile with a low calculation cost and a high accuracy. I apply this method to investigate the thermal evolution of two Saturnian icy satellites with subsurface oceans, Dione and Enceladus, under a wide variety of parameter conditions.

From the results, I find that each satellite requires several ten GW of heat to possess a severalten-km thick subsurface ocean. Dynamical tides may be able to account for such an amount of heat, though the reference viscosity of Dione's ice and the ammonia content of Dione's ocean need to be very high. This means that a nominal icy satellite model, which has been adopted by many previous studies, would not be appropriate for Dione. Note that such an extreme condition is necessary only when Dione has a thick subsurface ocean. Consequently, the results obtained in this study may indicate that Dione does not possess a thick subsurface ocean. If this is the case, it implies that the ice shell of Dione is stiff and is not in a minimum-stress state.

The major part of this study is published in JGR-Planets [1].

B5.3-0012-18 WHAT CONTROLS THE CONCENTRATION OF SEA SALT IN PLANETARY OCEANS?

Christopher Glein, cglein@swri.edu

Southwest Research Institute, San Antonio, Texas, United States

Sea salt (sodium chloride or NaCl) is the most abundant dissolved constituent in the oceans of Earth and Enceladus [1]. It is also widely suspected to be a key component of the Europan ocean [2-4]. The NaCl concentration in terrestrial seawater is 0.47 mol/kg, and the Enceladus ocean is inferred to contain 0.05-0.2 mol NaCl/kg [1]. The NaCl content of Europa's ocean is presently unknown. It is important to understand the geochemical and geophysical controls on oceanic NaCl, as this constituent seems to be the general driver of ocean salinity (total dissolved salt content). This affects other properties of the ocean that are of broader interest including the liquid density, freezing point depression, electrical conductivity, and the activity of H2O. Building on my previous work [5], I have constructed geochemical mass balance models to explore the relevant parameter space. There are two primordial sources of chlorine on ocean worlds: rocky and icy materials. Releasing Cl from rocks requires water-rock interaction (Enceladus) or volcanic outgassing (Earth). Chlorine can be acquired in accreted ices if they form at low enough temperatures to allow the condensation of HCl hydrates (Enceladus) [6]. The example of Earth shows that having a very low planetary water/rock ratio greatly facilitates the formation of a salt-rich ocean. Also, the sub-chondritic total Cl abundance and its distribution on Earth [7] emphasize the important roles of outgassing and volatile loss. Nominally, I find that Earth's Cl is 90% outgassed, but only 10% of that was retained. On Enceladus, a key factor influencing the chlorinity is the ice/liquid water ratio, because ice (particularly as it ages) has a much lower capacity for storing passive brines. The Europan hydrosphere system is especially interesting and likely to be highly informative for developing a more general understanding, because it appears to provide a system that is intermediate to Earth and Enceladus. A preliminary prediction for Europa's ocean is an NaCl concentration of mol/kg, reflecting Europa's assumed formation under warm conditions (consistent with its relatively rock-rich composition), modest outgassing and loss of chlorine, and an assumed average ice shell thickness of 20 km. The corresponding electrical conductivity from dissolved NaCl is 5 mS/cm at 273 K. These and other model results will be detailed at the conference, as well as future mission tests. Recent observations of Europa's surface suggest that a large quantity of exogenic sulfate originated from Io would have been supplied into its subsurface ocean. Despite the importance of sulfate to Europa's oceanic chemistry, little is known about its fate within the ocean. Here we report our experimental results on sulfate reduction in hydrothermal environments under the conditions comparable to Europa's seafloor. Using a newly-developed experimental system capable of performing on-line sampling of hydrothermal fluids during the experiments at 130 MPa and 300 deg.C., we first obtain the reaction rates of sulfate reduction under Europa's hydrothermal conditions. By introducing the experimental results into thermochemical equilibrium calculations of water-rock reactions, we also show that, if Europa's seafloor rock is basaltic, exogenic sulfate would be effectively consumed by hydrothermal reactions, leading to occurrence of a Na, Mg, H2S, and Cl-rich ocean. On the other hand, if Europa's rock is still chondritic, sulfate would accumulate within the ocean, resulting in occurrence of a Na and SO4-rich ocean. We propose that identification of salts on Europa's surface and in plumes through future missions would be critical to constrain Europa's rock composition and possible occurrence of hydrothermal activity.

B5.3-0014-18 THE GLOBAL GEOLOGY OF EUROPA: UNITS, THEIR DISTRIBUTION, AND IMPLICATIONS FOR FORMATION PROCESSES

Understanding the age relations and distribution of the geologic terrains on Europa is paramount to gaining insight into the potential habitability of this icy world. To this end, we have generated a geologic map at the scale of 1:15 million that incorporates data at all resolutions collected by the Voyager and Galileo missions, allowing us to constrain global geologic and tectonic relations. Ten major geologic units are identified which includes the following: Low Albedo Ridge Material (lam)-low albedo material that irregularly surrounds large (>20 km) ridge structures; Ridged plains (pr)-distributed over all latitudes and characterized by subparallel to cross-cutting ridges and troughs visible at high resolution (<100 m/px); Band material (b)-linear to curvilinear zones with a distinct, abrupt albedo change from the surrounding region; Crater material (c), Continuous Crater Ejecta (ce) and Discontinuous Crater Ejecta (dce)-features associated with impact craters including the site of the impact, crater material, and the fall-out debris respectively; Low Albedo Chaos (chl), Mottled Chaos (chm) and High Albedo Chaos (chh)-disrupted terrain with a relatively uniform low albedo, patchy/variegated albedo, and uniform high albedo appearance respectively; and Knobby Chaos (chk) - disrupted terrain with rough and blocky texture occurring in the high latitudes.

In addition to the geologic units, our mapping also includes structural features-Ridges, Cycloids, Undifferentiated Linea, Depression Margins, Bands, and Troughs. We also introduce a point feature (at the global scale), Microchaos, to denote small (<20 km diameter) patches of discontinuous chaos material.

The completed map constrains the distribution of the different Europa terrains and provides a general stratigraphic framework to assess the geologic history of Europa from the regional to the global scale. Based on crosscutting relationships, we find the ridge plains are generally the oldest followed by bands. Chaos and microchaos cut all other features indicating they are the youngest terrains. Initial analysis of the distribution of microchaos suggests that it is not uniformly distributed across Europa, instead, it appears

to show an increase in density associated with the bands. We are currently assessing this relation as it implies disruption of the crust and communication between the subsurface and surface. In this presentation we will discuss the global-scale geologic terrains as well as our preliminary findings regarding the distribution of microchaos.

B5.3-0015-18 EVIDENCE OF A PLUME ON EUROPA FROM GALILEO MAGNETIC AND PLASMA WAVE SIGNATURES

The icy surface of Jupiter's moon, Europa, is thought to lie on top of a global ocean. Signatures in some Hubble Space Telescope images have been associated with putative water plumes rising above Europa's surface. However, all telescopic detections reported were made at the limit of sensitivity of the data, thereby calling for a search for plume signatures in in-situ measurements. Here we report in-situ evidence of a plume on Europa from the magnetic field and plasma wave observations acquired on Galileo's closest encounter (E12) with the moon. On this flyby that dropped below 400 km altitude, the magnetometer recorded a 1000 km scale field rotation and a decrease of over 200 nT in field magnitude and the Plasma Wave Spectrometer registered intense localized wave emissions indicative of a brief but substantial increase in plasma density. Based on numerical modeling using a 3D multi-fluid magnetohydrodynamic (MHD) model, we show that the location, duration, and variation of the magnetic field and plasma wave signatures are consistent with the interaction of Jupiter's corotating plasma with Europa if a plume with characteristics inferred from Hubble images was erupting from the region of Europa's thermal anomalies. Our results provide strong independent evidence of the presence of plumes at Europa.

B5.3-0016-18 QUANTIFYING THE ACCESS OF JUPITER'S MAGNETOSPHERIC PLASMA TO EUROPA'S SURFACE THROUGH A MULTI-FLUID MHD MODEL

Europa's space environment is controlled by the wobbling of Jupiter's magnetic field, the magnetic response to this wobbling induced in the conducting subsurface ocean, and the interaction of Jupiter's magnetosphere with Europa's ionosphere and extended exosphere. We have developed a multi-fluid MHD model for Europa's plasma interaction which self-consistently solves for the bulk properties of 3 ion fluids and the electromagnetic fields in the vicinity of the moon. To validate our model, we have simulated the Galileo E4 Flyby using the observed plasma and magnetic field conditions. Our model has accurately reproduced Galileo magnetometer observations along the flyby trajectory, and provides full 3D density and velocity fields for O+ and O+ ionized from Europa's neutral O2 exosphere, and the thermal, corotating O+ from Jupiter's magnetosphere. Based on the three-ion-fluid MHD model, we have mapped the distribution of the magnetospheric plasma that was able to penetrate the plasma interaction to reach Europa's surface. We find that while the majority of downward flux impinges on the upstream hemisphere, the surface impact by the ambient magnetospheric O+ ions exhibits a slight preference towards the anti-jovian hemisphere due to the influence of the convectional electric field. Under the E4 flyby conditions, we estimate that about 13% of the available upstream O+ ions precipitate to Europa's surface. Most of the ambient plasma is instead diverted around the moon due to the plasma interaction with the ionosphere. This precipitation represents the contribution of thermal plasma to the sputtering interaction with Europa's icy surface which replenishes the O2 exosphere.

B5.3-0017-18 LABORATORY SIMULATION OF EUROPA'S SURFACE PROPERTIES UNDER RADIATION ENVIRONMENT

Murthy Gudipati, gudipati@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology/NASA, Pasadena, California, United States

Bryana Henderson, bryana.l.henderson@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology/NASA, Pasadena, United States Fred Bateman, fred.bateman@nist.gov

National Institute of Standards and Technology, Gaithersburg, Maryland, United States

Among the ocean-worlds targets, Europa has the most dynamic environment. Gravitational fluxing, radiation from Jovian magnetosphere, and potential subsurface ocean/mantle interface. It is important to understand surface properties and estimate their composition vs. physical properties for both remote sensing and in-situ missions to Europa. The Jovian magnetosphere consists of ions such as H+, O+, S+, and electrons at MeV energies. Electrons penetrate by far the deepest with estimates of a few centimeters to tens of centimeters on the trailing hemisphere of Europa, where electron energies up to 25 MeV are expected to reach the surface. Electrons with higher energy than 25 MeV would land on the leading hemisphere, though their flux drops exponentially [1]. In order to quantify this effect under realistic Europa trailing hemisphere conditions, we devised, built, tested, and obtained preliminary results using our ICE-HEART instrument. Our Ice Chamber for Europa High-Energy Electron And Radiation-Environment Testing (ICE-HEART) operates at 100 K. The telescopic chamber can accommodate ice cores up to 110 cm in length and diameters of 6 cm. We use a novel Halbach cylindrical mag- net to remove electrons allowing only X-rays to pass through, giving us unique opportunity to determine the role of secondary X-rays on Europa's near-surface habitability. Using this ICE-HEART instrument at the NIST Medical and Industrial Radiation Facility (MIRF), we conducted electron bombardment studies to simulate Europa's trailing hemisphere at electron energies between 10 MeV and 25 MeV. We determined surface hardness, electron-penetrating depths and secondary X-ray production, and coloration of both pure ice and hydrated salts of NaCl and MgSO4. Our preliminary results show that NaCl and MgSO4-containing ices that are thought to be relevant to Europa [2] show different hardness changes as well as secondary X-ray yields compared to pure water ice. Results from these studies will be presented and the relevance to the Europa lander mission concept will be discussed.

B5.3-0018-18 SALINIBACTER RUBER, A MODEL TO STUDY THE HABITABILITY OF EUROPA'S OCEAN

María Cristina Cardona, maria.cardona@uaem.mx

Universidad Autónoma del Estado de Morelos, Cuernavaca, Mexico Sandra Ignacia Ramírez Jiménez, ramirez_sandra@uaem.mx Universidad Autónoma del Estado de Morelos, Cuernavaca, Mexico

Life on Earth can develop in environments considered extremes when compared to the conditions in which most of life forms on Earth develops. The organisms that proliferate in these environments are called extremophiles. As some of the extreme environments possess conditions like those described for some bodies of astrobiological interest in the solar system, the organisms that thrive in extreme environments are then a good model to understand the limits of terrestrial life when they are exposed to those conditions [1]. Of our interest is Europa, one of the satellites of Jupiter. With temperatures between 50 and 125 K, a thin atmosphere composed mostly of molecular oxygen (O2), and a vast liquid water ocean found under its icy surface and enriched with sulfated salts like MgSO4 and Na2SO4, it is one of the places where habitability conditions can be evaluated [2][3].

We take Salinibacter ruber as our biological model to study the adaptation strategies of halophilic organisms when exposed to sulfated salts. S. ruber is an extreme halophilic bacterium whose growth and adaptation to different concentrations of NaCl and MgSO4 have been previously studied in our group [4]. Now, it was exposed to different concentrations of MgSO4and Na2SO4. Growth curves were used to determine the optimal growth concentration on each salt condition, the growth rate, and the duplication time. The presence of compatible solutes was evaluated by quantitative NMR, and the expression of proteins in different saline stress conditions was identified by electrophoresis and shotgun proteomics.

The experimental evidences will be used to propose arguments about the habitability of the salty ocean of the satellite Europa, and about the tolerance and adaptation strategies that can be used by this or other halophiles in an extraterrestrial scenario.

We investigate the geologic history of Titan through mapping and analyzing the distribution of observed geomorphologic features using a combination of Cassini data collected by RADAR, VIMS (Visual and Infrared Mapping Spectrometer), and ISS (Imaging Science Subsystem). Determining the spatial and superposition relations between geomorphologic units on Titan leads to an understanding of the likely time evolution of the landscape and gives insight into the process interactions that drove its geologic history. We have used all available datasets to extend the mapping initially done by Lopes et al. (2010, Icarus, 205) and Birch et al. (2017, Icarus, 282) to a global map at 1:800,000 scale in all areas covered by the RADAR Synthetic Aperture Radar (SAR). We show how we are extending the map to regions not covered by SAR, to produce a 1:1,500,000 scale map compatible with USGS standards. We use the map to infer the stratigraphic relations among Titan's different terrain types, which in turn allows us to establish the sequence of geologic processes that have shaped the satellite's surface.

Continuing the initial work described in Lopes et al. (2010, Icarus, 205) and the detailed mapping of the Afekan region by Malaska et al. (2016, Icarus, 270) and of the polar regions by Birch et al. (2017, Icarus 282), we have established the major geomorphologic unit classes on Titan. These broad classes are: hummocky/mountainous terrains, labyrinth terrains, dunes, plains, craters, and lakes. We have also mapped individual features such as craters, channels nd their deposits, and candidate cryovolcanic features. We have found that the hummocky/mountainous terrains are the oldest units on the surface and appear radiometrically cold, indicating icy materials (Janssen et al., 2016, Icarus, 270). The labyrinth terrains consist of highly incised dissected plateaux with medium radar backscatter and appear radiometrically warm, indicating organic materials. Dunes are the youngest units and appear radiometrically warm, indicating organic sediments (Janssen et al., 2016, Icarus 270). The plains are younger than both the mountainous/hummocky and the labyrinth unit classes. Undifferentiated Plains form the most widespread unit on Titan and are interpreted as aeolian deposits that also appear radiometrically warm (Lopes et al. 2016, Icarus 270). Dunes and lakes are the youngest unit classes on Titan; it is likely that the processes forming them are still active. Characterization and comparison of the properties of the unit classes and the individual features with data from radiometry, ISS, and VIMS provide information on their composition and possible provenance. VIMS analysis shows that compositional variations can also exist within the same class of unit (Solomonidou et al. 2016, Icarus, 270). For example, undifferentiated plains located closer to the equatorial dunes appear to be contaminated by dune materials. The correlations among the data sets not only aid in the interpretation of their origin, but also allow us to infer global distributions within regions not covered by SAR. This is particularly important as SAR data did not provide complete coverage of Titan during the Cassini mission.

B5.3-0020-18 IMPROVED RETRIEVAL OF TITAN SURFACE TOPOGRAPHY FROM THE DELAY-DOPPLER ALGORITHM APPLIED TO CASSINI RADAR ALTIMETER DATA

During its 13 years of activity the Cassini RADAR altimeter acquired 40 elevation profiles of Titan, Saturn's largest moon. Due to flyby geometry the spacecraft operated at various altitudes, providing broad-scale surface topography measurements. We applied the delay/Doppler algorithm to the radar altimeter data products, adapting it to the specific orbital geometry conditions of the Cassini spacecraft. We present results obtained for the observations of different terrain units, such as dunes, hummocks and mountains. We show that the coherent processing combined with multi-look of Doppler filters, can permit up to tenfold improvement of the along-track resolution and a remarkable radiometric enhancement respect to the standard products.

B5.3-0021-18 TITAN'S INTERIOR STRUCTURE FROM THE COMBINED ANALYSIS OF CASSINI GRAVITY AND TOPOGRAPHIC DATA

Although Titan is best known for its dense atmosphere and hydrocarbon seas and lakes, it is also an ocean world with a deep water ocean like Europa and Enceladus. One major difference is that this ocean may be sandwiched between the icy crust and a high-pressure ice layer, thus limiting the transfer between the silicate core and the atmosphere. This study uses the recently released shape data [1] to interpret the values of the degree 2 gravity coefficients that have been published [2, 3]. The shape data are transformed into topographic data by using a reference ellipsoid defined by the degree 2 gravity coefficients [2]. The difference between the topography using the reference ellipsoid and the topography relative to an equipotential defined with the higher degree gravity field [3] is equal to 25 m at max, which is less than the uncertainty on the measurements. Titan's long wavelength topography is characterized by polar depressions and elevated equatorial regions that strongly influence interpretations of the gravity data. Several geodynamic models can explain these topographic features: variations of the crustal thickness related to the amount of tidal dissipation inside the crust [4], latitudinal variations of the heat flux at the crust/ocean interface [5], or lateral density variations between the poles and the equatorial regions [6]. The models are explored with different degrees of compensation to investigate the effect of topographic anomalies on the values of the degree 2 gravity coefficients determined from Cassini spacecraft orbit. For each model, the three moments of inertia are computed numerically by discretizing Titan's interior in spherical coordinates and then the degree 2 gravity coefficients are deduced. The simplest model is a fully compensated Pratt model for the polar depressions and fully compensated Airy model for the equatorial topography. However, if the equatorial topography is not compensated because the icy crust is strong enough to prevent compensation, then the degree 2 gravity coefficients can be explained by a 80% compensation Pratt model (or 75% compensation Airy model) for the polar depressions. Although non-unique, the crustal model is bounded by the values of the gravity coefficients and topographic data provided by the Cassini mission. These two models imply very different interior structure. The fully compensated model suggests that Titan's ocean has been in contact with the silicate core in the recent past, providing an environment similar to the terrestrial sea floor.

This work has been performed at the Jet Propulsion Laboratory, California Institute of Technology, under contract to NASA.

We investigate the spectral and microwave properties of the raised rims of five liquid-filled Sharp Edged Depressions (SEDs) [e.g. 1;2;3] in Titan's North pole using both Cassini Visual and Infrared Mapping Spectrometer (VIMS) and RADAR data. The raised rims under investigation have been detected by RADAR stereogrammetry; they are a few hundreds of meters in height, a few kilometers wide, and in some cases, only partially surround the liquid-filled basin. Dedicated methods have been developed to extract their infrared spectra from a high-resolution VIMS cube [4;5] and their 2.2-cm emissivity from RADAR radiometry observations [6;7]. Comparison of the evaluated properties from the SEDs' terrains to that of other Titan regions of interest from all around the globe provide insights into the formation mechanisms of the elevated ramparts around Titan's SEDs. In particular, the emissivity of the considered raised rims is very close to that of the labyrinthic terrains and of the bottom of empty lakes. This suggests that the composition of the raised rims is most likely dominated by organics (rather than water ice). This is supported by the VIMS analyses that show spectral responses close to that of tholinlike materials and is consistent with of the hypothesis of a karst case-hardening post-deflation remnant hypothesis [8]. Titan, the largest moon of Saturn, is considered a prebiotic chemical laboratory on a planetary scale. Photochemistry in the atmosphere induced by solar radiation and energy from Saturn's magnetosphere causes a chemical cascade, as N2 and CH4 dissociate and generate organic molecules ranging from simple (ethane, acetylene, HCN) to complex (>10,000 Da). Most of these molecules are transported down to the surface, where they may react and interact as they become integrated into the unique geology of Titan. We have demonstrated in previous work that two common organic molecules on Titan, ethane and benzene, form a stable co-crystalline structure at Titan surface temperatures. This co-crystal represents an exciting new class of compounds for Titan's surface, which would fill the role equivalent to a hydrated mineral in this environment.

The discovery of one Titan organic mineral has led us to search for others. We have recently characterized several possible minerals incorporating acetylene, one of the primary solid photochemical products generated in Titan's atmosphere. These co-crystals - the acetylene series form spontaneously and are stable under Titan surface conditions. The acetylene-ammonia co-crystal, for example, is robust against exposure to pluvial (rain) events of methane, ethane or propane.

We are now investigating the HCN series. Hydrogen cyanide (HCN) may be even more abundant than acetylene on the surface of Titan. Preliminary evidence indicates that HCN associates with ethane and acetylene at 90 K, although the red and blue shifts observed in the Raman (up to 6 cm−1) are not quite as large as the shifts observed for the other co-crystal series involving benzene (up to 12 cm−1) and acetylene (up to 66 cm−1). This may be due to weaker associations between the species. We are exploring interactions of HCN with other hydrocarbons to better elucidate this relationship.

B5.3-0024-18 ON THE CARBON ISOTOPE RATIO IN TITAN'S ATMOSPHERE AND INTERIOR

Vladimir Krasnopolsky, vlad.krasn@verizon.net

Moscow Institute of Physics and Technology, Moscow, Russia

To study the evolution of carbon isotopes in Titan's atmosphere, the methane isotope ratio 12C/13C = 89.7 ± 1.0 (Nixon et al. 2012) should be compared with those in the haze precipitating to the surface and in sputtering and ion escape. The former is calculated at 12C/13C

= 88.3 ± 3.0 using the observed carbon isotope ratios in the photochemical products (hydrocarbons, nitriles, and oxides) and their column rates of condensation and polymerization from the photochemical model by Krasnopolsky (2014). Correction for sputtering and ion escape results in 12C/13C = 88.5 ± 3.0 as the final value for the total loss of carbon. If the current loss of methane of 7 kg cm−2 Byr−1 is replenished by outgassing of methane clathrate hydrate

CH4*5.75H2O, then this source should have 12C/13C equal to the above value. It is smaller but within the uncertainties of 12C/13C = 92.4 ± 5.4 in the outer Solar System and 89.4 on the Earth. The difference is even greater for a scenario with injection of methane into Titan's atmosphere and its gradual depletion to the present abundance.

Saturn's icy moon Enceladus harbors a global subsurface ocean, which is thickest (50 km) below the south polar region. There, through warm fractures in the less than 5 km thick ice crust, jets of vapor and nanometer to micrometer-sized ice grains emerge from the ocean into space. Two mass spectrometers aboard the Cassini spacecraft frequently carried out compositional in situ measurements of material emerging from the subsurface of Enceladus. These measurements were made inside both the plume and the E ring. The Cosmic Dust Analyser (CDA) showed that a large fraction of the ice grains are direct samples of subsurface alkaline ocean water with mild salinity. The CDA also uncovered the first evidence of hydrothermal activity taking place at the interface of the moon's rocky core and its ocean. The detection of molecular hydrogen in the plume by the Ion and Neutral Mass Spectrometer (INMS) provided further support for fluid-rock interactions, most consistent with exothermic serpentinization reactions, similar to certain alkaline hydrothermal systems of Earth's oceans, such as Lost City in the Atlantic Ocean. Because of the relatively low density (2500 kg/m3) of the moon's core it is likely porous and percolated by ocean water. Hydrothermal reactions thus probably take place deep inside the core and are likely powered by tidal dissipation.

Previous CDA and INMS measurements showed that the plume emits organic material of low molecular weight both, in the gas phase and in about 25% of the ice grains, so-called Type 2 grains but complex organics emerging from Enceladus oceans have not been reported before. Here we will present spectra of emitted ice grains containing concentrated, macromolecular organic material with molecular masses above 200u. The data provides key constraints on the macromolecular structure and is suggestive of thin a organic-rich film on top of the oceanic water table. We suggest a large-scale ocean convection mechanism that, together with bubbles of volatile gases, transports these and other materials from the moon's core up to the ocean surface and ultimately, by dispersion from bubble bursting, into space.

NASA MSFC, Huntsville, Alabama, United States

The magnetic fields of Saturn and Jupiter intensify the radiation environment and yield high energy electrons which continually bombard the surface of their icy moons Enceladus and Europa. Polycyclic aromatic hydrocarbons (PAHs) are a class of organic molecules which have been identified in comets, meteorites, and interplanetary dust particles (IDPs). It is estimated that 30,000 tons of PAH containing IDPs fall on the Earth each year (Matrajt, et al. 2006). Given PAHs nearly ubiquitous presence within the Solar System and their in-fall onto Earth's surface, it is expected that PAH or aromatic molecules would be part of any organic inventory present within the ices of these moons. Recently we concluded preliminary experiments regarding the processing of solid state PAH thin films and water ice via proton, electron and UV irradiation. As identified by infrared spectroscopy, these experiments produced some very interesting results. This presentation will discuss the experimental results and their implications for the chemistry occurring on these icy bodies.

The analysis of icy satellites surfaces provides hints regarding their interiors, as well as their surface mechanical behavior. Indeed, faults distribution and fault populations on the icy satellite can reveal insights into the evolution of its surface that cannot be gained with other techniques. Statistical characterization of fault-population attributes, such as length and clustering, are fundamental means to explore deformation rates, stress transmission modes, rheology of the medium, and mechanical stratification [e.g. 1,2,3,4,5]. Fractal analysis has been used in terrestrial studies to determine the thickness of the fractured (brittle) crust [e.g., 6,7,2,8]. In the same fashion, on icy satellites we can constrain the depth at which fractures penetrate the brittle ice layer exploring some of the main characteristics of fault populations, such as length and clustering. A previous work [9] has validated the use of this technique on Enceladus fractures estimating the depth of the mechanical discontinuity of the ice shell in five different regions. Such discontinuity is the depth to which fractures penetrate the brittle ice layer above the ductile one [9]. In this work, we analyze the grooves' spatial distribution on the surface of Ganymede to provide an estimate of the thickness of the brittle icy crust. Grooves occupy the majority of light terrains and are organized in systems that crosscut or intersect with each other [10]. They are interpreted as extensional fractures and/or faults, whose origin is still debated. We mapped grooves in well-defined geological units, such as light grooved units, light irregular units and light subdued units, related to tectonic deformation, as reported in the Ganymede geological map provided by [10]. Preliminary results obtained in the area around Harpagia Sulcus (10°S, 40°E) demonstrate i) the prevalence of fractal populations of grooves and ii) a depth to which fracture penetrate the icy crust is about 90 km. These preliminary results will be investigated by extending the analysis also to other regions of Ganymede as well.

B5.3-0028-18 PRESENT AND FUTURE ACTIVE CENTRES OF ENCELADUS

Leszek Czechowski, lczecho@op.pl University of Warsaw, Warszawa, Poland

Enceladus is the smallest body in the Solar System where volcanic activity is observed. It is concentrated in the South Polar Terrain (SPT) where every second 200 kg is ejecting into space [1, 2, 3, 4, 5, 6]. The loss of matter from the interior should lead to global compression. However, compressive forms are not dominant on Enceladus. [6, 7] proposed tectonic model that explains this paradox.

The loss of the volatiles results in a void and motion to fill the void in statu nascendi as: (i) subsidence of SPT, (ii) flow of the matter in the mantle, (iii) motion of plates towards SPT. If emerging void is being filled by the subsidence of SPT only, then the velocity of subsidence is mmyr-1 [6, 7]. Note that the reduction of the satellite area is not a result of compression but it is a result of the plate sinking.

[7] presents experimental model of SPT subsidence in viscoelastic material. He found that contrary to expectations, the 'kinks' (formed above vertices of plate) appear to be stable features.

We improve numerical model of [7] of suggested processes. The results indicate the subsidence rate of 0.04 mmyr-1 for Newtonian rheology. For non-Newtonian rheology the rate could be lower. If thermal convection is included the results are more complicated, the adjacent plates to move into or out of the SPT.

There are some traces that could be attributed to past active centers similar to STP. Moreover, the ovoid-shaped depression down to 2 km deep, of size 200×140 km with the center at 200E, 15S is a good candidate for the future center of activity [6, 7]. The depression could indicate the partial melting of the mantle. It could lead to an increase of heating and formation of the center of activity. More realistic calculations of distribution of tidal heating are necessary to achieve better understanding of the present and future activity of Enceladus.

B5.3-0029-18 FIRST TECTONIC STRESS MAP ACROSS ENCELADUS' SPT AND POSSIBLE DYNAMIC CAUSES

Ashley Schoenfeld, ashleyschoenfeld@gmail.com

University of California, Los Angeles, Los Angeles, California, United States An Yin, yin@epss.ucla.edu

University of California, Los Angeles, Los Angeles, California, United States

Enceladus is a small moon of Saturn (radius 250 km), distinguished by its uniquely active south pole. The moon's geological activity is expressed as regularly erupting plumes sourced from a series of parallel "tiger-stripe" fractures (TSF) (Porco et al., 2006). The cyclic nature of these eruptions are attributed to diurnal variations of tidal stress (Hurford et al., 2007). There is, however, a mismatch in timing between Cassini's observations of peak eruption and what is predicted by the theory of tidally modulated cracks (Nimmo et al., 2014). Existing models have attempted to reconcile the plume timing discrepancy by invoking stress relaxation in a viscoelastic ice sell (Běhounková et al., 2015). However, such an approach assumes the stress in the ice shell to be entirely induced by tidal stress, neglecting the role tectonically induced stress play in order to support the high (>1 km) topographic relief around the moon's south pole (Schenk and McKinnon, 2009). We propose to address this by relaxing the assumption of a tectonic stress-free ice shell and offering an analytical tensor analysis decomposing tidal and tectonic stresses in the ice shell. We thus investigate the total stress as a result of three sources: tidal stress from a bulged figure, stress induced by physical libration (Hurford et al., 2009), and tectonic stress. With the aforementioned framework, we derive the magnitude and direction of tectonic stress at numerous points along the active TSFs, resulting in a comprehensive tectonic stress map of Enceladus' South Polar Terrain (SPT). We find tectonically derived stresses to be non-trivial; while these results are perhaps not surprising, the need for a more comprehensive plume eruption model, one that includes both tidal and tectonic stresses in its mathematical framework, is evident. We posit that perhaps the fundamental question of eruption timing may lie in cultivating this understanding.

B5.3-0030-18 THE INTERIOR OF ENCELADUS JUST AFTER CASSINI

Charles University, Prague CZ, Prague, Czech Republic

While the observation of a large-scale plume emitted by Enceladus occurred early after the insertion of the Cassini spacecraft around Saturn, a coherent view on the interior processes that power and feed this activity started emerging only in the latest year of the mission. Thanks to a flexible payload as well as multiple flybys during the extended mission, analyses of Enceladus data (composition of materials originating from the moon's interior, geophysical measurements and long series of surface images) composed a view where a global salty ocean is present underneath an ice crust of very uneven thickness (20-25 km in average, less than 5 km beneath the south pole, more than 30 km in some equatorial regions). Density of the rock core implies a significant (water-filled) porosity. Furthermore, several independent chemical clues indicate that high-temperature (>363 K) hydrothermal processes probably occur at present, deep in the moon.

In this presentation, we show that tidal deformation within a rock core filled with interstitial liquid water can produce a sufficient amount of heat to enable the persistence of a global ocean, for at least tens of Myr. Thermal convection of interstitial water within the tidally heated core leads to strongly focused hot upwellings, especially beneath the poles. Modeled temperatures agree with the range inferred from compositional measurements by Cassini that indicate waterrock interaction and might be detected in the gravity data. Powerful hotspots (several GW) are thus predicted at the seafloor. While ocean dynamics partly filter this strongly heterogeneous heat flux at the seafloor, our models demonstrate that heat supply to the base of the ice shell is expected to be largest in regions coinciding with the lowest ice thickness - the transport time of organic products by ocean thermal vents would match the constraints derived from Cassini measurements (typically a few months).

JUICE - JUpiter ICy moons Explorer - is the first large mission in the ESA Cosmic Vision programme. Due to launch in May 2022 and arrival at Jupiter in October 2029, it will make detailed observations of the Jovian system, with a special focus on the planet itself, its giant magnetosphere, and the three icy moons: Ganymede, Callisto and Europa. The current mission baseline assumes a Jupiter tour of almost three years including two close flybys of Europa, fifteen flybys of Ganymede, and twelve flybys of Callisto, together with a high inclination phase of six months in order to characterize Jupiter high latitudes. In August 2032, JUICE will then orbit Ganymede for at least ten months, down to an altitude of 500km. The first goal of JUICE is to to characterize the conditions that might have led to the emergence of habitable environments among the Jovian satellites. Ganymede is a high-priority target as it provides a unique laboratory for analyzing the nature, evolution and habitability of icy worlds, including the characteristics of subsurface oceans, and its unique magnetosphere interaction with the Jovian magnetodisc. For Europa, the focus will be on recently active zones, while Callisto will be explored as a witness of the early Solar System. JUICE will also investigate the Jupiter system as an archetype of gas giants. The circulation, meteorology, chemistry and structure of the Jovian atmosphere will be studied from the cloud tops to the thermosphere and ionosphere. JUICE will also study the properties of the magnetodisc, and will analyse the coupling processes within the magnetosphere, ionosphere and thermosphere. The payload consists of 10 instruments plus a ground-based experiment (PRIDE) to better constrain the S/C position. A remote sensing package includes imaging (JANUS) and spectral-imaging capabilities from the UV to the sub-mm wavelengths (UVS, MAJIS, SWI). A geophysical package consists of a laser altimeter (GALA) and a radar sounder (RIME) for exploring the moons, and a radio science experiment (3GM) to sound the atmospheres and to determine the gravity fields. The in-situ package comprises a suite to study plasma and neutral gas environments (PEP) with remote sensing capabilities via energetic neutrals, a magnetometer (J-MAG) and a radio and plasma wave instrument (RPWI).

B5.3-0032-18 ADDRESSING THE HABITABILITY OF EUROPA WITH THE EUROPA CLIPPER MISSION

Haje Korth, haje.korth@jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, Maryland, United States

Robert Pappalardo, robert.pappalardo@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

David Senske, david.senske@jpl.nasa.gov JPL, Pasadena, California, United States

The ice-covered world Europa, one of the four large Galilean satellites, may be a habitable world. Europa is about the same size as Earth's Moon and is mostly rock, with an outer icerich shell that is quite dynamic. Its young, bright, icy landscape is crisscrossed by a network of cracks and ridges, interrupted by smooth bands, disrupted chaotic terrain, and exhibits few large craters. Several lines of scientific evidence, which include observations of gravity and induced magnetic fields as well as results from thermal modeling of the moon's interior, point to the conclusion that Europa likely has a global ocean of water under the ice, maintained in liquid form by tidal flexing and heating as the moon moves in its eccentric orbit about Jupiter. The orbital eccentricity is maintained by gravitational resonances with the other Galilean moons and is likely long-lived. While the presence of the ocean is compelling, it is unknown whether Europa is for certain habitable. Thus, investigation of Europa is a top priority for planetary exploration.

The science goal of NASA's Europa Clipper mission is: Explore Europa to investigate its habitability. The mission's three objectives are focused on Europa's ice shell and ocean, composition, and geology. To achieve the mission's science goal and objectives, the spacecraft will conduct more than 40 flybys of Europa with closest approach altitudes in the range of 25-100 km, with a capable suite of nine remote sensing and in situ instruments plus gravity science. During the time period near closest approach, the remote sensing instruments are in a nadir-looking orientation, the fields of view of the particle sensors encompass the Keplerian ram direction, and supplemental antennas enable gravity science. In this configuration, the entire payload can collect data simultaneously during the flybys. The anticipated observations will facilitate the search for subsurface water, chemistry compatible with habitability, and active geological processes. In studying Europa in depth, the Europa Clipper mission, currently in Phase B, will enable a leap in scientific understanding of ocean worlds and their potential habitability.

B5.3-0033-18 THE EUROPA LANDER MISSION CONCEPT AND SCIENCE GOALS OF THE 2016 EUROPA LANDER SCIENCE DEFINITION TEAM REPORT

Kevin Hand, khand.stuff@gmail.com

Jet Propulsion Laboratory, Los Angeles, California, United States

In June of 2016 NASA convened a 21-person team of scientists to establish the science goals, objectives, investigations, measurement requirements, and model payload of a Europa lander mission concept. The Europa Lander Science Definition Team (SDT), following a charter from NASA HQ, refined these requirements into a viable Europa Lander mission concept, and published the Europa Lander Study 2016 report (Europa Lander, 2016). Since the completion of the SDT report, the Europa Lander mission concept team at JPL has refined the mission concept through a Mission Concept Review (MCR), and subsequently through the advice and oversight of an external advisory board. This board was active during the Summer and Fall of 2017, and a final report was presented to NASA HQ in the late Fall of 2017. The Europa Lander mission concept team is currently addressing guidance from NASA HQ in terms of technologies and mission architecture. The science of the mission concept has remained largely constant with respect to the 2016 SDT Report.

Europa Lander SDT Science Goals The NASA HQ Europa Lander SDT Charter goals, in priority order, were as follows: 1. Search for evidence of life on Europa. 2. Assess the habitability of Europa via in situ techniques uniquely available to a lander mission. 3. Characterize surface and subsurface properties at the scale of the lander to support future exploration of Europa. Within Goal 1, the SDT developed four Objectives for seeking signs of life (i.e., biosignatures). These include the need to: a) detect and characterize any o ganic indicators of past or present life, b) identify and characterize morphological, textural, and other indicators of life, c) detect and characterize any inorganic indicators of past or present life, and d) determine the provenance of Lander-sampled material. Within the Goal 1 investigations and measurement requirements there are more than seven distinct and complementary approaches for detecting potential biosignatures within material sampled from Europa's surface and near-subsurface. Goal 2 focuses on Europa's habitability and ensures that even in the absence of the detection of any potential biosignatures, significant ocean world science is still achieved. The objectives within Goal 2 are to: a) characterize the non-ice composition of Europa's near-surface material and determine whether there are indicators of chemical disequilibria, and b) determine the proximity to liquid water and recently erupted materials at the lander's location. Goal 3 ensures that the landing site region is quantitatively characterized in the context needed for

Goals 1 and 2, and that key measurements about Europa's ice shell are made to enable future exploration. The objectives for Goal 3 include the need to: a) observe the properties of surface materials and sub-meter-scale landing hazards at the landing site, including the sampled area (connecting local properties with those seen from precursor Europa flyby remote sensing), and b) characterize dynamic processes on Europa's surface and ice shell over the mission duration to understand exogenous and endogenous effects on the physiochemical properties of surface and shallow sub-surface materials. The Europa Lander mission concept is capable of achieving a suite of measurements such that if potential biosignatures are present on Europa's surface they could be detected at levels comparable to those found in benchmark environments on Earth, and, further, that even if no potential biosignatures are detected, the science return of the mission will significantly advance our fundamental understanding of Europa's chemistry, geology, geophysics, and habitability.

B5.3-0034-18 CURRENT AND FUTURE EXPLORATION OF THE HABITABILITY POTENTIAL OF ICY MOONS AROUND GIANT PLANETS

Athena Coustenis, athena.coustenis@obspm.fr Paris Observatory, Meudon, France

Recent studies have demonstrated the habitability potential of the natural satellites of gas giants, which causes our thinking of the habitable zone to extend to the outskirts of the solar system. Several satellites around giant planets, Jupiter and Saturn in particular, show evidence of their harboring liquid water underneath the surface, organic chemistry in their atmospheres or exospheres, as well as energy sources. Measurements from the ground but also by the Voyager, Galileo and the Cassini spacecraft revealed the interest of these satellites in this context, and our understanding of habitability in the solar system and beyond can be greatly enhanced by investigating several of these bodies.

Indeed, several of the moons show promising conditions for habitability and the development and/or maintenance of life. Europa, Callisto and Ganymede are hiding, under their icy crust, undersurface liquid water oceans which, in the case of Europa, may be in direct contact with a silicate mantle floor and kept warm by tidally generated heat. Titan and Enceladus, Saturn's satellites, were found by the Cassini-Huygens mission to possess active organic chemistry with seasonal variations in their atmospheres, unique geological features and internal liquid water oceans. As revealed by Cassini, the liquid hydrocarbon lakes currently distributed mainly at polar latitudes on Titan are ideal isolated environments to look for biomarkers.

If the silicate mantles of Europa and Ganymede and the liquid sources of Titan and Enceladus are geologically active as on Earth, giving rise to the equivalent of hydrothermal systems, the simultaneous presence of water, geodynamic interactions, chemical energy sources and a diversity of key chemical elements may fulfil the basic conditions for habitability. These would be investigated with future space missions.

Indeed, after the discoveries by Cassini-Huygens at Saturn and Galileo at Jupiter, such potential habitats will be investigated with appropriate designed space missions in the future, like ESA's L1 JUICE and NASA's Europa Clipper mission. I will review our current knowledge of the habitable conditions around these moons and discuss future exploration, with a focus on the JUICE mission.

B5.3-0035-18 LABORATORY ANALOGUES FOR THE SURFACES OF JUPITER'S ICY MOONS

The surfaces of Jupiter's icy moons are continually irradiated by charged particles from the Jovian plasma environment. This irradiation triggers chemical reactions in the surface ice and also acts as an atmospheric release process. Remote observations, theoretical modelling, and laboratory experiments must be combined to understand this plasma-ice interaction.

Over the last years, we experimented with a wide variety of water ice samples, ranging from dense ice films (100 nm) on microbalances to thick (1 cm) and porous ice regolith. We subjected these ice samples to electron and ion irradiation and quantified the sputtering yields and other loss processes. Now we shift our attention to studying the chemical and physical alterations in ice samples upon long-term irradiation.

In this presentation, we will present first results of our recent and ongoing experimental work: We irradiate thick porous samples of water ice with an electron beam at energies representative of the Jovian plasma and monitor the sample with a camera in the visible and near-infrared spectral range.

B5.3-0036-18 COUPLED INTERIOR STRUCTURE AND EXTERIOR PLASMA MODELS OF EUROPA

Marshall Styczinski, mjstyczi@uw.edu

University of Washington, Seattle, Washington, United States

In the search for life elsewhere, Europa may be the top candidate. Remote sensing data suggest that beneath its icy shell lies a liquid water ocean, in contact with a rocky silicate mantle. Magnetic field measurements from the Galileo mission provide a strong confirmation that Europa has a subsurface ocean; an induced magnetic field is observed that implies a conducting layer consistent with salty water. However, Europa is immersed in a complex plasma environment that reacts to—and generates—its own magnetic fields, complicating any and all attempts to model Europa's magnetic induction. Past studies of Europa's ocean structure have applied simplified models for Europa's interior, or incomplete models of the surrounding plasma environment.

In this work, we simulate Europa's magnetic interactions with coupled models for both the interior and exterior, to better understand how ocean structure affects Europa's magnetic induction signature. We apply a 1D thermodynamic model for the interior of Europa, generated by PlanetProfile, to obtain realistic geophysical parameters such as electrical conductivity. These parameters form inputs to 3D global multifluid simulations of Europa's induction and plasma environment. The resulting coupled model has strong explanatory power, through self-consistent modeling of plasma behavior over many scale ranges, flexible representation of interior conducting layers, and more accurate accounting of planetary and upstream plasma conditions.

A detailed description of our coupled model, initial results, and plans for its use will be presented.

B5.3-0037-18 UNDERSTANDING EUROPA'S SURFACE TEXTURE FROM REMOTE SENSING PHOTOPOLARIMETRY

Robert M. Nelson, rnelson@psi.edu

Planetary Science Institute, Pasadena, California, United States Mark Boryta, mboryta@mtsac.edu

Mount San Antonio College, Walnut, California, United States Bruce W. Hapke, hapke@pitt.edu

California State Polytechnic University, Pomona, Pomona, California, United States

We use a Goniometric Photopolarimeter (GPP) to measure reflectance and polarization phase curves of the light reflected from particulate materials that simulate planetary regoliths. We compare these laboratory results to astronomical remote sensing observations in an effort to understand the chemical and textural state of an object's surface. Our GPP methodology employs the Helmholtz Reciprocity Principle (1, 2): the incident light is linearly polarized, and the intensity of the reflected component is measured. With this technique, the light encounters fewer optical surfaces, improving signal-to-noise. The Helmholtz Reciprocity Principle holds that these lab measurements are physically equivalent to the astronomical measurements. Here we present our new and improved reflectance and polarization phase curves of highly reflective, fine-grained, media that simulate the regolith of Jupiter's satellite Europa. We previously reported that these materials exhibit an increase in circular polarization ratio with decreasing phase angle; this suggests coherent backscattering (CB) of photons in the medium (3). Our new laboratory data exhibit reflectance and polarization phase curves that are remarkably similar to published astronomical results (4), and also to measurements reported from other GPP laboratories; e.g., Shkuratov et al. report that the polarization properties of these particulate media are also consistent with the CB enhancement process (5). The close match between our measurements (fine-grained and loosely packed, with void space exceeding 90%) and reported photopolarimetric measurements of Europa indicate that Europa's regolith may be similarly fine-grained and highly porous. We suggest that those who are developing lander vehicle concepts for Europa's surface might consider this evidence in their design. Furthermore, future spacecraft missions to the Jovian system will enhance science return by incorporating angular scattering measurements of the reflectance and polarization of the surface (6). This work supported by NASA's Cassini Science Office

B5.3-0038-18 A COMPREHENSIVE PICTURE OF CALLISTO'S MAGNETIC ENVIRONMENT DURING THE GALILEO ERA: IMPLICATIONS FOR JUICE

Lucas Liuzzo, lucas.liuzzo@eas.gatech.edu

Georgia Institute of Technology, Atlanta, Georgia, United States Sven Simon, sven.simon@eas.gatech.edu

Georgia Institute of Technology, Atlanta, Georgia, United States

We apply data analysis techniques and hybrid modeling to study Callisto's interaction with Jupiter's magnetosphere. Magnetometer data from the C3 and C9 Galileo flybys had been explained with a pure induction model, as the plasma interaction was weak. We expand this analysis to include the remaining five flybys (C10, C21, C22, C23, C30) where the plasma interaction was non-negligible. We therefore consider contributions to Callisto's magnetic environment generated by induction as well as the plasma interaction. We have identified a quasidipolar "core region" near Callisto's wakeside surface, dominated by induction and partially shielded from the plasma interaction. Outside of this region, Callisto's magnetic environment is characterized by field line draping. Future flybys during the upcoming JUICE mission may sample the wakeside "core region" to better constrain the conductivity, thickness, and depth of Callisto's subsurface ocean. Our analysis also shows that even during a single flyby, various non-stationarities in the upstream environment may be present near Callisto, which may partially obscure the magnetic signature of the moon's subsurface ocean. Overall, our study provides a complete three-dimensional picture of Callisto's magnetic environment during the Galileo era, based on all available magnetometer data from the Galileo flybys. We apply our understanding to the future JUICE flybys of Callisto to determine which encounters will be best to identify Callisto's inductive response in magnetometer data.

Investigation of Europa's icy crust from the ocean to its surface and atmosphere is a programmatic goal for the Europa Space Agency (ESA) and the National Aeronautics and Space Administration (NASA), achieved through the future JUpiter ICy moons Explorer (JUICE) and Europa Clipper missions, respectively. The ability to directly probe the subsurface makes radar sounders key instruments of those two missions for ice-ocean detection down to down to several to tens of kilometers deep, sampling the macro-structure and composition of the ice crust. However, radar sounder performance can be degraded by planetary ionospheres along the signal propagation path, affecting the nominal radar vertical resolution and signal-to-noise ratio. Typical vertical profiles of Europa's ionosphere, as measured by Galileo by occultation, can impact the 9-MHz channel of the Radar for Icy Moons Exploration

(RIME, onboard JUICE) and the Radar for Europa Assessment and Sounding: Ocean to Near-surface (REASON, onboard Europa Clipper) investigations. We review the current state of knowledge of the Europan plasma environment, its effects on radio wave propagation, and its impact on the performance and design of future radar sounders for the exploration of Europa's ice crust. The severity of these impacts decrease with increasing center frequency and increase with altitude, latitude, and bandwidth. We also explain strategies to correct these impacts based on the extensive heritage from the Mars Advanced Radar for Subsurface and Ionosphere Sounding (MARSIS) and the Shallow Radar (SHARAD) at Mars. Ionosphere correction will be a part of REASON's data processing, providing a Total Electron Content (TEC) data-product for characterization of the Europan plasma environment. Observations from the Hubble Space Telescope reported transient ultraviolet emissions from Europa's exosphere consistent with 200-km high plumes of water vapor venting upward materials from the sub-surface. Plume activity adds neutrals in the exosphere that can in turn be ionized by the incident Jovian magnetospheric flow, creating a plume-induced ionosphere as shown at Enceladus with the Cassini Spacecraft. TEC measured by REASON will address Europa Clipper's plume-search objectives by detecting localized plume-induced plasma-clouds under the spacecraft.

B5.3-0041-18 CANYONS ON TITAN: NEW INSIGHTS BY THE CASSINI RADAR ALTIMETER

Cornell University, Ithaca, New York, United States

The Cassini radar altimeter observed for the first time features similar to the liquid filled canyons already detected at Vid Flumina during the flyby T91. Herein, we present the analysis of data acquired during the fly-bys T49, and T108, and then processed to improve the radar resolution. We show that the altimeter detected liquid filled canyons, which can be seen in SAR images to connect to Ontario Lacus (T49) and Punga Mare (T108). We retrieved a topographic profile over these features, and performed quantitative measurements of backscattering behavior, showing that they are indeed liquid filled. Another tentative feature was observed in T126, where it too resembles a canyon-like feature. Further quantitative work is underway to more fully understand this putative feature.

B5.3-0042-18 GLOBAL GEOMORPHOLOGY MAP OF TITAN: A LOOK AT THE NORTH AND SOUTH POLES

Ashley Schoenfeld, ashleyschoenfeld@gmail.com

University of California, Los Angeles, Los Angeles, California, United States Tiffany Verlander, tiffany.verlander@gmail.com

University of Oklahoma, Norman, Oklahoma, United States Rosaly Lopes, rosaly.m.lopes@jpl.nasa.gov

JPL, Pasadena, California, United States Michael Malaska, michael.j.malaska@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, United States Samuel Birch, sb2222@cornell.edu

Cornell University, Ithaca, New York, United States

We carried out detailed geomorphology mapping of Titan's north and south poles as part of our global mapping effort. We used radar data collected by Cassini's Synthetic Aperture Radar (SAR) as our basemap, supplemented by images from VIMS, ISS, SARtopo, and microwave emissivity datasets. We mapped at a scale of 1:800,000 in all areas of the poles covered by SAR swaths, taking into consideration the 300 m/pixel resolution of the swaths. We extend our terrain classification from previous mid-latitude mapping efforts (Malaska et al. 2016) to the poles and find that the definitions of our mapping units remain applicable. The terrain classes relevant to the poles are Basin and Lakes, Hummocky, Labyrinth, and Plains. In both the north and south poles, the Plains units dominate by area. This is also true of the mid-latitude regions (Lopes et al., 2016). However, the Basin and Lake units are the second most dominant terrain type in the north pole, while the Labyrinth units are the second most dominant unit in the south. We find our mapping of the polar regions correlate well with previous polar mapping efforts, including consistency between analogous mapping classifications (Birch et al., 2017). Plains unit designated "scalloped plains" (Malaska et al., 2016) and "dark irregular plains" (Hayes et al., 2008) are prominently featured between the 50°S and 60°S latitudes of Titan. We also note a higher occurrence of fluvial channels and alluvial fans starting at this latitude zone and extending poleward. We suggest that these features indicate the transition zone between mid-latitude/equatorial regions and the poles. The detailed mapping of Titan's poles presents a significant step towards the end goal of a global geomorphology map of Titan, offering a more comprehensive analysis of global geologic trends and stratigraphic relationships.

B5.3-0043-18 RETURNING TO TITAN: ASSESSING TITAN'S TRANSMISSION FOR FUTURE MISSIONS

Georgia Institute of Technology, Atlanta, Georgia, United States

We present in this work an analysis of the transmission of Titan's atmosphere as a function of altitude modelled using radiative transfer. We find that unless close to the surface the spectral shape of Titan's atmosphere changes very little.

Despite a decade's worth of observations and discoveries with Cassini, the composition of Titan's surface still remains elusive. This is because there are only a few narrow "windows" that are able to see through Titan's thick atmosphere to the surface, due to methane absorption and scattering off of Titan's complex hazes. Despite these limitations, there are still some constraints for Titan's surface composition, suggesting complex hydrocarbons, and CO¬2 and H2O ices, although the limited spectral coverage makes species identification difficult. An increased range in the spectral regions sensitive to the surface would not only vastly improve our knowledge of composition, but would inform studies of surface processes and photochemical production in the atmosphere (and subsequent deposition onto the surface). Further, detailed studies of the surface would constrain astrobiologically relevant chemistry in the atmosphere and on the surface (e.g. water-organic interactions).

We model Titan's atmosphere using the radiative transfer code, PyDISORT. This code uses profiles measured by the Huygens probe to simulate Titan's atmosphere and contains contributions from multiple scattering off of hazes, collision-induced absorptions, and variable compositions with altitude. To model Titan's methane

absorption, we use the k-coefficients derived from laboratory measurements and direct observations of Titan's atmosphere. This allows for the most complete spectral coverage to even shorter wavelengths where current absorption databases are incomplete. The code permits any number of species in the atmosphere, but for this work we remain limited to methane only.

To best align with potential future missions to Titan, we model the transmission of Titan's atmosphere at three different characteristic altitudes: from orbit, a balloon, or for a lander/aircraft, at 1500 km, 10 km, and 10 m respectively. We find significant broadening in the spectral windows with decreasing altitude, but only at altitudes less than 10 km. This is a result of the increased atmospheric density and methane abundance close to the surface. However, because incident solar radiation is absorbed quickly in Titan's upper atmosphere, an onboard lamp is required to access these additional spectral regions. However, even a modest lamp, comparable to a common 100-W incandescent lamp, is sufficient to provide an observable signal over all the broadened spectral regions at a distance of 10m, thus greatly increasing the spectral regions accessible to future surface missions.

The dense atmosphere, rich organic chemistry and surfaces of liquid hydrocarbons make Titan a particularly intriguing object among the ocean worlds. Accordingly, Titan is a prime destination for future missions aiming to assess the habitability of icy moons. Liquid methane and ethane form liquid deposits on the surface of Titan, detected and mapped by RADAR and VIMS instruments on Cassini. Our knowledge of their composition relies mainly on thermodynamic modeling and assumptions based on Cassini observations. Several thermodynamic models have been used to calculate the composition of lakes, and their results on even the major lake components (methane, ethane, propane and nitrogen) exhibit large discrepancies. The Titan Lakes Simulation System (TiLSS) is a cryogenic vacuum system designed and developed at JPL to produce and characterize liquid hydrocarbons in equilibrium with the gas phase. The setup consists of a large "bell jar" high vacuum chamber (10-6 torr) that contains a stainless steel Pressure Vessel. This Pressure Vessel plays the role of condenser for hydrocarbons. Temperatures relevant to Titan surface are reproduced using a closed-cycle helium cryostat and liquid nitrogen flowing through a cooling plate. Feedthroughs in the top flange of the pressure vessel allow the injection of gaseous N2 to pressurize the chamber to 1.5 bar and to introduce hydrocarbons into the condenser. To analyze the chemical composition of liquid hydrocarbons, a solenoid valve allows for sampling the liquid and sending it to a SRI Gas Chromatograph (GC). A separate line allows to measure the composition of the gas in the headspace with the SRI GC as well. Optical fiber probes were installed inside the

Pressure Vessel, permitting spectral measurements of the liquid in the infrared wavelength. We accomplished preliminary studies of condensed pure CH_4, pure C_2H_6 and 1:1 CH_4:C_2H_6 mixture, all under 1.5 bar of N_2. This work shows the higher solubility of N_2 in liquefied methane compared to ethane. The CH_4:C_2H_6 mixture experiment shows clearly the difference between the liquid and gas composition at 92 K and its evolution as the temperature increases up to 103K. Infrared spectra were collected for methane and ethane pure liquids. Combining Infrared and GC measurements on the same samples will allow the calibration of the optical fiber probe for quantitative measurements. The potential of this new system to enhance the science and technology related to investigating Titan lakes will be discussed in this presentation. Acknowledgements: This work has been conducted at the Jet Propulsion Laboratory, California Institute of Technology, under contract to NASA.

B5.3-0045-18 EXPERIMENTAL CHARACTERIZATION OF FINE-GRAINED WATER ICE PARTICLES: EVOLUTION OF PHOTOMETRIC AND POLARIMETRIC PHASE CURVES DUE TO GRAIN SINTERING. APPLICATIONS TO PLUME DEPOSITIONS ON ICY SATELLITES

Nicolas Thomas, nicolas.thomas@space.unibe.ch University of Bern, Bern, Switzerland

The discovery of cryovolcanism on Enceladus [1] and recent potential findings on Europa [2,3] lead to questions about the nature and the age of plume deposits under the harsh conditions in the outer Solar System. The composition, structure and surface deposition rates of the plume material are major questions. The depositions rate defines the surface age and corresponding timescales for morphological processes such thermal sintering or space weathering.

To characterize potential plume deposits at the surface of icy satellites remote sensing observations are necessary to achieve sufficient spatial resolution compared to ground-based observations. To make the transition from observation data to physical interpretation, the study of well characterized materials in the laboratory is an appropriate approach.

The application of standardized and reproducible sample production methods and protocols is key when using laboratory analogues to interpret remote sensing data. The Laboratory for Outflow Studies of Sublimating icy materials (LOSSy) has been developed for this purpose at the University of Bern since 2010. We are able produce three different types of spherical water ice particles with different grain size distributions in the micrometer size range.

We have previously shown in laboratory experiments that morphological changes by grain sintering have a substantial impact on the light scattering properties of granular water ice surfaces in the 450 to 1064nm spectral range at phase angles from

0 to 140° [4]. The opposition effect is reduced as particle shapes evolve from spherical to more irregular, further sintered particles tend to be more scattering in the forward direction.

More recently, we measured the polarimetric phase curves of the same water ice particles at 530 nm It has been shown that the degree of linear polarization as a function of phase angle is very sensitive to properties such as particle shape, grain size and frost deposition.

We will present a selection of these recent laboratory measurements of photometric and polarimetric phase curves of fresh and sintered ice particles and we will show how this dataset can help to characterize the surface activity/ages of icy satellites.

The fresh, clean ice that dominates Enceladus' surface makes it the most reflective surface of any Solar System body across a broad range of wavelengths, from visible to microwave. Fine-grained micron to tens of micron particles resulting from plume or E-ring deposition dominate optical wavelengths, enabling enhanced geometric albedo due to coherent backscatter. However, high albedo at centimetric radar wavelengths suggests scattering from characteristic spatial scales of millimetric or greater. To date, no single model of surface material structure has been proposed that can explain all the observed phenomena. We propose that sintering of fine particles during past periods of low or zero cryovolcanic activity may create subsurface layers that enhance radar backscatter sufficiently to explain the observations. The thickness of the upper, unsintered layer is likely at least 1-2 cm, and probably well under a meter. More modeling and laboratory work is required to test the validity of our assertion that sintering during quiescent periods of plume activity is responsible for the enhanced radar backscatter.

B5.3-0047-18 EXPLORATION OF PLUTO WITH A NEW-FRONTIERS-CLASS LANDER OR ORBITER MISSION

With water-ice mountains, expansive glaciers, possible cryovolcanism, and an extended Nitrogen atmosphere, Pluto is a dynamic world shrouded in mystery. Surface features aligned with Pluto's tidal axis suggest that it has a hidden subsurface ocean of liquid water. Pluto could be the most distant "Ocean World" in our solar system. The best way to unravel the mysteries of Pluto is to get as close as possible with a new mission to explore the surface and atmosphere.

A low-cost, New-Frontiers-class Pluto lander or orbiter mission with a launch in 2029, Jupiter gravity assist in 2030, and arrival at Pluto in 2040 is possible. The next opportunity for a similar mission will not be possible until a 2042 launch when Jupiter is again positioned for a gravity assist.

So how can we land on or orbit Pluto without several hundreds of millions of dollars in nuclear power sources, a next generation launch vehicle, or a massive propulsion system? One way is to launch a probe on a trajectory similar to the Jupiter flyby trajectory of New Horizons, target it for entry at Pluto at 14 km/s, and deploy a large inflatable drag device prior to entry at an altitude of 1600 km. The low density Pluto atmosphere has a scale height of 60 km, nearly 8 times larger than at Earth, enabling atmospheric drag to slowly dissipate the 50 gigajoules of kinetic energy of entry.

Only one Multi-Mission Radioisotope Thermoelectric Generator (MMRTG), currently in production by NASA, is needed to power onboard spacecraft systems. Depending on the trajectory and flight path angle, the probe can either descend to the surface and deliver a 200-kg landerhopper or insert an orbiter via aerocapture. We deem this architecture Entrycraft.

The preliminary results of a NASA Innovative Advanced Concepts (NIAC) study will be presented including the results of the interplanetary and approach mission design; structural, aeroelastic, aerothermodynamic, and thermal modeling; aerodecelerator and lander/hopper system design; and possible orbiter mission design efforts.

B5.3-0048-18 MAPPING OF SURFACE OF ENCELADUS THROUGH A ROBOTIC VEHICLE

The scarves for the satisfactory settlement with all knowledge and experience in terms of life made human's to reach beyond the earth's orbit and the idea with advancement made in technology results proves it true creating several milestones of innovation lead by great ideas. These remarkable milestones give a glimpse of every innovation and brilliant approaches have done so far. In the present world, the idea for reaching moon, planets or stars is the current need for the advancement of human civilization. In fact, various studies have been done even for the terrestrial bodies some light years away, and of Enceladus by Cassini. For every revolutionary idea, all we need is to remember and learn from the past experience, applying it to present scenario keeping in mind for future outcomes and every possibility that can be think of. This approach of study Enceladus is all about to search for the hydra-characteristics on the moon of ring planet, Saturn, of our solar system, believing to have a rough center blended with water ice and a solidified mantle. In addition of the research and developing with the goals of safety, affordability, and sustainability, the proposed aerial rover's goal is ambitious including the mapping and collection of samples from the icy surface that a future mission could potentially give deep information and from that point, it will develop into the most capable dispatch unmanned vehicle at any point flown by means of a developmental approach that will give building pieces to future space investigation on Enceladus. Enceladus is a to a great extent frigid world with some level of its mass being silicates. Depending on the instrument, the target material can include things like icy plume materials, the cause of volcanic actions. It recommends a few insights for the fluid water sea under the surface. From studies, Enceladus is believed to be warmed from inside by either radioactive warming or tidal flexing as Saturn's huge gravity pulls on the moon. Likewise, with Europa at Jupiter, researchers speculate that Enceladus could be a tenable world for a few types of life. There is no confirmation of life there, however, future missions could test forever signs.

B5.3-0049-18 AN ARCHITECTURE FOR ACCESSING EUROPA'S OCEAN

The icy moon oceans beckon with ingredients that potentially may harbor extant life. Beginning with the Galileo and Cassini missions, measurements have revealed the presence of global oceans under the icy crust of several moons of Jupiter and Saturn. Among those moons, Europa and Enceladus have their ocean in contact with the rocky core, providing an environment similar to the conditions existing on the terrestrial sea-floor where life has developed at hydrothermal vents. Accessing these oceans presents considerable difficulty due to a number of issues including the depth and composition of the icy crust, the time needed to travel through the crust, the power needed to propel a probe, communication of scientific and engineering data though the ice and back to earth, entry and mobility in the ocean and autonomous operations for the life of the mission.

A detailed trade space study was conducted to develop a technology architecture defining a system that would access an icy moon's ocean. To specifically bound the architecture, Jupiter's moon Europa was chosen as the target body. The current understanding of the scientific properties of the ice crust and ocean was used to guide the development. A strawman scientific payload was devised to further develop a baseline set of requirements. Beginning with a launch and trajectory that can bring a system to Europa's orbit, a complete trade space was developed outlining the engineering systems needed to access the ocean. The launch system and trajectory provided a bound for the amount of mass that would be available to Europa's surface. The architecture was divided into specific phases for i) deorbit, descent and landing, ii) surface operations, iii) ice descent and iv) ocean access. The needed functions for each phase were then identified with potential options for each sub-system evaluated. The technical maturity of each of these sub-systems was assessed for systems that could be developed to a maturity ready for a preliminary design in 5-10 years. Integrated system parameters on power, communication capacity, and mass were developed to further define the overall system. To constrain the design, a total time in the ice, from the ice crust surface to accessing the ocean was limited to two years, and 10Km of ice was baselined with a temperature profile through the ice estimated from the scientific literature.

The results of this architecture will be presented in the paper. A complete system has been defined for a system that can access the ocean after two years of travel through the baseline 10Km of ice. Models with a range of fidelity are being developed to bring additional prediction to the effort. A description of testbeds that can validate the models as well as provide experimental validation of subsystems will be described. The trade space and key technology needs will be reported.

B5.3-0050-18 UNDER-ICE COMMUNICATION SYSTEM FOR EUROPA EXPLORATION MISSION

Sameer Hasan, sameerhad12@gmail.com Aligarh Muslim University, Aligarh, India Abhinandan Jain, abyjain007@gmail.com

Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

Jupiter's moon Europa is one of the best site in our solar system to explore the habitable zone beyond earth. Some ideas came in the past years for the exploration of this Jovian moon like the cryobot, VALKYRI etc. But for the exploration purpose there are many problems such as effective drilling technology for penetrating such deep ice crust and the development of smart instruments that will work even in such cold environment. Besides that communication from the bottom sea to the top surface lander is also a major problem. In this work a concept about the communication system between the ocean and surface of the moon is demonstrated. Using wireless Ice embedded transceivers for the complete communication link would involve much complexity, effect of radiation, low data transfer due to large number of nodes and interference. As expected the surface temperature of Europa is the order of -170C while the sub surface temperature at ice and ocean link is nearly -0C. The thermal gradient throughout enables the use of this heat power as the primary power source of the embedded transceivers. A number of pairs of transceivers spread into the ice which will offer various advantages as compared to fully wireless link, in each pair one transceiver is connected to other with a one kilometer long conductor wire. Space diversity and Multi Input Multi Output can be used to boost the data rate and reduces the total wireless nodes and hops required to half saving power on individual node. The proposed system is as - Both faces of the transceiver nearer to the lander acts as the cold side of the Thermo Electric Generator (TEGs) whereas both the faces of transceiver near the ocean acts as the hot side creating two virtual TEG's whose power can be shared mutually among the transceivers depending on the requirement. The effective wireless channel path is reduced is the limiting factor of the overall achieved data rate. This also addresses the problem of deploying more sensor nodes towards the ocean surface due to diminishing permeability offered by ice and mitigate the signal attenuation problem. The wired link on the other hand will have no problem regarding to this.

The Jupiter Icy Moons Explorer (JUICE) mission, whose launch is currently scheduled in 2022, is the first ESA-led mission devoted to explore the Jupiter system with an emphasis on the icy Galilean satellites Europa, Ganymede and Callisto. JUICE will indeed be the first spacecraft ever to enter orbit around an icy satellite, Ganymede, allowing an unprecedented analysis of its surface, interior and tenuous atmosphere. Among the remote sensing instruments onboard JUICE are a multispectral camera (JANUS) equipped with 13 filters covering the spectral range 0.34-1.08 µm, and an imaging spectrometer (MAJIS) whose sensitivity covers the overall spectral range 0.5-5.54 µm.

Once in orbit around Ganymede at 5000-km altitude (GCO-5000 phase), JANUS is committed to achieve global coverage in 4 filters at a resolution better than 400 m/px, but it can reach the maximum achievable resolution of 75 m/px where necessary. In this phase, MAJIS shall achieve global coverage at spatial resolution between 2 and 5 km/px.

In the following orbital phase carried out at 500-km altitude (GCO-500 phase), the actual color coverage will depend on the available data volume, but in principle it may be planned to observe specific regions of interest at the maximum achievable spatial resolution with both JANUS (7.5 m/px), also using contiguous color filters, and MAJIS (75 m/px).

The joint analysis of multispectral and hyperspectral datasets of past or ongoing planetary space missions permitted to achieve better scientific results than those obtainable from the individual analysis of these two kind of datasets. For instance, the correlation between the photointerpretation obtained at a high spatial resolution and the identification of spectrally homogeneous regions at lower spatial resolution, in principle would allow an extrapolation of hyperspectral data at spatial resolutions inaccessible to MAJIS in the spectral region 0.5-1.0 µm where JANUS and MAJIS overlap each other.

Here we describe the main complementarities and synergies that could be planned in the future, regarding the exploration of the icy Galilean satellites - most notably Ganymede - thanks to the combination of JANUS and MAJIS data. Moreover, we suggest further synergies potentially achievable through the integration of data sets from additional instruments. In doing this, we take into account the operational constraints imposed by the technical characteristics of the spacecraft during the different phases of the JUICE mission.

B5.3-0052-18 INVESTIGATING EUROPA'S GEOLOGY, ICE SHELL, AND POTENTIAL FOR CURRENT ACTIVITY WITH THE EUROPA IMAGING SYSTEM (EIS)

Elizabeth Turtle, elizabeth.turtle@jhuapl.edu JHU/APL, Laurel, Maryland, United States Alfred McEwen, mcewen@lpl.arizona.edu

University of Arizona, Tucson, Arizona, United States EIS Science Team

Geoff Collins, Ingrid Daubar, Carolyn Ernst, Leigh Fletcher, Candy Hansen, Alex Hayes, Terry Hurford, Dave Humm, Randy Kirk, Amy Mlinar, Francis Nimmo, Wes Patterson, Louise Prockter, Lynnae Quick, Jason Soderblom, Nick Thomas

Europa Clipper's Europa Imaging System (EIS) consists of narrow-angle and wide-angle cameras (NAC and WAC) designed to transform our understanding of Europa through global coverage, topographic and color mapping and unprecedented sub-meter-scale imaging. To investigate Europa's geology, composition, ice shell and ocean, and habitability, EIS will:

Constrain the formation processes of surface features by characterizing endogenic geologic structures, surface units, global cross-cutting relationships, and relationships to Europa's subsurface structure and potential near-surface water (e.g., Schmidt et al. 2015);

Search for evidence of recent or current activity, including potential erupting plumes (Sparks et al. 2017; Roth et al. 2014);

Characterize the ice shell by constraining its thickness and correlating surface features with subsurface structures detected by ice penetrating radar (Schroeder et al. 2016);

Characterize scientifically compelling landing sites and hazards by determining the nature of the surface at scales relevant to a potential lander (Hand et al. 2017).

EIS will provide comprehensive data sets, including cartographic and geologic mapping, regional and high-resolution digital topography, GIS products, color and photometric data products, a database of plume-search observations, and a geodetic control network tied to radar altimetry

The NAC will achieve 0.5-m pixel scale over a 2-km-wide swath from 50-km alt. A 2-axis gimbal enables independent targeting, allowing very high-resolution stereo imaging to generate DTMs with 8-m spatial scale and 1-m vertical precision over a 4-km swath from 100-km alt. The gimbal also makes near-global (>90%) mapping possible at 100-m pixel scale (to date, only 14% of Europa has been imaged at 500 m/pixel), as well as regional stereo imaging. With 10-km pixel scale at 1E6 km range, the NAC can take advantage of good illumination geometry to search for forward scattering by potential plumes even when distant from Europa.

The WAC is designed to acquire pushbroom stereo swaths along flyby ground-tracks. From 50-km altitude, the WAC achieves 11-m pixel scale over a 44-km-wide swath, generating DTMs with 32-m spatial scale and 4-m vertical precision. WAC and NAC data also support characterization of surface clutter for interpretation of radar sounding.

The cameras have identical rapid-readout, radiation-hard 4k x 2k CMOS detectors (Janesick et al. 2014) that image in both pushbroom and framing modes. Color pushbroom observations using six broadband filters (370-1050 nm) will map surface units to correlate with geologic structures and compositional units (Blaney et al. 2017). The rad-hard data processing unit (DPU) uses real-time processing for pushbroom imaging, including WAC 3-line stereo, digital TDI, and data to measure and correct pointing jitter, taking full advantage of the rapid, randomaccess readout of the CMOS arrays.

The astrobiological relevance of the Ocean Worlds - Enceladus and Europa in particular - is outstanding, as they possess liquid oceans that are in contact with a rocky core, where hydrothermal activity is assumed. Similar environments on Earth have been discovered to harbor unique and complex living ecosystems. There are natural processes that deliver samples of the surface ice and subsurface liquid ocean from these bodies to altitudes, where they become available for in situ detection and analysis using mass spectrometry techniques after the impact ionization of the icy dust particles. This detection method is demonstrated to provide outstanding sensitivity to organic and inorganic compounds solvated in the water ice and thus is a promising tool that is yet to be fully exploited. As of today, there are no existing laboratory capabilities for accelerating icy dust particles to typical velocities encountered in space (approx. 4 km/s). A design of a new facility has been completed that exploits a commercial electrospray source and a linear accelerator configuration to produce small, highly charged icy dust particle, and accelerate them to relevant velocities. Such capability is needed for high-fidelity studies of the impact ionization process of micronand submicron-sized particles, as it would help to lay the foundations of the detectability of diverse biomarker molecules through impact ionization. Of particular interest is the investigation of the detectability of organic molecules embedded in icy grains, and the constraints on the sensitivity posed by absolute and relative concentrations, ionization efficiencies, and the effects of the geochemical environment, e.g. salt concentrations, and pH values.

NASA's Europa multi-flyby mission is designed to provide a diversity of measurements suited to enrich our understanding of the potential habitability of this intriguing ocean world. The Europa Clipper mission's Ultraviolet Spectrograph, Europa-UVS, is largely based on the JunoUVS instrument, currently in orbit at Jupiter. Its design is even more similar to the Jupiter Icy Moons Explorer UVS (JUICE-UVS), which leads Europa-UVS in its development and delivery schedule by 18 months. The science objectives of Europa-UVS are to: 1) Determine the composition chemistry, source sinks, and structure variability of Europa's atmosphere, from equator to pole; 2) Search for and characterize active plumes in terms of global distribution, structure, composition, and variability; 3) Explore the surface composition microphysics and their relation to endogenic exogenic processes; and 4) Investigate how energy and mass flow in the Europa atmosphere, neutral cloud and plasma torus. Europa-UVS observes photons in the 55-210 nm wavelength range, at moderate spectral and spatial resolution along a 7.5° slit. Three distinct apertures send light to the off-axis telescope mirror feeding the long-slit imaging spectrograph: i) a main entrance airglow port is used for most observations (e.g., airglow, aurora, surface mapping, and stellar occultations); ii) a high-spatial-resolution port consists of a small hole in an additional aperture door, and is used for detailed observations of bright targets; and iii) a separate solar port allows for solar occultations, viewing at a 40° offset from the nominal payload boresight. Programmable acquisitions with customized detector array binning and windowing capabilities allow for observational flexibility and optimal science data management. Both photon event time-tagging (pixel list mode) and spectral imaging (histogram mode) acquisition types take advantage of this data volume optimization capability. As on Juno-UVS, the effects of penetrating electron radiation on electronic parts and data quality are mitigated through contiguous shielding, management of high-voltage settings, and careful use of radiation-hardened parts. Additional mitigation of radiation effects on UVS science measurement quality is provided by implementing microchannel

plates with ALD coatings (to eliminate gain-sag), borosilicate glass substrates (to decrease sensitivity to energetic particles and secondaries), and large global count rate limits and filtering of pulse height amplitudes (to process noise events). Europa-UVS passed its preliminary design review (PDR) milestone in November 2017. We present the current investigation details regarding the science we plan to address, the salient details of the instrument, and the basic concept of operations.

The science goal of the NASA's Europa Clipper mission is to "explore Europa to investigate its habitability". One of the primary instruments selected for the scientific payload is a multifrequency, multi-channel ice penetrating radar system. This "Radar for Europa Assessment and Sounding: Ocean to Near-surface (REASON)" could revolutionize our understanding of Europa's ice shell by providing the first direct measurements of its surface character and subsurface structure. REASON will address key questions regarding Europa's habitability, including the existence of any liquid water, through the innovative use of radar sounding, altimetry, reflectometry, and plasma analyses. These investigations require a dual-frequency radar (HF and VHF frequencies) instrument with simultaneous shallow and full-depth sounding that is designed for performance robustness (in particular against subsurface volume scattering, ionospheric distortion, and Jovian noise emissions) in the challenging environment of Europa. The flyby-centric mission configuration is an opportunity to collect and transmit minimally processed data back to Earth and exploit advanced processing approaches developed for terrestrial airborne data sets. The observation and characterization of subsurface features beneath Europa's chaotic surface requires discriminating abundant surface clutter from a relatively weak subsurface signal. Finally, the mission plan also includes using REASON as a nadir altimeter capable of measuring tides to test ice shell and ocean hypotheses as well as assessing roughness across the surface statistically to identify potential follow-on landing sites. We will present a variety of measurement concepts for addressing these challenges.

B5.3-0056-18 MAPX-PIXE: A FULL FIELD MICRO X-RAY FLUORESCENCE IMAGER FOR ASTROBIOLOGY APPLICATIONS ON OCEAN WORLDS

SETI Institute, Mountain View, California, United States

Introduction: Investigations of Ocean Worlds and other icy bodies as potential habitats for life require a knowledge of the mineralogy and elemental chemistry at the surface [1]. APXS, currently deployed on MSL, obtains compositional information from X-ray fluo-rescence (XRF) spectra with a spot size 1.6 cm in di-ameter [2]. However, the information on bulk samples leaves out spatial information which can reveal traces of physical, chemical, and biological processes. The Mapping X-ray Fluorescence Spectrometer (MapX) employs XRF at the micrometer scale (XRF) to ob-tain such information [3]. MapX-PIXE has been de-signed for use with radioisotope sources that will emit both and radiation. The radiation will induce XRF from heavy elements, while particles will be able to induce XRF from lighter elements via particle induced X-ray emission (PIXE). Thus, MapX-PIXE will be ca-pable of imaging both heavy elements for mineralogi-cal characterization and light elements for possible identification of biological material. MapX Prototypes to Date: MapX is a full-field XRF imager which employs a CCD detector operated in single photon counting mode. The number of elec-tron hole pairs created by an incident photon is energy dependent, and by summing multiple frames it is pos-sible to produce XRF spectra for each pixel of the CCD. The same technology is employed in the CheMin instrument on MSL, which provides qualitative bulk compositional information as well as spatially-resolved diffraction information for mineral identifica-tion. MapX combines this CCD with a micro-pore op-tic (MPO) which focuses X-rays 1:1 onto the CCD. The resulting instrument is capable of producing XRF maps with a resolution of 100 m. Data is currently being collected using two prototypes employing X-ray tube sources, MapX-II and MapX-III, which are at TRL3 and TRL4 respectively. The MPO/CCD geometry has significant ad-vantages over other XRF systems. MapX has no moving parts. Further, the MPO provides a greater depth of field than instruments which employ poly-capillary optics. MapX has a measured depth of field of approximately 10 mm, which means that rough, unprepared surfaces can be imaged with minimal loss of resolution. Employing Radioisotope Sources: So far, MapX has been developed with X-ray tube sources which efficiently excite elements heavier than Ne. Using fun-damental parameters methods it is possible to calculate the overall composition in terms of weight percent for heavy elements without directly measuring the light elements. However, detecting life or its precursors on Ocean Worlds will require the detection and mapping of C and N on the surface. To this end, MapX-PIXE will employ 244Cm which emits 14 keV and 18 keV -rays as well as 5.8 MeV -particles [4]. The -rays effi-ciently excite heavy elements (20

< Z < 30) similarly to X-ray tubes, while -particles excite lighter elements (6 < Z < 19) via PIXE. GEANT4 simulations show the increased signal from light elements when using 244Cm compared to X-ray tubes [5]. A 244Cm equipped MapX-PIXE instrument will be smaller, less complex and more robust than an X-ray tube based instrument. Radioisotope-based XRF instruments have been em-ployed on the MER and MSL rovers, demonstrating their feasibility in flight [2]. Applications to Ocean Worlds: MapX-PIXE will be well suited to answer a range of scientific questions on Ocean Worlds. Designed to be included in the in-strument vault of a Europa lander, it will be able to map and quantitatively analyze as-received ice frag-ments. It will be able to determine the ion content of the ice at the surface as well as quantify the amount of dissolved C and N. As water ice freezes, ions are pushed to grain boundaries forming brine channels. These channels create patterns at scales MapX will be well suited for, and will inform the provenance of sur-face ice as well as any surface weathering processes. For Ocean Worlds such as Europa, the surface is expected to contain micro-meteorites which have “gardened” the surface to a depth of 2 cm [6]. This rough material can be imaged without sample preparation, and MapX will be able to characterize embedded meteorites in the immediate sub-surface. While -particles will only induce emission at the surface, the 14 and 18 keV -rays are expected to penetrate to a depth of 3.5 and 6.5 mm respectively with only 50% loss of intensity. This will render elements heavier than Fe detectable at depths ranging from 1 to 2 mm in the ice based on the energy of the XRF lines. Data Processing: The full x, y, energy data cube produced by MapX and MapX-PIXE will be too large to send back from space; algorithms are in develop-ment to automate the selection of regions of interest (ROI). The XRF spectra from these autonomously selected ROIs can be sent back in addition to element maps. The summed spectra will be processed on the ground for element quantification which will then be used to constrain possible minerals present in the ana-lyzed material based on the RRUFF database [7]. B5.3-0057-18 EXPECTED PRECISION OF EUROPA CLIPPER GRAVITY MEASUREMENTS

Ashok Kumar Verma, ashokverma.iitkgp@gmail.com

University of California, Los Angeles, Los Angeles, California, United States Jean-Luc Margot, jlm@epss.ucla.edu

University of California, Los Angeles, Los Angeles, California, United States

The primary gravity science objective of NASA’s Clipper mission to Europa is to confirm the presence or absence of a global subsurface ocean beneath Europa’s Icy crust. Gravity field measurements obtained with a radio science investigation can reveal much about Europa’s interior structure. Here, we conduct extensive simulations of the radio science measurements with the anticipated spacecraft trajectory and attitude (17F12v2) and assets on the spacecraft and the ground, including antenna orientations and beam patterns, transmitter characteristics, and receiver noise figures. In addition to two-way Doppler measurements, we also include radar altimeter crossover range measurements. We concentrate on 2 hour intervals centered on the closest approach of each of the 46 flybys. Our covariance analyses reveal the precision with which the tidal Love number k2, second-degree gravity coefficients $\bar{C}20$ and $\bar{C}22$, and higherorder gravity coefficients can be determined. The results depend on the Deep Space Network (DSN) assets that are deployed to track the spacecraft. We find that some DSN allocations are sufficient to conclusively confirm the presence or absence of a global ocean. Given adequate crossover range performance, it is also possible to evaluate whether the ice shell is hydrostatic.

Radiation Hard Electron Monitor (RADEM) is a particle measurement monitor dedicated to a Jupiter Icy Moons Explorer (JUICE) space mission. Its purpose as a part of a JUICE environmental monitor system is to provide a handful of important information about Jupiter radiation belts such as particle fluxes with their energy ranges, incoming particle discrimination and directionality. Those properties would be of a great importance due to the lack of sufficient and precise measurements so far.

RADEM consists of three independent detector systems: Proton and Heavy Ion Stack Detector (P&HID), Electron Stack Detector (ED) and Electron Directionality Detector (DD). Each of them has a dedicated, radiation-hard IDE3466 ASIC responsible for readout, signal conversion and communication with spacecraft. ED is build out of eight silicon detectors, separated by different absorbers, in a way to cover the energy range from 0.1 to 40 MeV. Combined with DD, which is a pixelated silicon detector placed under directional collimator, RADEM is optimized to detect electrons within wide energy range and determine their incoming direction in nearly 2π. Beside that, P&HID will provide additional information concerning proton spectra in a range within 5 and 250 MeV as well as heavy ion discrimination for particle fluxes even up to 109/cm^2/s. The whole instrument inclusive all three detector heads, their PCBs and ASICs, outer shielding and connectors is designed in a way to fulfill JUICE mission requirements, that is for example a total mass below 1 kg and a power on a level of 1 W.

Current status of RADEM project is Engineering Model development. Its purpose is to test all important functionalities of the device with assumption, that this model will be as close to the final Flight Model as possible. During this phase the detection capabilities as well as the data collection and processing will be tested with a usage of various measures such as proton and electron beams.

We present a novel design of a surface sample acquisition and delivery system for Ocean Worlds, with emphasis on Titan and Europa. The near-term missions that could take advantage of this system, called Cryogenic Sample Acquisition and Delivery System (CryoSADS), are the Applied Physics Lab's Dragonfly relocatable Titan lander (currently undergoing a New Frontiers Phase A study) and Europa Lander (NASA Flagship mission). CryoSADS is funded under NASA's COLDTech program and it will reach TRL 6 in 2019.

To date, a limited number of sampling systems have been developed for Europa and Titan. The optimal system would need to deal with a range of Europa's cryogenic materials: ice and salty ice, and Titan's cryogenic materials: ice, organic solids and liquids, and mixtures thereof. The other environmental constrains include hard vacuum, cryogenic temperature and significant radiation on Europa, and 1.5 bar atmospheric pressure and cryogenic temperature on Titan. In essence, apart from different atmospheric pressure and radiation levels, the two bodies are similar with respect to temperature and gravity.

Most science instruments such as GC/MS, Raman, LDMS require subsurface samples in powdered form. For Europa, these samples should come from greater depths (depths where radiation alteration is minimal) while for Titan, there are no radiation effects and near surface samples may suffice. The design of CryoSADS is such, that it will be able to reach samples in the 10-20 cm range. Greater depths are possible with the addition of a longer drill bit. The baseline sample volume is 1 cc per each centimeter of depth.

CryoSADS consists of a deployment system, rotary-percussive drill with powder sample acquisition and capture bit, and pneumatic sample transfer and drop-off system. The Weight on Bit will be limited to <40 N because of the low gravity and low spacecraft mass. To enable penetration into cryogenic material with such a low bit-ground contact pressure, the hammer system will deliver 2 J/blow at 20 Hz. To minimize reaction forces and vibration into the lander, the drill will be mounted on vibration isolator.

The pneumatic approach allows extremely fast sample transfer to an instrument, with minimal heating of the sample itself. The gas options include compressed gas from a dedicated tank for Europa's probe and a suction blower for Titan's probe. In essence, the difference between the two options is how the deltaP across the pneumatic system is being generated. On Europa the sample is 'blown' into an instrument by compressed air ("air gun" approach) while on Titan the sample is 'sucked' because of lower pressure generated by a blower ("vacuum cleaner" approach). To enable pneumatic transfer, the drill bit is a combination of a coring bit and a full faced bit. The coring cutters ensure a hole can be started even on a steep incline while the full faced cutter ensures generation of cuttings rather than a core.

CryoSADS is currently undergoing breadboarding and testing in Titan and Europa relevant materials. The test results will drive the final CryoSADS design and architecture. The fabrication of CryoSADS will be performed in the summer of 2018, and end to end tests will continue into 2019. CryoSADS will also undergo vibration and vacuum thermal tests to reach TRL6.

Today, a number of community-driven space mission concepts have been dedicated to the exploration of icy worlds, particularly those orbiting the Giant planets Jupiter and Saturn. The investigation of such environments and their chemistry, including the dense atmosphere of Titan, the possible sub-surface ocean of Europa, or the plumes of Enceladus, is among the highest priority objectives of new space missions. Mass spectrometers are among the key instruments that will be embarked for the in situ characterization of those environments, but require a new generation offering, for example, higher mass resolution than currently available.

A new mass analyzer based on the OrbitrapT M technology (extensively used in ground-based laboratories) is currently being developed, as a part a future development of more capable space mass spectrometers. The analytical cell is an ion trap (1) and its main assets are the high mass resolution combined with the design and the size of the analyzer (40 mm in diameter, 60 mm long). The Research and Development project is called Cosmorbitrap (2). This kind of instrument in space would provide us a very deep analysis capability of the chemical compositions of these moons.

This work aims at evaluating the analytical performance of a prototype of the Cosmorbitrap with respect to the detection of organic molecules in a variety of Titan and Europa analog samples. Lab-produced tholins, analogs of Titan aerosols (synthesized with the PAMPRE experiment (3)), have been analyzed in addition to dilute aqueous amino acid mixtures. In the context of a future space mission, these measurements demonstrate the capability of the Cosmorbitrap mass analyzer to identify and study a wide range of compounds (pure and complex organics, inorganics, and biosignatures) with ultrahigh mass accuracy (less than 5 ppm with internal calibration, Indium in our experiments) and resolving powers (more than 100 000 at m/z 136 and 80 000 at m/z 431). Work on the accuracy of the measurements of isotopic ratios is ongoing.

A concept is described for a biosignature-detection enhancement for the ocean-worlds flagship mission Europa Clipper. The investigation would use two instruments on the Clipper payload (MASPEX gas mass spectrometer and SUDA impact ionization mass spectrometer), plus a small, dual-channel version of SUDA deployed on a free-flying probe called Sylph. Together this instrument suite would directly sample the chemistry of plumes that Clipper may discover. Cassini measurements at Enceladus prove that these instruments can exquisitely measure the composition of ice grains, dust, and gas in a plume, profiling the habitability of the source water reservoir, and even detecting biomolecules. Sylph is a single-purpose probe designed to enable this investigation by performing the one critical measurement that Clipper itself cannot make: in situ, hypervelocity impact-ionization mass spectrometry of large ice grains. At Enceladus such large grains are known to be frozen ocean spray; at Europa, they would fall out of a plume 20km below the reach of Clipper. Sylph is a rad-hard, terrain-guided AutoNav freeflyer. Its small size (45kg, about the size of a home propane tank), simple instrument, and modularity allow it to be brutally sterilized during assembly, to meet anticipated Category IV planetary protection requirements. Target-initialized and deployed from a shielded, biobarrier hangar eight hours before a Clipper plume fly-through, Sylph drops down to 2-5 km altitude, skimming along the moon's surface to make a 3-second pass through the densest part of the plume. Cation and anion mass spectra, and AutoNav images, are relayed to Clipper within 30 minutes; the sterile probe eventually impacts Europa. With grain and gas mass spectra, the Clipper science team can quantify habitability of Europa plume water reservoirs. The first Sylph unit would cost about $85M; copies would cost less, and Clipper could carry two or three. The Sylph concept extends Cassini's demonstration of hypervelocity ice-grain spectrometry, and demonstrates cost-effective planetary protection for in situ exploration of ocean worlds in the outer solar system.

B5.3-0062-18 ZEOLITE-LOADED AEROGEL GETTERS AS A PRIMARY VACUUM SORPTION PUMP IN PLANETARY INSTRUMENTS

Mihail Petkov, mihail.p.petkov@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Steven Jones, steven.m.jones@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Gerald Voecks, gerald.e.voecks@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Zeolite-loaded aerogel (ZLA) getters were devised, developed and produced for maintaining vacuum in the CNES seismometer instrument (SEIS) on the NASA InSight mission to Mars. The ZLA are very light compound materials (typically 0.1 g/cm3) with tunable density and very high surface area (>500 m2/g), when loaded with zeolite of choice. These materials are capable of maintaining medium vacuum (<10−3 mbar) for extended periods of time (months to years at room temperature) without any maintenance or consumption of power. The outgassing constituents of a typical vacuum system are vastly dominated by water, for which adsorption on zeolites is extremely efficient when properly conditioned. Ion exchange (Na+, Ca+, Mg+, Pd+, etc.) of the zeolites, prior to incorporation into the ZLA, can be used to further enhance the adsorption of non-dominant species, such as CO2, organic volatiles and, potentially, hydrogen.

The ZLA are prepared using a modified two-step silica aerogel process, and are loaded with fumed silica and zeolite particles in the liquid aerogel precursor. The precursor composition was chosen such that the zeolite particles stay homogeneously dispersed during the gelation process. The aerogel precursor with the dispersed zeolite particles forms a wet gel, locking the zeolite particles into the silica network formed. The material is then dried supercritically to produce a rigid silica network and to minimize shrinkage. The ZLA can be cast in practically any shape while in the liquid state, thus minimizing special engineering efforts. For particle-sensitive applications, the ZLA can be isolated by sub-micron filters without noticeably affecting the adsorption rate. The open pore network of the primarily mesoporous silica aerogel matrix, in which the zeolite particles are dispersed, provides excellent molecular conductance to the zeolite particles. This dramatically increases the effectiveness of the zeolite adsorption in comparison with their standard pellet form applications.

The ZLA getters are especially suitable for planetary instruments operating in extremely cold planetary environments, such as Europa, Enceladus, Titan, as well as Mars. The effectiveness of the getters at such conditions increases by several orders of magnitude due to the lowtemperature dependence of the adsorbance. It appears feasible that ZLA getters may be suitable to maintain even high vacuum (<10−6 mbar) for many years without any maintenance or power consumption. The low mass, 0.1-1 g per liter volume, and no detectable organics outgassing is particularly beneficial for optical instruments.

NASA/ARC, Moffett Field, California, United States

Missions to Enceladus that seek to determine the habitability of its icy ocean and search for extant life must acquire a pristine sample of the Enceladus ocean water. This can either be accomplished via a lander or flythroughs of the plumes. From the mission and flight system design perspective, flythroughs incur less risk and cost, and the planetary protection requirements are easier to meet. One of the key challenges for these missions is to avoid ambiguity of results in the search for life. Therefore, the system must collect a large enough sample to enable analysis by several independent techniques. In addition, the sample collection process must not alter or contaminate the sample. The reliability of the collector after a long cruise time, its cleanliness, and low mass are also key concerns.

Maturation of the Enceladus Funnel (or EFun) sample collection mechanism is funded under the NASA COLDTech program. EFun's goal is to obtain a pristine sample of the ocean water via multiple flythroughs of the Enceladus icy plumes. The requirements for the sample collector include a large area to acquire as much sample as possible while ensuring that it is efficiently transferred into a very small holding volume. It must preserve the sample in its pristine ice form until the instruments are ready to perform analysis and then efficiently transfer the sample to the downstream instruments. EFun is the enabling technology for a suite of analytical instruments that determine the biological content of the Enceladus plume and determine Enceladus' habitability.

EFun collector development to date includes the verification of high-velocity (km/sec) ice particle capture using collector prototypes at the Ames Vertical Gun Range (AVGR), for range of particle sizes expected in the Enceladus plumes. It also includes measurements of capture efficiency and organics' alteration through collision with the collector walls. Methods for strict contamination control of the collecting surfaces are developed and tested. They involve cleaning protocols to minimize cross contamination in the AVGR shooting chamber environment, microbial reduction, and NASA approved bioburden monitoring practices. Multiple trades and a detailed design of the transfer and expulsion mechanisms are completed. The prototypes of those mechanisms are currently in test, and are on track to reach the expected level of maturity by the end of the COLDTech project.

Life detection missions to the Ocean Worlds Jupiter and Saturn, such as Europa and Enceladus, will collect ice samples by either landing on the surface, or flying through the moon plumes using sample collection devices. Ice particles plumes, ejected into space from the underlying ocean, have been mapped on Enceladus [1-2] and, most recently, detected on Europa [3]. A key issue for highly sensitive life-detection instruments for sample analysis (e.g., capillary electrophoresis with laser-induced fluorescence, gas chromatography-mass spectrometry, and antibody microarray chips) is how to determine that a positive signal of life in a sample is intrinsic to the planetary body and not a result of exogenous contamination from Earth. Contamination management methods involve the use of blank control samples to calibrate the instrument against biomarker contamination just prior to receiving samples. However, in space or planetary surface environments, it is difficult or impossible to run blanks that fully sample the collection-and-handling devices, limiting the efficacy of this contamination management tool. In addition, the instrument detection sensitivity for target organics must be adequate for the lower limit of the anticipated concentration range of cellular and organic biomarkers in the target Ocean World, which can be very low, e.g., less than 80-120 cells/mL, in the range of the lowest values detected in the Antarctic subglacial Lake Vostok ice counterpart [4]. In this context, NASA Ames Research Center (ARC) has been simulating plume fly-throughs of prototype collectors of ice particles as well as surface ice sampling. During these impact tests at ARC's Vertical Gun Range (AVGR), basic ancillary experiments involve measurement of microbial and biomarker survival, and simultaneous management/monitoring of contamination levels of the prototype collectors and the AVGR chamber using NASA-approved practices [5]. The objective was to evaluate cleaning and microbial reduction techniques. These involved an ultrasensitive adenosine 5 triphosphate (ATP) luminometry assay (limit of detection: 0.2×10-15 moles (femtomoles, or fmol) for pre-screening of collector surfaces, which is below the threshold cleanliness limit of 2.3×1011 mmol ATP/ 25 cm^2 (0.9 fmol/cm^2) [6], and bioburden monitoring. The ATP does not survive cellular death and is a proxy for recent biological activity being used for bioburden monitoring in spacecraft [5] and cross-contamination during field trials. Furthermore, we used protocols that enabled mitigation of false negatives (kinetic-inhibited) and false positives (by reaction enhancement) in salt-rich samples. During sampling of the target sea ice (< 2 to 0.3 fmol ATP/100 µL) and on collector surfaces (< 0.2 to < 0.9 fmol/cm^2), contamination levels were negligible and did not affect scientific evaluation of biomarker survival upon impact in natural and synthetic seawater experiments (e.g., 5×103 fmol ATP/100 µL). These results are preliminary as test data are still being analyzed.

Introduction:. Astrobiology Search Kit (ASK) instrument is a field portable spectrometer that: 1) Searches for evidence of biomarkers common to life on Earth; and 2) Assesses the habitability of the surface material (liquid, ice, soil) by measuring chemical constituents and mineralogy. The scientific basis of the instrument is wet chemistry combined with spectroscopy. Specifically, transmission, reflectance and organic (biological and geochemical) native fluorescence. For the geochemical assessment, we use wet-chemistry protocols that are well established and proven assays. ASK uses both contact ad non-contact methods. The contact method is similar to current techniques in environmental assays and medical diagnostics. These methods are indicative of specific lipids and proteins, common to most organisms on Earth. The non-contact method is spectroscopyfluorescence, transmission, and reflectance. We search for extant life,a nd the chemistry surrounding those biomolecules. Employing multiple techniques allows for redundancy within the same sampleessential to life detection verification. The ASK instrument is relevant to several potential near-term missions. We compare the ASK instrument capability to the mission goals/objectives of the Europa Lander directed mission. Science Goal:

1. Search for evidence of biomarkers and /or life, especially extant life. On Earth, all organisms that we know of have similar biochemistrythey use the same 20 amino acids, have nucleic acids (DNA or RNA), use the TCA Krebs cycle for energy and rely on Carbon, Hydrogen, Nitrogen, Oxygen, Phosphate, and Sulfur elements (CHNOPS). Due to these commonalities of life on Earth, our life detection instrument suite aims to detect aspects of each of these. The ASK instrument utilizes complementary biomolecule (life detection) methods using spectroscopy (including fluorescence) and biochemical assays based on enzymatic reactions in the Krebs cycle to gain an understanding of the biological mileau of the sample. The biomarker assay employs dry chemistries, transmission and fluorescence spectroscopy. The core detection technology utilizes the Patent Pending (US 2017/0038357-A1) Retego Labs advanced spectrometer. We have a complement of wet chemistry and fluorescence assays to detect universal compounds (DNA, RNA, NADH, and ATP for instance) and unique compounds to a specific extant life process such as (F420) in methanogens. The biomarker assays provide an insight into the diversity and evolution of microbial life providing a glance into the microbiome of the planetary body. Science Goal 2: Asses the habitability (particularly through quantitative compositional measurements) of Europa via in situ techniques uniquely available to a landed mission. Our search for extant life on Ocean Worlds begins with assessing the habitability by determining the basic chemistry of the sub-surface brine. The Retego Labs Advanced Spectrometer is designed for chemistry assays in brine produced water from the oil and gas industry. The brine water from these fields ranges from low to near saturation. Retego Labs designed a method using dry chemical assays combined with fluorescence to measure the desired constituents within the brine. These assays are specifically designed for brine environments, have more than a four year shelf-life and require no additional liquid reagents. The size of the ASK instrument is in the 1U range and could be a payload on a mission ranging from an interplanetary cubesat size to a New Frontiers Icy moons mission.

B5.3-0066-18 ADVANCED SPATIAL METHODS OF LOW COST MISSION DESIGN FOR JOVIAN MOONS EXPLORATION

Keldysh Institute of Applied Mathematics, RAS, Moscow, Russia

Spatial mission design of low-cost Delta V gravity assists tours for the Jovian moons exploration is considered, taking radiation hazard into account. The future space missions—the Laplace-P project of Roskosmos with the possible cooperation with the ESA's JUICE project which involves a landing on one of Jovian moons must be very refined. This is caused by a fact that the necessary cruise, flyby, and landing on the Jovian moon imply multiple reductions in the approach velocity of the spacecraft (SC), which, in view of contemporary restrictions for propellant consumption, can be ensured only by using of gravity assist maneuvers (GAMs) near Jovian moons. For these projects the execution of limitations on a mission duration, minimization of the level of total ionizing dose (TID) of radiation, and the delta V budget are required. The urgency of the creating a regular procedure for the construction of optimal scenarios or schedules of flybys of the appropriate celestial bodies and the development of conditions for executing of these schedules becomes evident. Advanced of the 3D construction methodology for such scenarios taking into account the spatial model of the Jovian radiation is descripted. The reduction of the SC's asymptotic velocity relative the satellite for the moon's capture is impossible. A valid reason is in the invariance of the Jacobi integral and the Tisserand parameter in the restricted three-body problem model (R3BP). Formalized spatial beam's algorithm of multibody GAMs used the refined ephemeris model has been implemented. Advanced modifications of the spatial Tisserand-Poincare graph for this purpose are introduced taking into account the 3D Divine/GIRE model of the Jovian radiation. Tisserand parameters of SC in several local R3BP for this purpose are used. The Multi-Tisserand graphs based on them are built. It is shown that the "cross" gravity assists at the early stage of SC's orbital energy reduction for TID-comfortable tours are required. As a result, a reasonable increase in the duration of the mission for Jovian moons exploration can be exchanged on a sharp decline TID and "comfortable" spatial 3D tours can be found in the Jovian system: less than 65 Krad for standard SC protection 8 mm Al.

B5.4-0001-18 RADIO OBSERVATIONS OF THE DEEP TROPOSPHERE OF URANUS: COMPARING GASAND ICE-GIANT PLANETS

Mark Hofstadter, mark.hofstadter@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Virgil Adumitroaie, virgil.adumitroaie@jpl.nasa.gov

NRAO, Socorro, New Mexico, United States

Ground-based radio observations of the giant planets at wavelengths from 1 millimeter to 1 meter probe the atmospheres from pressures near 0.1 bar (the tropopause) to pressures of 100's of bars or more. Our main focus in this talk will be disk-averaged quantities to highlight average composition, cloud formation and chemistry in Uranus' atmosphere, and how it compares to the gas giant planets. Planetary formation models for Uranus and the observed CH_4 abundance suggest the bulk abundances of both NH_3 and H_2S on the planet should be 50 to 100x solar, and that the NH_3 mixing ratio should be greater than the H_2S mixing ratio. As expected from previous works (e.g. Gulkis et al. Icarus 1978; de Pater and Massie Icarus 1985) we find that Uranus' atmosphere at pressures less than 20 bars has very little ammonia in it (on the order of 1 part per million, which is 1% of a solar abundance). Cloud formation in the deep troposphere (at pressures much higher than a pure NH_3 cloud would form) has been suspected of removing NH_3 from the atmosphere, but quantitative models do not achieve that level of depletion. Our new inverse modeling analysis finds NH_3 is only modestly depleted relative to solar (0.2 to 0.6x solar) between 20 and 50 bars pressure, while H_2S is moderately enhanced relative to solar in this region (1 to 2x solar). Equilibrium models indicate this region is bounded by an NH_4SH cloud on the low pressure side and a liquid water cloud on the high pressure side. In this region, the absolute abundance of H_2S molecules is greater than the abundance of NH_3. The radio data also suggest the presence of an upper tropospheric absorber such as PH_3 at 3x solar (or H_2S if its mixing ratio is allowed to increase with altitude), and the data suggest that the deep atmospheric H_2O abundance is >3x solar.

To explain the discrepancy between the high NH_3 and H_2S abundances in ice giant formation models and the low observed values, chemistry and dynamics can be invoked. We speculate that the presence of a high pressure water ocean in the deep interior of ice giant planets could account for much of the depletion of NH_3 and H_2S, if the solubility of those species under ocean conditions is high. (We do not know the state of the ocean, e.g. if it is ionic or not, nor do we know the thermodynamic properties of the H2O, NH3, H2S system under extreme conditions.) We note that the gas giants, which lack an ocean, have atmospheres which are not depleted in NH3. If water (or other) chemistry in the interior of ice giants can reduce the atmospheric NH3 mixing ratio to less than the atmospheric mixing ratio of H2S, formation of an NH4SH cloud at pressures near 25 bars can remove virtually all of the remaining NH3, leaving primarily H2S at higher altitudes. The radio data also requires an atmospheric opacity source at high altitudes (near 1 bar) which is greater than can be supplied by the equilibrium abundance of H2S. This could be due to another highly volatile species, such as PH3, or H2S if its mixing ratio is allowed to increase with altitude (which a simple lifted-parcel equilibrium model would not allow). We note that recent microwave measurements by the Juno spacecraft at Jupiter (Bolton et al. Science 2017) suggest spatial variations of the NH3 mixing ratio are very complex and do not always follow the predictions of equilibrium thermodynamics.

At the meeting, we will present refined estimates of the abundances and vertical profiles of species in the atmosphere of Uranus, and compare the chemistry and circulation of all the giant planets.

B5.4-0002-18 DISCOVERY AND DEMISE OF A DARK VORTEX ON NEPTUNE

Hubble Space Telescope images in 2015 revealed a dark vortex at 45° south planetographic latitude, named SDS-2015 for "southern dark spot discovered in 2015." Observed four times over a two-year span, the feature was seen to drift slightly toward the pole, and to decrease in size and contrast. Its companion clouds also grew more centered, particularly in the 2017 observations. Aspects of this evolution are similar to two previous dark spots (in 1989 and 1994), suggesting that a common mode of vortex demise may involve fading contrast and centered companion clouds. Latitudes of 45° to 65° south (home to both SDS-2015 and DS2

seen by Voyager) hosted bands of variable albedo over the past three decades, without any observable fine structure in the zonal wind field. Reasonable assumptions about the vorticity of SDS-2015 and its surroundings lead to a conclusion that the meridional wind shear may be twice as strong at the deep level of the vortex as it is at the level of cloud-tracked winds.

Centre d'Etudes Atomique, Gif-sur-Yvette, France

Observations of spatial variability in the atmosphere of Uranus have been limited to cloud properties and temperatures in the troposphere from a combination of spacecraft and ground-based observations. We report observations of the spatial distribution of (1) the stratospheric temperature field and (2) the distribution of stratospheric acetylene from ground-based mid-infrared observations using giant telescopes that resolve the planet spatially. (1) Temperatures in the stratosphere were derived from spectral scanning of the H2 rotational S(1) quadrupole using the TEXES spectrometer at the Gemini North observatory in 2007, near Uranus' equinox at high resolution (R=55,000). The H2 S(1) line was mapped by scanning the slit longitudinally across the entire disk of the planet. The observed radiances from the line center emerge primarily from the 0.1-0.3mbar pressure level. As expected for the "thermally-inverted" stratosphere, the planet is limb brightened at all latitudes, generally consistent with the predictions for the temperature structure derived from Spitzer IRS disk-averaged spectra (Orton et al. 2014 Icarus 243, 494). A pole-to-pole cut through the central meridian shows a generally smooth variability, with the (IAU-defined) northern hemisphere emerging from winter darkness marginally brighter than the southern hemisphere, consistent with a smooth meridional gradient of temperatures. A latitudinal cut across the equator reveals an ostensible central brightening, as well as equal brightening toward the limbs. (2) The distribution of C2H2 in the stratosphere was derived from images of thermal emission made in 2009 using the mid-infrared imager/spectrometers VISIR at the Very Large Telescope and T-ReCS at the Gemini South Observatory using a 13.04-µm moderate-band (NeII-2) filter. Because the continuum in this spectral region is so faint, the upwelling radiation is dominated by acetylene emission from roughly the same pressure level at the radiation from the H2 S(2) quadrupole line. Although the general center-to-limb structure is consistent with predictions from the C2H2 distribution derived from the low-eddydiffusion rate models fitting the Spitzer IRS data (Orton et al. 2014 Icarus 243, 471), there is a strong latitudinal gradient with elevated C2H2 emission poleward of 25° latitude in both hemispheres. Given the apparent smooth meridional variability of temperature, this implies a distinct boundary of higher vs. lower C2H2 abundance regions. This boundary is most likely to be maintained dynamically, being quite different from the expectations of photochemical models with temporal and spatial dependence.

B5.4-0004-18 VLT/VISIR SPECTROSCOPY OF ICE GIANT STRATOSPHERES IN PREPARATION FOR JWST/MIRI

Leigh Fletcher, leigh.fletcher@leicester.ac.uk University of Leicester, Leicester, United Kingdom Glenn Orton, glenn.orton@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Julianne Moses, jmoses@spacescience.org

Space Science Institute, Seabrook, United States Naomi Rowe-Gurney, nrg13@le.ac.uk

University of Leicester, Leicester, United Kingdom Therese Encrenaz, therese.encrenaz@obspm.fr Paris Observatory, Meudon, France

The James Webb Space Telescope (JWST) MIRI instrument will provide global, spatiallyresolved 5-30 µm spectroscopy of Uranus and Neptune in 2020. These data can be inverted to determine the spatial variability of atmospheric temperatures, winds, and composition from the troposphere to the stratosphere. The results will offer unique constraints for radiative, dynamical, and chemical models of the ice giant atmospheres ahead of future missions to these destinations. Latitudinal temperature gradients have already been identified in both ice giant tropospheres (by Voyager 2 and ground-based 17-20 µm imaging, Orton et al., 2015, doi: 10.1016/j.icarus.2015.07.004; Fletcher et al., 2014, doi:10.1016/j.icarus.2013.11.035), and in Neptune's stratosphere via ground-based imaging, showing the presence of a warm polar vortex (Orton et al., 2007, doi:10.1051/ 0004-6361:20078277). Imaging of Uranus' stratosphere has proven challenging (see Orton et al., this meeting), and spatially-resolved spectroscopy of both stratospheres has been even harder. To date, only low-spectral-resolution (R 100) observations from Keck/LWS and Gemini-S/TReCS (Fletcher et al., 2014), along with high-spectral-resolution (R 85,000) observations from Gemini-N/TEXES (Greathouse et al., 2011, doi:10.1016/j.icarus.2011.05.028), have probed the spatial distribution of Neptune's stratospheric temperatures, and none have detected Neptune's summer polar vortex that is evident in photometric imaging.

We acquired VISIR long-slit spectroscopy of Neptune's CH4 emission from 7.1-8.7 µm (R 300) and C2H6 emission from 11.5-11.7 µm (R 3500) on September 13th 2009 (programme ID 083.C0163B). Neptune's polar hotspot was evident in 12.3-µm acquisition imaging and 11.6-µm spec tra, suggesting elevated temperatures and/or ethane within the seasonal vortex. However, the hotspot was not visible in 7.1-8.7 µm spectra, suggesting either (i) that stratospheric temperatures are not elevated within the vortex; or (ii) the slit did not properly align on the south pole, highlighting the difficulties involved in slit spectroscopy. JWST/MIRI will resolve this conundrum, and we present simulated IFU (Integral Field Unit) images based on the photochemical distributions of Moses et al. (submitted) and reasonable assumptions of latitudinal temperature gradients. In addition, we present a marginal detection of the 11.3-13.5 µm spectrum of Uranus (R 250) from September 16th 2008 (programme ID 081.C-0505B), revealing acetylene emission from the Uranian stratosphere. The warm stratospheric emission appears to be localised at mid-to-high latitudes in both spring and autumn hemispheres, whereas the equator appears cold. Comparisons to photochemistry model predictions suggest that this must be driven by an equator-to-pole circulation system in Uranus' middle atmosphere, an idea which will soon be tested by JWST.

B5.4-0005-18 SPATIAL STRUCTURE IN NEPTUNE'S STRATOSPHERIC CH4 EMISSION, AS MEASURED BY VLT-VISIR

James Sinclair, james.sinclair@jpl.nasa.gov

Therese Encrenaz, therese.encrenaz@obspm.fr Paris Observatory, Meudon, France

Cedric Leyrat, cedric.leyrat@obspm.fr Observatoire de Paris Meudon, Meudon, France

Neptune's atmosphere is dynamically active despite receiving limited solar radiation. In Neptune's southern polar stratosphere, a 'hot spot' of enhanced CH_4, C_2H_2 and C_2H_6 emission is evident. Fletcher et al., 2014 suggested subsidence and therefore adiabatic heating in a polar vortex as the source of the brighter mid-infrared emission while Orton et al., 2007 suggested this resulted from upward propagating waves originating in the troposphere. Greathouse et al. [2011] also suggested that waves may be important at lower latitudes to explain temporal variability in the C_2H_2 and C_2H_6 meridional distributions between observations in 1989 and 2007. In this paper, we will present observations made by VLT's VISIR (The VLT spectrometer and imager for the mid-infrared, [Rio et al., 1995]) instrument In September 2008. At 7.8 microns, Neptune's stratospheric CH_4 emission exhibits both latitudinal and longitudinal structure, which might be further evidence that Neptune's stratosphere is dynamically active at lower latitudes. We will test different image deconvolution techniques to optimize the effective spatial resolution. Subsequently, we will perform a forward-model analysis of the VLT-VISIR observations in order to investigate how much of the observed latitudinal/longitudinal variability in CH_4 emission is a result of changes in temperature or the vertical profile of CH_4. Results will also be compared with the near-coincident H-band Keck-NIRC2 [Wizinowich et al., 2000] observations to search for potential correlations between the stratospheric and tropospheric morphology.

B5.4-0006-18 A DIFFERENT NATURE OF SOLAR WIND INTERACTION AT THE ICE GIANT MAGNETOSPHERES?

Adam Masters, a.masters@imperial.ac.uk

Imperial College London, London, United Kingdom

The mysterious magnetospheres of Uranus and Neptune have barely been explored by spacecraft, yet they are distinct from all other solar system magnetospheres in many respects. Determining how each magnetosphere is coupled to the flow of solar wind plasma from the Sun is central to understanding energy flow through each planetary system, in which different elements are coupled (magnetosphere, moons, rings, and atmosphere). Here we assess how the solar wind interacts with each ice giant magnetosphere via magnetic reconnection. Analytical models of conditions at the magnetopause are combined with current understanding of reconnection onset to predict where reconnection may occur on each boundary. We highlight the dynamic location of reconnection sites, and potential seasonal dependence of coupling to the solar wind via this mechanism. We also consider the role of the "viscous-like" interaction between the solar wind and each ice giant magnetosphere, exploring the possibility that the relative important of the two modes of interaction may be different at the outermost planets. This topic represents only one of the many compelling aspects of magnetospheric science to be addressed by a future ice giant mission.

B5.4-0007-18 IMPACT CRATER DISTRIBUTIONS OF THE URANIAN SATELLITES: NEW CONSTRAINTS FOR OUTER SOLAR SYSTEM BOMBARDMENT

Michelle Kirchoff, kirchoff@boulder.swri.edu

Southwest Research Institute, Boulder, Colorado, United States Luke Dones, luke@boulder.swri.edu

Southwest Research Institute, Boulder, Colorado, United States

Impact crater distributions of regular Outer Solar System satellites and large Kuiper Belt Objects are vital constraints for models of Outer Solar System impactor populations and impact fluxes [e.g., 1]. Data from the Galileo, Cassini, and New Horizons missions have provided important constraints at Jupiter and Saturn and in the Kuiper region [e.g., 2-5]; however, little has been developed for region in between, i.e., the Uranus and Neptune systems. This is partially because close-up imaging of these systems has not been obtained since Voyager 2. Nevertheless, analyses of Voyager 2 imaging of Neptune's moon Triton potentially indicated its crater distribution did not look like that seen at Jupiter, leading to a tentative suggestion that the impactor population had changed as it moved inward from Neptune [e.g., 6-7]. However, because craters had not yet been measured at that time for Kuiper Belt Objects, the possibility of an evolution of the impactor population could not be resolved. We now have that information from New Horizons imaging of Pluto and Charon, which seems to indicate crater distributions within the Kuiper Belt have a shallow slope at diameters (D) < 10-20 km, more like distributions at Jupiter and Saturn than at Triton, which has a steeper slope for these diameters [e.g., 5]. The reason for this is currently unresolved.

A key piece of missing information that may help resolve this conundrum is the crater sizefrequency distributions (SFDs) of the uranian satellites. However, characteristics of the craters on these satellites are still not agreed upon [e.g., 8]. The two efforts, one led by Robert Strom and the other by Jeff Plescia, performed just after the Voyager 2 flyby disagreed about the density of craters with D < 70 km on Titania, Oberon, and Umbriel, and D > 20 km on Miranda [summarized by 8]. Since this time no new analyses have been performed to attempt to resolve these discrepancies.

Therefore, we have identified and measured craters in the imaged regions on all five of the mid-sized uranian satellites - Miranda, Ariel, Umbriel, Titania, and Oberon - using newly calibrated Voyager 2 images (Paul Schenk, personal communication) imported into JMARS. We then computed the crater spatial density of the region analyzed using a kernel density computation that keeps the circular kernel radius across the surface constant in kilometers

(=10º latitude). The resulting density maps are used to define terrain boundaries based upon changing crater density, along with observed geologic boundaries, so we can explore if and how the crater SFD has changed with time. We then compare our crater SFDs with those from Strom and Plescia using the relative

(R) plot format [9]. Once the likely characteristics of the uranian satellite crater distributions have been settled, we will compare to the crater distributions of other Outer Solar System bodies from Jupiter to the Kuiper region.

B5.4-0008-18 TRITON: THE CONNECTION BETWEEN ROSETTA, NEW HORIZONS AND A FUTURE ICE GIANTS MISSION

Kathleen Mandt, kathleen.mandt@jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, United States Adrienn Luspay-Kuti, adra30068@gmail.com

United States

Several planetary missions have made observations intended to evaluate the origin and evolution of volatiles in solar system atmospheres. This is an important topic that connects how planets, moons and small bodies formed to the question of past or present habitability. Comet isotope observations have been ongoing and have played a crucial role in this research. Measurements of the D/H in cometary water and 14N/15N in NH3, in particular, have been critical for evaluating the origin of water and nitrogen in the terrestrial planet atmospheres and for that of Saturn's moon Titan. We have conducted comparative studies modeling the escape, photochemistry and evolution of the atmospheres of Titan and Pluto to try to understand whether the nitrogen in these atmospheres originated as N2 or NH3 in the protosolar nebula. The origin of Titan's nitrogen has been well constrained, but uncertainties about isotope processes in Pluto's atmosphere leave the origin of Pluto's nitrogen difficult to resolve. Because of their similarities, Triton is subject to the same uncertainties and is of particular interest for understanding the origin of Triton's and Pluto's volatiles as well as of Kuiper Belt Objects in general. We will discuss how Rosetta, New Horizons and a future Ice Giants mission will each contribute to understanding the origin of nitrogen in these atmospheres and to the origin of volatiles in atmospheres throughout outer solar system.

B5.4-0009-18 FUTURE EXPLORATION OF ICE GIANT SYSTEMS AND KBO PLANETS

Amy Simon, amy.simon@nasa.gov

NASA/GSFC, Greenbelt, Maryland, United States Mark Hofstadter, mark.hofstadter@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

S. Alan Stern, alan@boulder.swri.edu

Southwest Research Institute, Boulder, Colorado, United States

In this talk, we will examine a two mission program that achieves Ice Giant, Ocean Worlds, and Kuiper Belt science objectives. This program takes advantage of ground system, spacecraft design, and flight dynamics efficiencies to achieve missions to BOTH Ice Giants at a total cost similar to that of the Mars Science Laboratory rover. This concept includes a Neptune Orbiter with an atmospheric probe and a significant number of Triton flybys that also flies by a Centaur in cruise. The second mission is a KBO dwarf planet flyby mission that includes a Uranus flyby, with the potential to deliver a near-identical, contributed, atmospheric probe. These two missions will together revolutionize scientific understanding of ice giant and dwarf planet origins, the processes that shape the evolution of planets, their satellites, and KBOs, and shed new light on the nature of exoplanets. When combined with the Europa Clipper and New Frontiers Saturn system missions, this approach achieves many of the Planetary Science Decadal's highest priority science objectives, dramatically advancing our understanding of the outer solar system.

B5.4-0010-18 ICE GIANT WORKSHOP

Mark Hofstadter, mark.hofstadter@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Amy Simon, amy.simon@nasa.gov

NASA/GSFC, Greenbelt, Maryland, United States Leigh Fletcher, leigh.fletcher@leicester.ac.uk University of Leicester, Leicester, United Kingdom

This time slot is an opportunity for COSPAR participants to discuss future missions and science priorities for the exploration of the ice giants. It will start with a summary of the conclusions from the recently completed NASA/ESA Ice Giant mission study (see Poster by Hofstadter et al. for details), and then describe mission and technology ideas that have been proposed since that study. After reviewing ways the community can provide inputs to NASA's planning process via the Outer Planets Assessment Group and White Papers to the upcoming Decadal Survey, attendees will be invited to comment on and discuss all matters relating to ice giant exploration. The session moderators will allow time for several topics based on the interests of those attending. It is anticipated we will touch upon science priorities within the ice giant systems, mission ideas, and secondary science that can be achieved (including observations that might support Astrophysics, Heliophysics, and Exoplanet objectives).

B5.4-0011-18 IN SEARCH OF LONGITUDINAL VARIATIONS IN THE STRATOSPHERE OF URANUS

Naomi Rowe-Gurney, nrg13@le.ac.uk

University of Leicester, Leicester, United Kingdom Leigh Fletcher, leigh.fletcher@leicester.ac.uk University of Leicester, Leicester, United Kingdom Glenn Orton, glenn.orton@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Amy Mainzer, amainzer@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Julianne Moses, jmoses@spacescience.org

Space Science Institute, Seabrook, United States

The NASA Spitzer Infrared Spectrometer (IRS) acquired 5-37 micron spectra of Uranus and Neptune between 2004 and 2007. Uranus was observed in Cycle-1 Time November 2004 (Burgdorf et al., 2006, doi: 10.1016/j.icarus.2006.06.006), and again during Directors Discretionary Time very near its equinox in December 2007. The mean of the four observed longitudes in 2007, spaced equally around the planet, have provided the opportunity for the most comprehensive characterisation of Uranus' vertical structure (temperature and hydrocarbon composition) ever obtained (Orton et al., 2014, [paper 1] doi: 10.1016/j.icarus.2014.07.010; [paper 2] doi: 10.1016/j.icarus.2014.07.012). Given the 0.85-m diameter primary mirror, the Spitzer spectroscopy lacked the spatial resolution to show how these properties varied across the planet, meaning that the results of Orton et al. should be considered as global averages. However, in this work we analyse the differences in temperature and composition between the four separate hemispheres to shed light on the variability of Uranus' stratosphere in 2007. The IRS acquired a similar set of spectra for Neptune in May 2004 (Meadows et al., 2008, doi: 10.1016/j.icarus.2008.05.023) and November 2005, which gives us a unique opportunity to compare the longitudinal variability of the two planets for the first time.

We present initial findings that include the discovery of a definite longitudinal variability occurring across the spectrum on both Uranus and Neptune. On Uranus, the tropospheric H2-He continuum looks to be relatively constant from longitude to longitude. The emission as a function of longitude from all stratospheric hydrocarbon species (e.g., methane, ethane, acetylene, etc.) does, however, appear to vary by around 10% from the mean in an approximately sinusoidal fashion. This wavenumber-2 pattern could indicate the presence of planetary wave activity or meteorological phenomena over wide areas in the stratosphere. A similar pattern was observed over the three longitudes used in the November-2004 Uranus dataset, albeit with a smaller amplitude of approximately 5%. Conversely, the November-2005 Neptune data displays much smaller levels of variability between the three longitudes sampled, despite typically being considered the more active planet. Building on the forward-modelling analysis of Orton et al., we will present full optimal estimation inversions (using the NEMESIS retrieval algorithm, Irwin et al., 2008) of the 2007 Uranus spectra at each longitude to distinguish between thermal and compositional variability in the stratosphere.

B5.4-0012-18 A STUDY ON EXPLORING URANUS AND NEPTUNE: SCIENCE OBJECTIVES AND MISSION REQUIREMENTS

Mark Hofstadter, mark.hofstadter@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Ice Giant Science Definition Team

M. Hofstadter, A. Simon, S. Atreya, D. Banfield, J. Fortney, A. Hayes, M. Hedman, G. Hospodarsky, A. Masters, K. Mandt, M. Showalter, K. Soderlund, D. Turrini, E. Turtle

The Ice Giant planets, Uranus and Neptune, are priority targets for future exploration because they challenge our understanding of how planets form and evolve, unique physical properties are on display in their rings, satellites, and magnetospheres, and because ice giants are common around other stars. NASA and ESA recently undertook a mission study whose complete report is available at https://www.lpi.usra.edu/icegiants/mission_study/.

This study identifies the two highest-priority science objectives as • Characterize the planet's interior. • Determine the planet's bulk composition, including noble gases and isotopic ratios.

Ten additional objectives are • Improve knowledge of the dynamo. • Determine the atmospheric heat balance. • Measure the tropospheric 3-D flow. • Characterize the structures and temporal changes in the rings. • Obtain an inventory of moons. • Determine the surface composition of rings and moons. • Map the shape and geology of satellites. • Determine the density and internal structure of satellites. • Characterize Triton's atmosphere. • Investigate solar wind-magnetosphere-ionosphere interactions.

The study finds that Uranus and Neptune are equally compelling science targets. Each planet has things to teach us which the other cannot, so ultimately both systems must be explored.

The study investigated many mission architectures and finds that achieving these objectives would require a well instrumented orbiter making multiple flybys of each major satellite and dropping an atmospheric probe into the planet. The study does not recommend a specific payload, but discusses a range of possible instruments and suggests an orbiter payload of 150 kg is needed.

The information in this abstract is predecisional and is provided for planning and discussion purposes only.

B5.4-0013-18 ELECTROSTATIC SAIL PROPULSION FOR RAPID DEEP SPACE TRAVEL

Charles Johnson, les.johnson@nasa.gov NASA/MSFC, Huntsville, Alabama, United States

Travel time is a limiting factor in our exploration of the outer solar system and beyond. The immense distances, combined with the limitations of rockets, using either chemical propulsion or electric propulsion, has made robust scientific exploration of: the Ice Giants, outer solar system dwarf planets and the heliopause extremely difficult or outright infeasible. Propulsion-intense inner solar system missions such as those that might view the sun at high solar inclinations, are also problematic.

To meet these challenges, NASA is developing Electrostatic Sail propulsion technology. Electric Sails have the potential to enable rapid and robust outer solar system exploration as well as inner solar system missions with high Delta V requirements. Electrostatic Sails use positively charged bare wire tether(s) that extend radially outward from a spacecraft spinning at a rate of about one-third revolution per hour up to one revolution per hour. When a positive voltage is applied to the tether(s), an electric field and associated Debye Sheath is created around them. The sheath stands off of the bare wire tether at a sheath diameter that is proportional to the voltage in the wire coupled with the flux density of solar wind ions within the solar system (or the location of spacecraft in the solar system). Solar wind protons traveling at speeds ranging from 400 to 800 km/sec are electrostatically repelled away from these positively charged Debye sheaths and propulsive thrust is produced in the wires and tethered spacecraft via the resulting momentum transfer. The amount of thrust produced is directly proportional to the total wire length.

Most of the subsystem technologies required to field an Electric Sail are at Technology Readiness Levels (TRL) greater than 4, with several having been previously space-qualified. Engineers and scientists at the NASA George C. Marshall Space Flight Center recently completed Phase 2 of a NASA Innovative Advanced Concepts (NIAC) study are working toward an eventual flight test of the technology. The physics of the Electrostatic Sail, its potential application to science missions, and technological maturity will be described.

B5.4-0014-18 NUCLEAR THERMAL PROPULSION: ENABLING ROBUST MISSIONS TO THE ICE GIANTS

Charles Johnson, les.johnson@nasa.gov NASA/MSFC, Huntsville, Alabama, United States

NASA is developing nuclear thermal propulsion (NTP) stages for future human and robotic scientific exploration of the solar system. First generation systems under development, when coupled with the lift capability of NASA's Space Launch System, will enable spacecraft with dry masses between two and five metric tons to be captured into orbit at Uranus and Neptune with reasonable trip times. No state-of-the-art or near-term new propulsion system can come close to matching this performance. This capability may enable robotic landers the size and mass of Curiosity (900 kg), used for exploring Mars, to be landed on the moons of the Ice Giants. Spacecraft comparable to the Cassini (2500 kg) may also be sent to explore the Ice Giants and their moons.

First generation NTP system will provide high thrust at a specific impulse above 900 s, roughly double that of state of the art chemical engines. And, using Low Enriched Uranium (LEU), comparable to that use in university-class research reactors worldwide, will allow these systems to be developed at a much lower cost than previously-considered NTP systems.

An overview of the propulsion systems being developed, estimated performance for first generation NTP systems (for exploration of the Ice Giants and beyond), as well as a status of the NASA program will be discussed.

B5.4-0015-18 ICE GIANTS EXPLORATION: DUAL AND TWIN SPACECRAFT APPROACHES

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States

With the progression of the robotic exploration of the Solar System and the continuous advance in exoplanetary studies, filling the gap represented by the limited knowledge we possess of Uranus and Neptune is becoming more and more critical. Not only these ice giant planets represent the archetype for studying one of the most abundant classes of exoplanets, but their characteristics and those of their satellite systems have been shaped by the earliest and most violent phases of the life of the Solar System. Understanding them is therefore an essential step in understanding our place in the galactic context. Because of their similarities and differences, both ice giants are compelling targets and much can be learned by their comparative study. With this rationale in mind in 2013 we submitted to the European Space Agency the ODINUS white paper (http://odinus.iaps.inaf.it), where we described the scientific case of exploring both planets and their satellites in the framework of a single European L-class mission. To achieve this ambitious goal, we proposed the first mission scenario based on the use of two identical spacecraft to two different planets. Both the scientific case and the original twin orbiter scenario were assessed as feasible by ESA and were further refined and consolidated by the ODINUS team during the following interactions the scientific community. The recent joint NASA-ESA study for future missions to the ice giants (https://www.lpi.usra.edu/icegiants/) allowed for confirming the feasibility of the dual/twin spacecraft approach to the two ice giant planets and for considering more ambitious mission profiles, involving larger payloads and the possibility of including atmospheric probes, in the framework of scenarios of international cooperation.

C0.1-0001-18 UPDATE OF THE EUROPEAN SPACE ENVIRONMENT STANDARD

Mark Millinger, mark.millinger@esa.int ESA/ESTEC, Noordwijk, Netherlands Piers Jiggens, piers.jiggens@esa.int ESA ESTEC, Noordwijk, Netherlands Hugh Evans, hugh.evans@esa.int ESA/ESTEC, Noordwijk, Netherlands

The European Coordination for Space Standardization (ECSS) aims to develop and establish a coherent set of standards for use in all European space activities. In this framework the standard ECSS-E-ST-10-04C 'Space Environment' in particular provides models to determine the environmental conditions for space missions. Following aspects are covered by this standard: gravity, magnetic felds, electromagnetic radiation, neutral atmospheres, plasmas, energetic particle radiation, space debris, micro-meteoroids and contamination.

The recent issue of the standards dates back to 2008. Since then many new data sources and models became available. In order to reflect the more recent developments and provide unambiguous guidelines to the space engineering community it was decided to update the standard. The commissioned working group consists of a selection of representatives from European industry and agencies, namely Thales Alenia Space, OHB System AG, Airbus Defence and Space, SES, Centre National d'Études Spatiales, Offce National d'Études et de Recherche Aérospatiales, Deutsches Zentrum fur Luftund Raumfahrt and European Space Agency.

The update activity is in progress and scheduled for final draft release for public review in mid of 2018. This paper aims to present the proposed changes in the various fields to the community with a request for feedback preferably in the scope of the public review exercise.

Please note that the update of this standard is work in progress at the time of the abstract submission. A consolidated view on the update and the potential impacts on spacecraft development will be presented at the conference.

C0.1-0002-18 TOWARDS MODERNIZATION OF ISO 16457 STANDARD: EIGHT PROXY INDICES OF SOLAR ACTIVITY FOR THE INTERNATIONAL REFERENCE IONOSPHERE AND PLASMASPHERE MODEL

Tamara Gulyaeva, gulyaeva@izmiran.ru

Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation of the Russian Academy of Sciences (IZMIRAN), Moscow, Russia

Feza Arikan, arikan@hacettepe.edu.tr HACETTEPE UNIVERSITY, ANKARA, Turkey

Umut Sezen, u.sezen@ee.hacettepe.edu.tr HACETTEPE UNIVERSITY, Ankara, Turkey

The ISO16457-2014 standard "The Earth's ionosphere model - International reference ionosphere (IRI) and extensions to the plasmasphere" should be re-approved by ISO (International Standardization Organization) as new ISO16457-2019 standard in 2019. In view of the recent recalibration of the sunspot number time series SSN2, a need has arisen to re-evaluate solar and ionospheric indices in the IRI and IRI-Plas models, which are developed using the predecessor SSN1 index. To improve efficiency of the model, eight solar proxy indices are introduced in IRI-Plas system: the daily measured solar emissions - the Ottawa 10.7-cm radio flux F10.7 and the H Lyman-α line at 121.6 nm; the core-to-wing ratio of the magnesium ion h and k lines at 279.56 and 280.27 nm, MgII index; sunspot number SSN1 observed before 05.2015 and modeled afterwards; re-calibrated SSN2 sunspots time series; the ionosonde foF2-based global IG-index; the Global Electron Content, GEC, index; the new ionospheric TEC-noon index based on GPS-derived Total Electron Content measurements at 288 IGS stations for 1998-2018. The regression relations are deduced between the different solar and ionospheric proxy indices smoothed by 12-month sliding window. Relevant subroutines are incorporated in IRI-Plas system (http://ftp.izmiran.ru/pub/izmiran/SPIM/) and IRI-PLas online (http://www.ionolab.org/) for automatic conversion of user's predefined index to other related indices used by the different model procedures. Evaluations of accuracy of IRI-Plas with GPS-TEC and ionosonde data demonstrate advantages and shortcomings of the different selected solar proxies.

C0.1-0003-18 A NEW GLOBAL ELECTRON AND PROTON SPECIFICATION MODEL: GREEN

Angelica Sicard, angelica.sicard@onera.fr ONERA/DESP, Toulouse, France Vincent Maget, vincent.maget@onera.fr ONERA/DESP, TOULOUSE, France

Sébastien Bourdarie, sebastien.bourdarie@onera.fr ONERA/DESP, Toulouse, France

Didier Lazaro, didier.lazaro@onecert.fr ONERA/DESP, Toulouse, France Robert Ecoffet, robert.ecoffet@cnes.fr

Centre National d'Etudes Spatiales, Toulouse, France Denis Standarovski, denis.standarovski@cnes.fr CNES, Toulouse, France

The well known AP8 and AE8 NASA models are commonly used in the industry to specify the radiation belt environment. Unfortunately, there are some limitations in the use of these models, first due to the covered energy range, but also because in some regions of space, there are discrepancies between the predicted average values and the measurements. Moreover, new US models AE9/AP9 were developed a few years ago. These models are better than AE8/AP8 in some cases but are still very controversial in some regions of radiation belts. Therefore, our aim is to develop a radiation belt model, covering a large region of space and energy, from LEO altitudes to GEO and above, and from plasma to relativistic particles. GREEN (Global Radiation Earth ENvironment) is a model providing fluxes at any location between L*=1 and L*=8 all along the magnetic field lines and for any energy between 1 keV to 10 MeV for electrons and between 1 keV and 800 MeV for protons. This model is composed of global models: AE8/AP8 and SPM for low energies and local models. Ten years ago we developed the IGE-2006 model for geostationary orbit electrons. This model was proven to be more accurate than AE8, and used commonly in the industry, covering a broad energy range, from 1keV to 5MeV. From then, a proton model for geostationary orbit, called IGP, was also developed for material applications. These models at geostationary orbit were followed by the OZONE model covering a narrower energy range but the whole outer electron belt, a SLOT model to assess average electron values for 2<L*<4, and finally the OPAL model, which provides high energy proton flux values at low altitudes (up to 1336 km). As most of these models were developed using more than a solar cycle of measurements, these ones being checked, cross calibrated and filtered, we have no doubt that the obtained averages are more accurate than AP8 and AE8 for these particular locations. These local models were validated along different orbit with independent data sets or effect measurements. GREEN is not just a collection of various models, it calculates the electron and proton fluxes from the more relevant existing model for a given energy and a given location. Moreover, some existing models can be updated or corrected in GREEN. In 2017, a new version of GREEN was developed (GREEN-V1), in which a new SLOT model (up to L*=5) and a correction of AE8 model at high energy for L*<2.5 have been implemented. Up to now, some efforts have mainly been made to better estimate high energy

electron fluxes, but in 2018, some improvements will be done for energetic proton fluxes and low energy protons and electrons fluxes. Of course, the way the model is developed is well suited to future enhancement with new models developed locally or under international partnerships. In a near future, GREEN model would be accessible for space industry in the OMERE software.

C0.1-0004-18 SPACE WEATHER INFORMATION FOR USE IN SPACE SYSTEMS OPERATIONS

W Kent Tobiska, ktobiska@spacenvironment.net

Space Environment Technologies, Pacific Palisades, California, United States Vladimir Kalegaev, klg@dec1.sinp.msu.ru

Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russia Alyssa Tomky, tomkya@excite.com

California, United States

Effective space systems operations require an accurate knowledge of recent, current, and forecast conditions of the space environment. These conditions change dynamically on timescales of seconds to years and are driven primarily by the Sun's photon and particle interactions with the near Earth environment. We call this phenomenon of short-term variation space weather. ISO TC20/SC14/WG4 is developing an international standard on space weather information for use in space systems operations. The objective will be to describe the main space weather factors affecting space systems operations and to identify tools and parameters needed for effective space weather risk management. We report on the development status of the document that will establish definitions of space weather information and aid in harmonizing key space weather tools provided by international organizations, national government agencies, and industries. Areas covered will include time frames for space weather information as well as environments from galactic cosmic rays through the solar environment within the heliosphere to the near-Earth environment including effects such as ionospheric, magnetic, and radiation storms. A first annex will include a listing of space weather indices with their: 1) description such as content, derivation, assumptions, uncertainties and limitations; 2) application utility to system operation and maintenance; 3) contributors with dates of development, authors/sponsors, collection frequency, locations or instruments; and 4) publication references and index access including URLs. A second annex will include space weather effects to systems by environmental region including Ground Systems, Lower Atmosphere, Upper Atmosphere, Suborbital, Low Earth orbit, Mid-Earth orbit, Geostationary Earth orbit, High Earth orbit, and Interplanetary orbits.

C0.1-0005-18 INTERNATIONAL STANDARD FOR KP PREDICTION

Irina Zhelavskaya, irina.zhelavskaya@gmail.com

Helmholtz Centre Potsdam, GFZ German Research Centre for Geosciences, Potsdam, Germany Yuri Shprits, shprits@gmail.com

German Research Centre for Geosciences, Potsdam, Germany

The Kp index is a global measure of geomagnetic activity and it represents short-term magnetic variations driven by space weather. Kp index is used as an input to various thermosphere and radiation belt models, and it is therefore important to predict it accurately. A prototype model of Kp nowcast and forecast is currently under development. The model predicts the Kp index based on the solar wind measurements from ACE and DSCOVR satellites, recurrency and persistence. We give an overview of the model, describe its concept, design, access to the produced forecast, and demonstrate the forecast results. We also compare the model performance to the historical forecast of the Kp index by other models.

C0.1-0006-18 AE9/AP9-IRENE VERSION 1.5: UPDATED SPACE RADIATION CLIMATOLOGY MODEL

William Johnston, william.johnston.19@us.af.mil

Air Force Research Laboratory, Kirtland AFB, New Mexico, United States Paul O'Brien, paul.obrien@aero.org

Atmospheric and Environmental Research, Inc., Lexington, Massachusetts, United States

This presentation describes version 1.5 of the AE9/AP9 family of space radiation climatology models. The most significant update is inclusion of new data sets that change the flux maps. These new data include measurements from Van Allen Probes, Azur, and the HiLET sensor. In recognition of international contributions to the models, we introduce the IRENE nomenclature for International Radiation Environment Near Earth.

C0.1-0007-18 ONGOING AND FUTURE DEVELOPMENT OF THE COSPAR INTERNATIONAL REFERENCE ATMOSPHERE AND RELATED ISO STANDARDS FOR THE EARTH'S ATMOSPHERE.

David Rees, walnut1@easynet.co.uk

The Paradigm Factor, Robertsbridge, United Kingdom

The paper will present a discussion of the current and future developments of the COSPAR International Reference Atmosphere and related ISO Standards for the Earth's Atmosphere.

C0.1-0008-18 CURRENT STATE OF SINP MSU MODEL OF SOLAR ENERGETIC PARTICLE FLUXES BASED ON ISO/TR 18147 MODEL. COMPUTATIONS OF THE RISKS FOR MANNED MISSIONS

Mikhail Podzolko, spacerad@mail.ru

Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russia Rikho Nymmik, nymmik@sinp.msu.ru

Skobeltsyn Institute of Nuclear Physics, MSU, Moscow, Russia Helen Popova, popovaelp@mail.ru

The Schmidt Institute of Physics of the Earth of the Russian Academy of Sciences (IPE RAS), Moscow, Russia

The description and basic principles of the model of solar energetic proton fluxes being developed in the Institute of Nuclear Physics of Moscow State University are presented, which is based on the ISO/TR 18147 model of proton fluxes. The development of the model for the fluxes of solar heavy ions with charge number z = 2-28 based on the same principles is described.

The comparison of SINP MSU model with other existing models of solar energetic particle fluxes is shown.

Computations of radiation doses for different scenarios of the manned space missions are made using this model. In particular the results of computations using the prediction of solar activity for the next weak solar cycles 25 and 26 are shown.

C0.1-0009-18 ENERGETIC DEPENDENCES OF HIGH LATITUDE BOUNDARY OF THE OUTER RADIATION BELT AS MEASURED BY RUSSIAN LEO SATELLITES IN 2005-2017

Vera Barinova, alisawera@gmail.com

Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russia Vladimir Kalegaev, klg@dec1.sinp.msu.ru

Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russia Minh Duc Nguyen, nguyendmitri@gmail.com

Skobeltsyn Institute of Nuclear Physics, MSU, Moscow, Russia Valery Eremeev, eremeev@dec1.sinp.msu.ru

Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russia

The empirical model of high-latitude boundary of the outer radiation belt has been updated on the base of LEO satellite measurements of energetic electron fluxes obtained during long time period, larger than one solar cycle (2005-2017). The model was corrected taking into account internal magnetic field secular variations and corresponding magnetic poles movement during the observation period. Analytical equation for the high-latitude boundary of the trapped 100 keV energetic electrons was obtained in dependence on UT, energy and geomagnetic activity level. Forecasting capability of the model was realized in the framework of MSU's Space Monitoring Data Center using the forecast of the DST index. Automatic boundary detection method was developed based on LEO satellite measurements of charged particle fluxes for different energetic channels and at different altitudes. The experimentally obtained position of high-latitude boundary of the outer radiation belt was compared with the results of model calculations.

C0.1-0010-18 ISO STANDARDS FOR LIDAR SYSTEMS REQUIRED FOR METEOROLOGY, AVIATION SAFETY AND WIND FARM APPLICATIONS.

David Rees, walnut1@easynet.co.uk

The Paradigm Factor, Robertsbridge, United Kingdom

With increasing, even wide-spread use in meteorology, aviation safety, monitoring and tracking pollution, ISO-TC146-SC5-WG6 has been developing a series of new standards covering the appropriate applications of Lidar and Doppler Wind Lidar Systems. Three standards have already progressed through the ISO process (ISO 28902 parts 1, 2 and 3). Further items, including a standard for Particle back-scatter Lidar (related to meteorology and pollution) and Direct-Detection Doppler Wind Lidar Systems (as will be exploited by ESA's Aeolus Wind Lidar Mission) are the subjects of ongoing and future work. The presentation will briefly describe the previous and ongoing work of the Working Group.

C0.1-0011-18 GENERAL PRINCIPLES OF SPACE ENVIRONMENT SIMULATION TO STUDY ITS EFFECTS ON SPACECRAFT MATERIALS

Lev Novikov, novikov@sinp.msu.ru

Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russia Victor N. Butrim, butrim53@mail.ru

OAO "Kompozit", Korolev, Russia Yugo Kimoto, kimoto.yugo@jaxa.jp

Japan Aerospace Exploration Agency (JAXA), 305-8505, Japan

Under the aegis of ISO, there have been developed numerous standards that regulate the testing of materials and spacecraft equipment components to the impact of various space environment components: vacuum, radiation, solid particles, etc. ISO documents often consider specific objects to be tested, e.g. thermal control coatings, electronic components, solar elements, but not the space environment itself and its impact on materials in general. However, even for each type of near-Earth orbits a set of space components that are the most important for spacecraft operation, may differ substantially. Therefore, there was a need to develop an ISO document that determines sets of main space environment components for different near-Earth orbits and interplanetary regions, including Moon, Mars and Jupiter environments, and describes main physical and chemical processes caused by effects of the given space environment components on materials as well as criteria of material durability to such an influence.

There are several objective reasons to require improvements in the forecasting of spacecraft material durability in relation to outer space environment impact, namely: increase of the spacecraft lifetime; development of the new spacecraft designs (non-hermetic spacecraft, microsatellites, etc.); application of new materials, including nanomaterials; complexity and sensitivity improvement of the spacecraft onboard equipment; development of new orbits in the near Earth space; implementation of new space projects (manned flight to Mars, building of manned bases on the Moon, etc.).

Such a document has been developed by Russian and Japanese scientists, it was published in 2016 as ISO 17851:2016 Space systems - Space environment simulation for material tests

-General principles and criteria. The paper presents the detailed description of the Standard, considers potential fields of its application along with other ISO documents, and discusses its further development.

C0.1-0012-18 MODELING OF SPACE ENVIRONMENT IMPACT ON NANOSTRUCTURED MATERIALS. GENERAL PRINCIPLES

Lev Novikov, novikov@sinp.msu.ru

Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russia Ekaterina Voronina, voroninaen@nsrd.sinp.msu.ru

Skobeltsyn Institute of Nuclear Physics, Lomonosov Moscow State University, Moscow, Russia

Nanomaterials surpass traditional materials for space applications in many aspects due to their unique properties associated with nanoscale size of their constituents. This superiority in mechanical, thermal, electrical and optical properties will evidently inspire a wide range of applications in the next generation spacecraft intended for the long-term (15-20 years) operation in near-Earth orbits and the automatic and manned interplanetary missions. ISO activity on developing standards concerning different issues of nanomaterials manufacturing and applications is high enough. Most such standards are related to production and characterization of nanostructures, however there is no ISO documents concerning nanomaterials behavior in different environmental conditions, including the space environment. In accordance with the resolution of ISO TC20/SC14 WG4/WG6 joint meeting, Technical Specification ISO/NP TS 22295 'Modeling of space environment impact on nanostructured materials. General principles' which describes computer simulation methods of space environment impact on nanostructured materials is being prepared.

This document considers the application of multiscale simulation approach to study physical and chemical processes that may occur in nanostructured materials under the influence of different space components. General guidelines to evaluate the durability of nanostructured materials to the space environment influence on the ground of results mathematical simulation and principles of choosing materials for various fields of space are presented. The document determines ordered sequences of methods that should be applied to simulate different space environment effects on nanostructured materials. Methods and software packages described in this document can be used to evaluate the durability of nanostructured materials to space environment effects and to make recommendations on their usage in various space missions. The Technical Specification is intended for researchers and engineers involved in developing and testing next-generation spacecraft.

C0.2-0001-18 IMAGING MESOSPHERIC WINDS USING THE MICHELSON INTERFEROMETER FOR AIRGLOW DYNAMICS IMAGING (MIADI)

William E. Ward, wward@unb.ca

University of New Brunswick, Fredericton, NB, Canada Jeffery Langille, t383r@unb.ca

University of New-Brunswick, Fredericton, Canada Takuji Nakamura, nakamura.takuji@nipr.ac.jp

National Institute of Polar Research, Tachikawa, Tokyo, Japan

The first ground based images of mesospheric winds in airglow are presented and discussed in this paper. These were obtained with the Michelson Interferometer for Airglow Dynamics Imaging (MIADI) a ground based field widened Michelson interferometer designed to obtain two dimensional images of the line of sight Doppler wind and irradiance field in the mesosphere. The purpose of this instrument is to measure perturbations in line-of-sight wind and airglow irradiance associated with gravity waves. In its current configuration, the instrument observes an 80 km x 80 km region of the night sky in 33 minutes using the O(1S) emission at 557.73 nm and the OH (6, 2) P1 (2) emission at 839.918 nm. The instrument was installed and tested at a field site outside Fredericton, NB (45.96 N, 66.65 W) during the summer of 2014. Successful measurements over a six hour period were obtained on July 31, 2014. Variations in the meridional and zonal wind were observed that are consistent with a semi-diurnal tide with an amplitude of 35 m/s. Small scale variations (< 10 m/s) were also observed that indicate the presence of gravity waves. In this paper, the instrument concept will be presented and the field measurements and their precision and accuracy discussed.

C0.2-0002-18 AN INTRODUCTION FOR FUV IONOSPHERIC PHOTOMETER ON BOARD FY-3(D) METEOROLOGICAL SATELLITE

Liping Fu, fuliping@nssc.ac.cn

Center for Space Science and Applied Research, Chinese Academy of Sciences, Beijing, China Tian Mao, maotian@cma.gov.cn

National Center for Space Weather, CMA, Beijing, China

FUV Ionospheric PhotoMeter,one of the four new instruments on board FY-3(D) Meteorological Satellite which was launched on 15th.Nov.2017, measure the atomic oxygen 135.6 nm and nitrogen molecule LBH145nm-180nmemissions.During nighttime, the electron density of the ionosphere is estimated using the measured spatial distributions of brightness from the 135.6 nm emission.During daytime, the ration between atomic oxygen and nitrogen molecule can be estimated by measured the brightness from 135.6nm and 145nm-180nm.In this report, we will introduce the design and performance of the IPM, finally, the primary on-orbit results of IPM will be shown.

C0.2-0003-18 OBSERVATION FOR THE WHOLE ATMOSPHERE OVER TIBET PLATEAU WITH THE ATMOSPHERIC PROFILING SYNTHETIC OBSERVATION SYSTEM (APSOS)

Daren Lu, ludr@mail.iap.ac.cn

Chinese Academy of Sciences, Beijing, China Weilin Pan, panweilin@mail.iap.ac.cn

Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing, China

To understand the whole neutral atmosphere and the coupling from lower to upper atmosphere, a synthetic system called "Atmospheric Profiling Synthetic Observation System (APSOS)" has been developed and funded by the National natural Science Foundation of China (NSFC) since 2012. It is a system mainly consisted of five lidars devoting to observe the vertical structure of atmospheric temperature, wind, air density, water vapor, ozone, CO2, SO2, NO2, aerosol, cirrus cloud, and sodium layer with high vertical and temporal resolution, a W-band Doppler dual polarized radar, a THz radiometer. Three of the five Lidars commonly use a composite optical receiving telescope with equivalent diameter of 2-meter. Seven research institutes and universities have been engaged in this project. Since late 2016 APSOS has been completed the development of each unit. In 2017, APSOS fulfilled the system tests and the whole system has been deployed at Yangbajing, a field site near Lhasa and with altitude of 4300 m ASL for multi - disciplinary observation. In this paper, we will present the system techniques, data and retrieval system, preliminary results of the atmospheric vertical structure of temperature, water vapor, GHGs, high clouds, ozone, aerosols, as well as wind profiles from the lower troposphere to mesopause.

C0.2-0004-18 TOWARD A NEW CAPABILITY FOR UPPER ATMOSPHERIC RESEARCH USING ATOMIC OXYGEN LIDAR: THE TOMEX-PLUS EXPERIMENT

The Turbulent Oxygen Mixing Experiment Plus (TOMEX-Plus) sounding rocket investigation is presented. This mission will explore the three-dimensional nature of turbulent phenomena near the mesopause through a three-rocket salvo combined with ground-based remote-sensing instrumentation. The centerpiece of the experiment is an ultraviolet lidar system capable of measuring atomic oxygen in-situ, and the progress on its development is discussed. Also described are the other components of the experiment, including in-situ measurements of temperature, density, and winds; two chemical release rockets used to provide context measurements of winds and atmospheric mixing; a ground-based complement of instruments that features imaging of waves through OH airglow measurements and an iron lidar to give context measurements of the temperature and winds; and a modeling component. The architecture of the overall experiment is presented, and the conditions under which the experiment will be performed discussed.

C0.2-0005-18 DEVELOPMENT OF DIFFERENTIAL ABSORPTION LIDAR SYSTEM (DIAL) AT NATIONAL ATMOSPHERIC RESEARCH LABORATORY,INDIA

Karnam Raghunath, kraghunath@narl.gov.in

National Atmospheric Research Laboratory, Tirupati, India Madineni Venkat Ratnam, vratnam@narl.gov.in

National Atmospheric Research Laboratory, Tirupati, India Achuthan Jayaraman, jayaraman.achuthan@gmail.com National Atmospheric Research Laboratory, Gadanki, India Amit Patra, akpatra@narl.gov.in

National Atmospheric Research Laboratory, Tirupati, India

A DIfferential Absorption Lidar (DIAL) is developed at National Atmospheric Research Laboratory, Gadanki (13oN, 79oE), India for measurement of ozone concentrations to understand Upper Troposphere Lower Stratosphere (UTLS) exchange processes and statospheric ozone changes. The system measures ozone concentrations in the height regions of 2-45km. The system is developed in two channels, one for tropospheric ozone and another channel for stratospheric ozone monitoring taking ozone absorption crosssection in these regions into consideration. Accordingly ON-OFF wavelength pair of 289 and 299 nm is chosen for tropospheric ozone concentration measurements. The wavelengths are generated by pumping Raman Converter filled with Deuterium, Hydrogen and Argon with fourth harmonic of Nd:YAG laser. The energy at Raman shifted wavelengths are about 20mj with an efficiency of about 10%. The backscattered wavelengths from the atmosphere are collected by Newtonian feed telescopes in multiple receiver concept with 50cm effective aperture. The signals from the telescope are fed to a monochromator by an optical fiber. The monochromator is in Czerny Turner configuration and consists of 1200 lines/mm UV enhanced holographic grating with an efficicency of 60%. All the three wavelengths (266, 289, 299nm) are thus collected simultaneously by using three PMT detectors, with 60% efficiency, in different planes. The signal is then given to a data acquisition unit with analog and photon counting features. The analog and photon counting modes are chosen to give a high dynamic range to the system, from high intensity signal at lower altitudes to low intensity signals from higher altitudes. The analog signal is acquired at 16 bit resolution with sampling rate of 20MSPS. With Photon counting, maximum count rate of 250 MHz is achieved with temporal resolution of 25ns. The ozone concentration profile is obtained from the acquired signal by merging the two types of signals by standard methods. An

ON-OFF wavelength pair of 308-355nm is chosen for stratospheric ozone concentration measurements. The wavelengths are generated with XeCl based Excimer laser and third harmonic of Nd:YAG laser. Same receiver for both tropospheric and stratospheric ozone concentrations with appropriate changes in

optics is used. The tropospheric channel of the system is realised and is in testing stages. The design details, configuration of DIAL system and first observations will be presented.

C0.2-0006-18 OBSERVATIONS FROM RAYLEIGH DOPPLER LIDAR SYSTEM AT NATIONAL ATMOSPHERIC RESEARCH LABORATORY, INDIA

Karnam Raghunath, kraghunath@narl.gov.in

National Atmospheric Research Laboratory, Tirupati, India

A Rayleigh Doppler lidar has been developed at National Atmospheric Research Laboratory, Gadanki (13.5° N, 79.2° E) to measure winds in the height region of 10-50km. The system measures mean wind velocities in the height regions where Mie scattering is negligible. The Doppler lidar system is an incoherent system and uses edge technique for wind derivation. The system has an Nd:YAG laser operating at an energy of 600 mJ at 532 nm with 50Hz repetition frequency. The laser line is frequency stabilized and operates in single longitudinal mode. An optical fiber collects the return light from a 750mm diameter telescope and guides the signal to a servo stabilised Fabry-Perot Interferometer, scrambling the light homogenously. The signal is detected by means of Photo Multiplier Tubes (PMT) and the detected signal is given to a data acquisition unit. The FPI acts as amplitude discriminator and its specifications is determined based on the Doppler broadening of the Rayleigh backscattered light. Single Edge technique is adapted in which the backscattered signal is made to fall on the steep falling edge of the transmission characteristics of FPI and changes in the output amplitude is viewed proportional to wind velocities. Any wavelength and energy changes in laser is monitored continuously by a second channel in the receiver and the ratio between the FPI channel and monitor channel gives the parameter deviation. As the vertical velocities are smaller in magnitude and therefore difficult to measure, the study is limited to determine the two horizontal wind components namely Zonal and Meridional winds. The radial winds are calculated as a difference from the reference beam i.e vertical beam, and by knowing the sensitivity of the FPI for zero winds the horizontal winds are computed from beam tilt angle and radial winds. The system was operated on a few cloud free days and the results are presented. Intercomparison of the lidar winds with GPS Radio sonde balloons measured winds have shown good comparison.

C0.2-0007-18 THE DEVELOPMENT OF THE COMPREHENSIVE LIDAR STATION IN YANQING AND UPPER ATMOSPHERIC STUDY WITH LIDAR DATA

Wuhan Institute of Physics and Mathematics, Chinese Academy of Science, Wuhan, China

A lidar station was constructed in 2009 in Yanqing (40.5°N, 116.0°E), under the support of Chinese Meridian Project. This lidar is a dual -wavelength lidar, mainly for sodium and atmospheric density observations. The signal noise ratio of this lidar is so high, and then the observations with high spatial or temporal resolutions have been done. Later, based on this lidar, we successfully get the daytime sodium atom layer measurements, as well as the potassium layer detection. Otherwise, under the support of NSFC of China and the State Key Lab, an all solid sodium temperature/wind lidar and a Doppler wind lidar were also developed in recent years. And now we are working on the Ni, Ca+ and Ca layers detection with a new telescope and lasers. Thus a comprehensive lidar station has been developed in Yanqing. Very large amounts data have been obtained by the above lidars, and upper atmospheric study was done with these data. The study mainly includes the properties of mental layers study and gravity wave study: A series of low-thermospheric sodium layer cases were detected by Yanqing lidar and it aroused people's interest worldwide to study sodium layers at high altitudes; The maximum of the seasonal variation of potassium layer density is in winter, different with other potassium lidar observations; The gravity wave activity above Yanqing was obtained and was compared with other lidar results in China. Until now, based upon Yanqing lidar data, more than 30 papers has been published.

C0.2-0008-18 DEVELOPMENTS OF IMAGING LIDAR SYSTEMS RELEVANT TO STUDIES OF THE ATMOSPHERE AND TO SURVEILLANCE

David Rees, walnut1@easynet.co.uk

The Paradigm Factor, Robertsbridge, United Kingdom

A novel Imaging Lidar System has been developed and demonstrated, exploiting an innovative multi-element photon-counting photo-detector. The photo-detector has a 32 * 32 element anode proximity-mounted behind a photocathode and micro-channel plate stack. The data stream from the detector provides 100psec time-tagging of individual detected photon events - in addition to the identification of the detection channel. A 16 * 16 registration is currently used while the electronics for the full 32 * 32 unit is under development and testing. When used with an appropriate pulsed laser source, it replaces an individual optical fibre / photon-counting detector at the focal plane of a lidar receiving system, the Imaging Lidar System generates instantaneous 3-D images with a potential range resolution of as little as a few mm. Many tests of this novel Imaging Lidar System have been conducted with a "standard" Nd-YAG laser with 7 nsec pulse duration. Contrary to scanning Lidar systems exploited for autonomous vehicle operations, the range of the Imaging Lidar System is currently up to 3 - 5 km. Although the "extended" pulse duration of the current laser limits the potential range resolution of the Imaging Lidar, the initial results clearly demonstrate the potential of the Imaging Lidar System. A steering system is used to acquire and track specific targets of interest, however, no rapidlyscanning moving parts are required to construct its "instantaneous" images. The initial tests of the Imaging Lidar System have investigated the complex 3-D internal structures of fog banks and clouds, in addition to 3-D imaging of a range of targets.

C0.2-0009-18 THE NEW MERLIN MISSION FOR ATMOSPHERIC METHANE: QUALITY AND PERFORMANCE MONITORING

Mourad Hamidouche, mourad.hamidouche@dlr.de German Aerospace Center (DLR), Wessling, Germany Günter Lichtenberg, guenter.lichtenberg@dlr.de

DLR-IMF, Weßling, Germany Bernd Aberle, bernd.aberle@dlr.de DLR-IMF, Wessling, Germany

DLR, Institut für Methodik der Fernerkundung, Oberpfaffenhofen, Germany

After water vapor and carbon dioxide, methane is the most abundant greenhouse gas in the Earth's atmosphere. The new generation space borne Lidar mission MERLIN (Methane Remote Sensing Lidar Mission) will make very sensitive measurements of the methane distribution with unprecedented quality, i.e. 50km averaged methane columns with a precision of < 2%. After its launch, MERLIN will track down methane sources and sinks on a global scale. The instrument will be mounted on a satellite platform flying at 500 km altitude in a Sun synchronous orbit. The instrument will continuously send and receive a pair of pulses at two different wavelengths. One wavelength is centered on CH4 (methane) absorption line Λon 1645.552 nm. The second pulse is a reference at Λoff which is slightly shifted by a few tenths of nm. It is located where CH4 absorption is relatively smaller, but yet it is close enough to have a nearly identical interaction with the atmosphere and the reflecting surface. From the back-scattered signals of both pulses (on and off), the DAOD (Differential Absorption Optical Depth) of methane is measured, and thus its column density. We will present our approach and strategy to perform a key ground segment work component that supports MERLIN scientific activities which is the long-term monitoring of the Lidar instrument and its measurements. This function includes tracking the behavior of the instrument and its subsystems over time as well as verification and validation of the scientific data during the entire lifetime of the mission. It mainly monitors the instrument's performance in response to expected or unexpected natural events or technical situations. These are achieved by analyzing the measurement data and housekeeping information over different time frames. We will additionally show how our expertise in SCIAMACHY can be applied to MERLIN.

C0.2-0010-18 INVESTIGATION SPECTRAL IMAGE THE UPPER ATMOSPHERE OVER REGIONS WITH THUNDERSTORM USING DATA FROM THE SV "TERRA / MODIS"

Valentina Grichshenko, gri@gzi.kz

National Center of Space Researches and Technologies, JSC, Almaty, Kazakhstan

The results of the two-level experiment, including registration of the electric field in the surface layer during thunderstorm on TSCRS (Almaty) and synchronous image the top of the cloud cover over the test range from satellite "Terra / MODIS" are presented. Spectral image of the upper atmosphere over of the thunderstorm related to lighting discharge has been created. As a result of the processing of satellite images Terra / MODIS created a new index of "lightning discharge," which will be used to search for and investigation of optical phenomena (such as Sprites, Elves, Blue Jet) over the regions with thunderstorm activity. The developed technique of space picture processing will be used for studying optical phenomena above other regions too.

C0.2-0011-18 A MECHANISM TO EXPLAIN THE VARIATIONS OF TROPOPAUSE AND TROPOPAUSE INVERSION LAYER IN THE ARCTIC REGION DURING A SUDDEN STRATOSPHERIC WARMING IN 2009

Rui Wang, wangrui@pric.org.cn

Polar Research Institute of China, Shanghai, China

The mechanism to explain the variations of tropopause and tropopause inversion layer (TIL) in the Arctic region during a sudden stratospheric warming (SSW) in 2009 was studied with MERRA reanalysis data and GPS/COSMIC temperature data. During the prominent SSW in 2009, the cyclonic system changed to the anticyclonic system due to the planetary wave with wavenumber 2 (wave2). The GPS/COSMIC temperature data showed that, during the SSW in 2009, the tropopause height in the Arctic decreased accompanied with the tropopause temperature increase and the TIL enhancement. The variations of the tropopause and TIL were larger in higher latitudes. A static stability analysis showed that the variations of the tropopause and TIL were associated with the variations of the residual circulation and the static stability due to the SSW. Larger static stability appeared in the upper stratosphere and moved downward to the narrow region just above the tropopause. The descent of strong downward flow was faster in higher latitudes. The static stability tendency analysis showed that the strong downward residual flow induced the static stability change in the stratosphere and around the tropopause. The strong downwelling in the stratosphere was mainly induced by wave2, which led to the tropopause height and temperature changes due to the adiabatic heating. Around the tropopause, a pair of downwelling above the tropopause and upwelling below the tropopause due to wave2 contributed to the enhancement of static stability in the TIL immediately after the SSW.

C0.2-0012-18 THE RESULTS OF THE TURBOPAUSE ALTITUDE MEASUREMENTS BY THE ARTIFICIAL PERIODIC IRREGULARITIES TECHNIQUE

Ariadna V. Tolmacheva, tolmacheva@nirfi.unn.ru

Nizhny Novgorod State University, Nizhny Novgorod, Russia

Turbopause is the region of the atmosphere below which turbulent mixing dominates, and above it molecular diffusion predominates. The artificial periodic irregularities of the ionospheric plasma [1] (APIs-technique) allows determining the altitude of the turbopause region. The APIs are created in the antinodes of the power standing radio wave produced as a result of the interference of the incident wave and reflected one from ionosphere. The vertical scale of the APIs is equal to one half of wavelength of the transmitted wave. The APIs diagnostics is based upon observation of the Bragg backscatter of the pulsed probe radio waves from the periodic structure. The amplitudes and phases of the probe signals back scattered by the APIs are measured. Time for which the scattered signal amplitude diminishes in e-times after turning out powerful transmitter is the relaxation time of the APIs. The relaxation time above a certain level zt decreases with increasing altitude in accordance to the diffusion law. Below the level zt, the turbulent mixing begins, and zt is the upper boundary of turbopause. Observations of the APIs were carried out in the autumn of 2007-2014 using the SURA facility of (NIRFI-UNN)in Vasil'sursk (56.1°N,46.1°E). The results of determining of zt are presented here. 1)The boundary zt of turbopause was located in average between 97 km and 102 km. 2)The turbopause boundary could vary from 94 km up to 107 km. This altitudinal interval can be considered as the turbopause region.3) In those cases when in the overlying region the instabilities were developed [2], the temporal variations of the zt boundary near its mean level with period 10 min were observed. Their period was equal is closed to the period of internal gravity waves (IGW). This fact indicates the exchange of energies between IGW and the environment.

C0.2-0013-18 AN ANALYSIS ON THE ASCENT AND DESCENT RATES OF INFLATED METEOROLOGICAL BALLOONS

Venkata Appa Rao Bhamidipati, bvarmv@gmail.com Bangalore University, Bengaluru, India

Nagaraja Kamsali, kamsalinagaraj@bub.ernet.in Bangalore University, Bengaluru, India

Scientific ballooning is part of the exploration in meteorology and atmospheric science. Hydrogen or helium inflated rubber balloons or plastic balloons are released into the atmosphere as carriers of meteorological payloads for atmospheric sounding from the surface of the ground to the upper layers in the atmosphere reaching even 40 km height from mean sea level. The atmospheric data sensed in-situ, by the meteorological sensors tied to the ascending balloons, is collected by the ground based receivers. Apart from the meteorological data received, the ground based radar tracked or GPS based high temporal resolution balloon track data with time based positional coordinates of the balloons provide the fine details of rate of the ascent and descent of the balloon (after the balloon is burst attaining the apogee point in the atmosphere and falls down to the earth).

The buoyant balloon, inflated by the known amount of hydrogen or helium gas is supposed to ascend with a uniform rate of ascent, is perturbed by non-uniform scales of turbulent eddies embedded in the atmosphere causing irregular three dimensional motion of the balloon. This causes a fluctuating vertical profile of the rate of ascent of the balloon.

An analysis on this rate of ascent / descent of the meteorological balloons of various types is carried out. Various hidden details of the atmospheric motions and certain weather phenomena of different height scales are observed from the rate of ascent profiles. The extent of statistical smoothing required to obtain a reliable vertical profiles of the atmospheric parameters is studied and presented here.

C0.2-0014-18 HIGH RESOLUTION PROFILES OF ATMOSPHERIC PARAMETERS USING PISHAROTY GPS-RS INSTRUMENT

Venkata Appa Rao Bhamidipati, bvarmv@gmail.com Bangalore University, Bengaluru, India

Nagaraja Kamsali, kamsalinagaraj@bub.ernet.in Bangalore University, Bengaluru, India

During May-June 2017, short period upper air ascents were conducted from Bangalore University Campus (12.930N, 77.580E), Bengaluru, India, using indigenous GPS-RS instruments and ground based receiver developed by Indian Space Research Organization, Government of India. These instruments were flown by helium filled rubber balloons to collect in-situ data of standard atmospheric parameters (pressure, temperature, relative humidity and horizontal wind speed and direction: PTU and wind). Modulated data was transmitted to ground based receivers to provide the atmospheric data at 1Hz sample rate.

Thus the base raw data of an ascent provides time based altitude, latitude and longitude of the sonde and corresponding data of PTU along with information on number of GPS satellites in view and PDOP at very moment of the data. Using 1Hz sampled raw data and considering the response characteristics of the PTU sensors, suitable smoothing windows are devised for each atmospheric parameter to carry out moving average and obtain the smoothed output at 1Hz rate.

From the smoothed output, vertical profiles of the atmospheric parameters are obtained at high resolution height intervals (at least 300 meters) from the ground level to the level of balloon apogee for each ascent. The derived vertical high resolution data provides the base to study smaller-scale and high frequency atmospheric phenomena.

C0.2-0015-18 COMPREHENSIVE RESEARCH TO DESIGN ROCKET NOSE SHAPE FOR LEO SATELLITES

University of Petroleum & Energy Studies, Dehradun, India

From those big machines to those tiny microchips capable of storing 100 times more data, a time has come for advanced engineering techniques to make the world more developed. Now a day's scientists and engineers are trying to convert the abilities of big massive satellites into smaller Nano satellites. Sounding Rocket can be an alternative approach for launching such Nano-satellites into the Lower Earth Orbit. It offer scientists, a vehicle that will carry their instruments to almost any altitude they desire ranging from a few kilometers to thousands of kilometers. It can provide several minutes of observation time above the Earth's atmosphere, insulating the scientific instruments from much of the radiation, plasma, and micrometeoroid flux pervading outer space. With just a few minutes above the atmosphere it would be sufficient to make many fundamental discoveries about the nature of the Sun, the stars, and our celestial environment. Just like the fin of a rocket, nose cone shape plays more important role but the detailed research is not yet done resulting in the comparative study among the conventional nose shapes which are conical, Elliptical, Parabolic Series, Power Series or the HAACK series, which shape will result in the best performance under what circumstances for designing and building a sounding rocket capable of reaching Lower Earth Orbit. Nose cone is the key structural part which decides the overall performance of the sounding rocket and it should be chosen keeping in mind the following parameters: number of stages in the rocket, location of center of gravity, location of center of pressure, design of rocket fins and most importantly the material used and this depends on nose cone to nose cone. This paper deals with the detailed comparative study in support with experimental data and simulations of fluid flow over the nose cone and stress simulations due to the impact of high pressure and temperature. A six-degree-of-freedom study is made on the different nose shapes showing their individual importance and hand calculations are done to obtain exact dimensions using the respective nose cone equations and plotting coordinates and later joining those coordinates in CATIA to obtain a perfectly designed 3-D geometry of each conventional nose cone. Further, the generated 3-D geometry is extracted in "Fluent" and "Static Structural" in ANSYS for fluid flow and stress simulations. This paper discuss the effect of nose shapes on altitude performance depending upon the overall vehicle stability and bending moments about the payload rocket interface.

C0.2-0016-18 RENEWED POSSIBILITIES FOR STUDIES OF THE ATMOSPHERE BY SOUNDING ROCKETS FROM ESRANGE SPACE CENTER, SWEDEN

Krister Sjölander, krister.sjolander@sscspace.com Swedish Space Corporation, Solna, Sweden

From the 1960's to the end of the last millennium one or two Swedish sounding rockets were launched each year, not accounting for all the numerous metrology rockets in the same era.

Now the first three sounding rockets for studies in the atmosphere, within a new Swedish national balloon and rocket programme initiated by the Swedish National Space Board (SNSB) in 2012, have been successfully launched from Esrange Space Center. These three mark the beginning of a new era for advanced sounding rocket studies in the atmosphere from Esrange Space Center.

O-STATES 1 & 2, "Oxygen Species and Thermospheric Airglow in The Earth's Sky" by the Department of Meteorology at Stockholm University (MISU) and Swedish Space Corporation (SSC). A single payload, carrying a core of optical instrumentation, launched twice into different conditions during one single campaign with abbreviated on-site refurbishment between flights.

SPIDER/LEEWAVES, "Small Payloads for Investigation of Disturbances in Electrojet by Rockets" & "Local Excitation and Effects of Waves on Atmospheric VErtical Structure" by the Space and Plasma physics department of the Royal Institute of Technology (KTH), the Department of Meteorology at Stockholm University (MISU) and Swedish Space Corporation (SSC). Two missions combined in one payload carrying an instrumentation of in total 10 + 4 freeflying sensor sets being deployed into the atmosphere from one single rocket.

These will be followed by upcoming missions such as SPIDER-2 (accepted in January 2018).

This is a report on O-STATES 1 & 2, SPIDER/LEEWAVES and upcoming missions and flights as well as future possibilities for studies in the middle and upper atmosphere by sounding rockets from Esrange Space Center, Sweden.

C0.2-0017-18 A NOVEL APPROACH FOR THE DETERMINATION OF ELECTRIC FIELD VECTORS AND ITS USE FOR THE CALIBRATION OF ELECTRON TEMPERATURES AT 110 KM DURING STRONG ELECTRIC FIELD EVENTS.

Jean-Pierre St-Maurice, jp.stmaurice@usask.ca University of Saskatchewan, Saskatoon, Canada Lindsay Goodwin, lindsaygoodw@gmail.com ISAS, Univ. of Saskatchewan, Saskatoon, Canada Ashton S. Reimer, ashton.reimer@sri.com

SRI International, Menlo Park, California, United States

The analysis of very strong electric field data has allowed us to test a new technique to obtain the electric field vector by simultaneously sampling the E and F regions with AMISR radars on closely spaced magnetic field lines. A comparison with a reconstruction technique based on sampling the F region from various azimuths shows an excellent agreement between the two techniques. For weaker electric field events this implies that the technique could be used to find E region neutral winds once a multi-azimuth determination of the electric field based on F region measurements has been retrieved. The new technique has been used to calibrate the E region electron temperature at 110 km during strong electric field events. As is now well-known, the E region electron temperatures at 110 km can increase by as much as an order of magnitude or maybe more under very strong electric field conditions. For a particularly strong event we have established that the electron temperature was reaching more than 3500 K when the electric field was of the order of 175 mV/m. The observations were obtained during a smooth variation of the electric field and came from several beams that recorded the temperature independently, meaning that it was documented with an unusually large data sample for this kind of event.

C0.2-0018-18 A STATISTICAL STUDY OF THE RELATIONSHIP BETWEEN RIOMETER ABSORPTION SIGNALS AND PRECIPITATING ELECTRONS

Adam Kellerman, akellerman@igpp.ucla.edu UCLA, Los Angeles, California, United States

Ground-based riometers provide an inexpensive means to continuously remote sense the precipitation of electrons in the dynamic auroral region of Earth's ionosphere. Riometer's have been observing fluctuations in cosmic noise power for several decades, at multiple locations across the northern and southern hemisphere. These radio-wave power fluctuations are primarily caused by 1) the variation in power emanating from distant stars and galaxies, across the sky, and (2) absorption of those radio waves by free electrons in the charged ionospheric medium. The first case may be removed by suitable application of a quiet day curve, while the second is directly related to energy dissipation through electron-neutral collisions. With several spacecraft, and advanced numerical models, there exists an opportunity to further investigate how the precipitating electrons relates to the riometer signals, known as cosmic noise absorption. In this study, we present an analysis of how the precipitating electron spectrum relates to the observed riometer signals. A combined drift and conjunction analysis is employed, which brings together multipoint groundand space-based observations and numerical modeling. The result is a multi-year classification of riometer signals as related to geomagnetic activity, and a measure of how those signatures relate to the estimated electron precipitation during this time.

C0.2-0019-18 FIRST TIME DETERMINATION OF THE O+ ION TEMPERATURE ANISOTROPY IN THE F REGION UNDER STRONG ELECTRIC FIELD SITUATIONS AND IMPLICATION FOR THE O+ O COLLISION FREQUENCY.

Jean-Pierre St-Maurice, jp.stmaurice@usask.ca University of Saskatchewan, Saskatoon, Canada Ashton S. Reimer, ashton.reimer@sri.com

ISAS, Univ. of Saskatchewan, Saskatoon, Canada Lindsay Goodwin, lindsaygoodw@gmail.com ISAS, Univ. of Saskatchewan, Saskatoon, Canada

Under strong electric field conditions the F region ion temperature becomes anisotropic with larger temperatures perpendicular to the magnetic field than along it. We have quantified this anisotropy through the use of Monte Carlo simulations based on available collision cross section information. Perpendicular to parallel ion temperature ratios as high as a factor of 5 were expected. Using AMISR Incoherent Scatter Radar data based on a sampling of the same magnetic field lines from various directions during particularly strong electric field events, we have obtained a preliminary characterization of this anisotropy and have found to our surprise that it appears to be greater than predicted by theory, in turn indicating that the resonant charge exchange collision cross section used by researchers may actually be underestimated.

C0.2-0020-18 ES-LAYER CRITICAL FREQUENCY INVESTIGATION WITH INCREASED TEMPORAL RESOLUTION

Kamil Yusupov, kamil.usupov@kpfu.ru Kazan Federal University, Kazan, Russia Takashi Maruyama, tmaru@nict.go.jp

At present, it is well known that thin plasma layers are formed sporadically in the lower ionosphere, which are referred to as sporadic E (Es) layers and play an important role in the propagation of HF/VHF radio waves. Sporadic E layers often have very high electron concentrations. The main theory explaining Es-layer formation at middle latitudes is the wind shear model, which is based on the collection of positive ions moving in the Earth's magnetic field under the effect of a non-uniform horizontal wind at a certain height in the E region of the ionosphere. Internal gravitational waves (IGW) propagating in the atmosphere can create gradients of vertical velocity, which is necessary for metal ions collection into thin layers, which leads to formation of Es-layers with an increased electron concentration at middle latitudes. These layers (they can already be called "classical Es") exist for several hours, often they have a constant height and a horizontal scale from a few to hundreds kilometers and a heterogeneous structure. The main features of Es-layers have been well studied, in this paper the Es-layer critical frequency with an increased temporal resolution (1 ionogram per minute) is studied for a long time interval. The research algorithm consists in the precise definition of foEs using manual processing of A-maps. The analysis shows the quasi-periodic variations of foEs with a period of 5-15 min. Often the variation of foEs is similar to that of foF2. Additionally, the oscillation periods of foEs well correlate with the appearance of medium-scale TIDs in the F region of the ionosphere at mid-latitudes.

Temporally and spatially varying, dispersive, anisotropic and inhomogeneous nature of ionosphere makes it a major player in space weather. The determining parameter of ionosphere is the electron density. Yet, electron density cannot be measured or determined directly. Total Electron Content (TEC), which is defined as the line integral of electron density on a given ray path, is an observable parameter of ionosphere that can be estimated from earth based GPS receivers in a cost-effective manner as GPS-TEC. International Reference Ionosphere (IRI), and one of its extensions to plasmasphere, IRI-Plas, are the foremost acknowledged climatic models of ionosphere that provide electron density profile and hourly, monthly median values of critical layer parameters of the ionosphere for a desired location, date and time from 60 to 2,000 km and 20,000 km in altitude, respectively. One of the most important advantages of IRI-Plas is the possible input of GPS-TEC to update the background deterministic ionospheric model to the current ionospheric state. This option is highly useful in regional and global tomography studies and HF link assessments. IONOLAB group developed unique IONOLAB-TEC that includes IONOLAB-BIAS algorithm that forms the basis of 1-D TEC estimation, that is available at www.ionolab.org. Combining TEC in a given region using IONOLAB-MAP algorithm provides very high resolution interpolated TEC maps both in space and time. Using IRI-Plas as a background model and updating the ionospheric state using GPS-TEC, IONOLAB group developed Computerized Ionospheric Tomograpy, IONOLAB-CIT, and ray propagation algorithm, IONOLAB-RAY. Both IONOLAB-CIT and IONOLAB-RAY use state-of-the-art signal processing in a unique manner to fuse the model with GPS-TEC. The reconstructed state of ionosphere with IONOLAB algorithms allows the most reliable 1-D, 2-D, 3-D and 4-D imaging of electron density profiles and HF and satellite communication link simulations. This study is supported by TUBITAK 115E915 and joint TUBITAK 114E092 and AS CR 14/001.

C0.2-0022-18 IMPROVING THE TOPSIDE IONOGRAM SCALER WITH TRUE-HEIGHT (TOPIST) ALGORITHM TO AUTOMATICALLY SCALE ISIS/ ALOUTTE DIGITAL IONOGRAMS

Mohamed Osman, mohamed_osman1@student.uml.edu

University of Massachusetts Lowell, Lowell, Massachusetts, United States Robert Benson, robert.f.benson@nasa.gov

NASA/Goddard Space Flight Center, Geospace Physics Laboratory, Code 673, Heliophysics Science Division, Greenbelt, MD 20771, Maryland, United States

Abstract: [1][2] More than 1/2 million digital ionograms from the Alouette-2, ISIS-1, and ISIS-2 ionospheric topside sounders are now available as a result of the data restoration project for the original analog telemetry tapes recorded between 1965 and 1984 from 24 globally distributed ground stations as part of the International Satellites for Ionospheric Studies (ISIS) program designed primarily to produce vertical topside electron density profiles Ne(h). [3] The Topside Ionogram Scalar With True-Height (TOPIST) software was designed to automatically invert ISIS-2 topside ionogram traces into vertical electron-density profiles. It has been used for the automatic inversion of the ionogram reflection traces on more than 250,000 ISIS-2 digital topside ionograms into topside vertical electron density profiles Ne(h). However, it encounters problems that can lead to misleading results when processing ISIS-1 topside-sounder data due to the much higher altitudes reached by ISIS-1 (up to 3,500 km) compared to ISIS-2 (1,400 km). In this research we aim to improve the resonance detection process in TOPIST so as to get the best starting point at the satellite for the trace inversion leading to the correct topside Ne(h). Such improvements would allow to reap the greatest benefit from the current efforts being made to produce enhanced ISIS-1 digital topside ionogram files that are more suitable for automatic processing.

The Aguadilla Radio Array is intended for broad-band medium and high-frequency (MF/HF, roughly 2 to 25 MHz) radio and bistatic radar observations of the ionosphere. The array is being installed at the Interamerican University Aguadilla Campus, located in northwestern Puerto Rico. The array will consist of multiple antenna elements, each of which is a single active (electromagnetically short) crossed electric dipole. Elements in the core array are arranged in a partly regular and partly semi-random pattern providing a good distribution of baseline vectors, with 6-meter minimum spacing to eliminate spacial aliasing. In addition, five elements are located in a partial ring around the central core, providing a roughly four times expanded region in u-v space for improved image resolution and quality. Phase is maintained between the core and ring elements via cabled connections to a central location. Relocatable cable-less array elements will also be included, in which phase is maintained between elements by through the use of GPS-disciplined rubidium clocks. Primary scientific goals of the array are to study the mechanisms of ionospheric radio emissions stimulated by the Arecibo Observatory highpower high-frequency radio transmitter through the creation of high-resolution radio images of the emission region, and to study ionospheric structure and dynamics via wide-area coherent radar imaging of the ionosphere in collaboration with the University of Colorado and NOAA Versatile Interferometric Pulsed Ionospheric Radar (VIPIR), located at the USGS San Juan Observatory in Cayey, Puerto Rico. In addition to ionospheric research in collaboration with the Cayey and Arecibo Observatories, the goals of the project include the development of radio sounding, polarization, interferometry, and imaging techniques, and training of students at the university and high school levels.

C0.2-0024-18 A NEW AURORAL VHF RADAR FOR E-REGION IONOSPHERE STUDIES: FIRST RESULTS

Devin Huyghebaert, devin.huyghebaert@gmail.com University of Saskatchewan, Saskatoon, Canada Glenn Hussey, glenn.hussey@usask.ca

University of Saskatchewan, Saskatoon, Canada Juha Vierinen, jvierine@gmail.com

University of Tromsø, Tromsø, Norway

Jean-Pierre St-Maurice, jp.stmaurice@usask.ca University of Saskatchewan, Saskatoon, Canada Kathryn McWilliams, kathryn.mcwilliams@usask.ca University of Saskatchewan, Saskatoon, Canada

The Ionospheric Continuous-wave E-region Bi-static Experimental Auroral Radar (ICEBEAR) is an ionospheric radar located in Saskatchewan, Canada. The new radar was designed and developed at the University of Saskatchewan for E-region radar studies and became operational in December, 2017. The ICEBEAR radar system configuration is bi-static with the transmitter site about 170 km south-west of the receiver site, with the receiver site located close to the University of Saskatchewan in Saskatoon, Canada. The transmitter signal is a modulated continuous-wave radio signal with a center frequency of 49.5 MHz. The ICEBEAR radar applies modern advanced digital radio and/or software defined radio techniques, including highly accurate timing. A unique property of the radar is both high temporal and spatial resolution simultaneously. Nominal operation is to use a 10,000 symbol binary pseudo random code with a single symbol code length of 10 µs, although any radar code is possible. This gives a high spatial resolution of 1.5 km and a high temporal resolution of 100 ms. This, coupled with the interferometry abilities of the radar, allows for detailed 'maps' or 'images' of the E-region.

The scientific objectives of the ICEBEAR radar are for studies of E-region plasma irregularities and Magnetosphere-Ionosphere (MI) coupling. This paper presents initial results from the ICEBEAR radar and is focused on E-region plasma irregularities and meteor observations. Long term objectives are for MI coupling studies, such as the distribution and evolution of field-aligned-currents (FACs) from the magnetosphere, their relation to discrete arcs and their dynamics, ELF resonances, etc.

This paper presents first observations of E-region plasma irregularities from the new ICEBEAR radar and new insights into their physics.

C0.2-0025-18 IONOSPHERIC THREE-DIMENSIONAL GPS-TEC TOMOGRAPHY OVER JAPAN AND ITS STATISTICAL VALIDATION WITH IONOSONDE AND COSMIC OCCULTATION MEASUREMENTS

Measurement of ionospheric total electron content (TEC) by using ground-based GPS receivers is now widely used, which we refer to as GPS-TEC. In Japan, there is one of the densest network of GPS receivers that is named as GEONET (GNSS Earth observation network system) operated by Geospatial Information Authority of Japan (GSI). We have developed three-dimensional (3D) tomography analysis based on the constrained least-squares fitting method, and applied it to the GPS-TEC data from GEONET. We started the real-time analysis with 15 minutes interval and about five minutes latency since March 2016. In this paper we report that we analyzed most of GEONET data since 1996 by using the supercomputer of Kyoto University. We assign one core of the supercomputer to one-day analysis (15-minute interval from 200 GPS receivers), and achieved that processing time for one-year data was about 30 hours only. The results are statistically validated through comparisons with ionosondes and COSMIC occultation measurements. The maximum density from the 3D tomography showed good agreement with the foF2 parameter from ionosondes. We also found that the F2-peak of the 3D tomography density profile is lower in density, and higher in altitude compared with corresponding parameters from the COSMIC occultation measurements. These results of the 3D tomography analysis start being used by other ionospheric studies.

C0.2-0026-18 THE NIGHTTIME WINTER ANOMALY (NWA) EFFECT - A PROMINENT FEATURE OF THE MID-LATITUDE IONOSPHERE AT THE AMERICAN AND ASIAN LONGITUDE SECTORS

Norbert Jakowski, norbert.jakowski@dlr.de

Deutsches Zentrum fuer Luft-und Raumfahrt (DLR), Neustrelitz, Germany

GFZ German Research Centre for Geosciences, Potsdam, Germany

The ionospheric Nighttime Winter Anomaly (NWA) was reported at the first time more than three decades ago based on Total Electron Content (TEC) and vertical sounding data. The aim of this talk is to provide further observational evidence that the NWA effect occurs regularly under low solar activity (LSA) conditions at the American and Asian longitude sectors where the geomagnetic latitude exceeds the geographic latitude by more than 10° in the Northern and Southern hemispheres, respectively. The NWA effect will be analysed using Faraday rotation measurements on geostationary satellites, ground and space based dual frequency measurements on signals from Global Navigation Satellite Systems (GNSS) and vertical sounding measurements covering a time span of more than 40 years since the 70s. In particular, the derived TEC and peak electron density data (NmF2) but also the equivalent slab thickness illustrate clearly the occurrence of the NWA effect under LSA and geophysical conditions mentioned above. Of particular interest is the close coupling of the NWA with the Mid-Summer Nighttime Anomaly (MSNA) that becomes manifest in the Weddell Sea and Okhotsk Sea anomalies. The talk will convincingly demonstrate the close relationship of these different ionospheric anomalies. The observations confirm earlier explanations considering strong ionosphere-plasmasphere and associated interhemispheric coupling as the main origin. A coordinated modelling study will investigate the potential of dynamic forces such as thermospheric winds and electric fields to understand the coupling mechanism in detail.

C0.2-0027-18 THE NIGHTTIME WINTER ANOMALY (NWA) - CONTRIBUTIONS TO EXPLORE COMMON IONOSPHERE-PLASMASPHERE COUPLING MECHANISMS WITH THE MID-SUMMER NIGHTTIME ANOMALY (MSNA)

Deutsches Zentrum fuer Luft-und Raumfahrt (DLR), Neustrelitz, Germany Martin Kriegel, martin.kriegel@dlr.de

Deutsches Zentrum fuer Luft-und Raumfahrt (DLR), Neustrelitz, Germany

The ionospheric Nighttime Winter Anomaly (NWA) was first reported in the 1980-ies resulting from total electron content (TEC) data based on Faraday rotation measurements as well as due to vertical sounding data of ionosondes. It has been shown to be a regular phenomenon at mid-latitudes under low solar activity conditions for certain longitudinal sectors, which are characterized by large offsets between geographic and geomagnetic parallels. From the outset of this finding, it was supposed that the interhemispheric plasma transport and the plasmaspheric storage plays an important role for this effect. The thermospheric wind circulation and the global dynamo electric field act in favour of corresponding interhemispheric plasma fluxes. Immediately related to the NWA effect are midsummer nighttime anomalies (MSNAs), which are characterized by the fact that nighttime upper ionosphere plasma densities might be larger than daytime densities in the local summer. Particularly known in this respect are the Wedell Sea Anomaly (WSA) and the Okhotsk Sea Anomaly (OSA). By means of global numerical modelling of the coupled system of thermosphere, ionosphere-plasmasphere, and magnetosphere together with its electrodynamic interconnection, we will show the close relationship of these various anomalies. The causes for the NWA are plasmaspheric storage as well as interhemispheric transport processes. They appear to occur regularly during nighttime hours for certain longitudinal sectors, while they become prominent in particular during low solar activity conditions in the local winter ionosphere. Both the wind induced vertical transport of ionospheric plasma along the geomagnetic field lines and the action of magnetospheric and thermospheric

(dynamo) electric fields will be investigated by numerical simulations with respect to plasma fluxes into and out of the plasmaspheric reservoir.

C0.2-0028-18 GLOBAL MORPHOLOGY OF IONOSPHERIC SPORADIC E LAYER USING FS3/ COSMIC GPS RADIO OCCULTATION DATA

Lung-Chih Tsai, lctsai@csrsr.ncu.edu.tw

National Central University, Taoyuan, Taiwan, China Shin-Yi Su, sysu@jupiter.ss.ncu.edu.tw

National Central University, Tauyuang City, Taiwan, China Chao Han Liu, chliu2@gate.sinica.edu.tw

National Central University, Chung-Li, Tauyuang City, Taiwan, China

Ionospheric sporadic-E (Es) activity and global morphology have been studied using the 50-Hz signal-noise-ratio amplitude and excess phase measurements from the FormoSat-3/ Constellation Observing System for Meteorology, Ionosphere and Climate (FS3/ COSMIC) GPS radio occultation (RO) observations. The results are presented for data collected during the years of the last sunspot cycle from mid-2006 to the end 2017. The FS3/COSMIC generally performed more than 1000 complete E-region GPS RO observations per day, which were used to retrieve normalized L1-band amplitude standard deviation (SDL1) and relative electron density (Ne) profiles successfully. More or less 25 percent of those observations were identified as Es events based on SDL1 and peak SDL1 altitude criteria. We obtained that the peak SDL1 values of Es events are approximately and linearly proportioned to the corresponding logarithms of peak Ne differences. We also obtained five major zones in which the seasonal and/or local-time variations of Es-layer occurrence are markedly different. The five zones include two extended geomagnetic mid-latitude zones (15° < magnetic latitude (ML) < 55°, and -55° < ML < -15°), geomagnetic equatorial zone (-5° < ML < 5°), and two auroral zones (70° < ML, and ML <

-70°). The Es-event climatology, namely, its variations with each identified zone, season, and local time have been documented.

Two sources of ionospheric plasma irregularities are considered to be of major importance for disruption of satellite communication and navigation in polar regions: 1) the Gradient Drift Instability (GDI), and 2) the Kelvin Helmholtz Instability (KHI). GDI is driven by plasma drift across a steep plasma density gradient of the correct sign perpendicular to the magnetic field (drift in the opposite direction sets up polarization fields that stabilize vs. destabilize the plasma). KHI requires plasma flow-shears to dominate the structuring of irregularities. The Investigation of Cusp Irregularities (ICI) rocket program has been developed to investigate these plasma instabilities and formation scintillation irregularities. High resolution measurements are critical to get realistic quantities on the growth rates. In situ observations demonstrate that cusp ionosphere precipitation can give rise to km scale plasma structures on which grow rates are down to a few tens of seconds compared to earlier measures of ten minutes based on ground

observations. This has to do with the spatial resolution required for these measurements. Growth rates for the KHI instability is found to be of the same order, which is consistent with growth rates calculated from the EISCAT Svalbard Radar. I.e. both instability modes can be highly efficient in the cusp ionosphere, and they may co-exist. The ICI-5 rocket, which is the Norwegian contribution to the Grand Challenge Initiative - Cusp (https://www.andoyaspace.no/the-grand-challenge-initiative/), will carry two 4DSpace modules, from which 12 daughter payloads will be deployed in order to explore the 3D nature of plasma turbulence in the ionosphere cusp.

C0.2-0030-18 ESTIMATION AND STATISTICAL ANALYSIS OF THE 3D ELECTRON DENSITY GRADIENTS IN THE POLAR CAP F REGION USING THE ADVANCED MODULAR INCOHERENT SCATTER RADAR SYSTEM

Victoriya Forsythe, victoriyaforsythe@gmail.com

Geophysical Institute, University of Alaska, Fairbanks, Alaska, United States Roman Makarevich, rmakarevich@alaska.edu

University of Alaska Fairbanks, Fairbanks, Alaska, United States

Remote sensing of the polar cap ionosphere by the Advanced Modular Incoherent Scatter Radar (AMISR) system is utilized in this study to evaluate the 3D electron density gradients and to analyse their properties. Electron density gradients in the polar F region ionosphere are essential for structuring processes through the gradient-drift instability (GDI). The information about the typical strength of gradients is important for the theoretical studies and modeling of the GDI waves, but rarely available because of significant experimental challenges in evaluation of the gradients, particularly at small scales and in 3D. In this study, multi-point density measurements of the Resolute Bay Incoherent Scatter Radar (North) (RISR-N) working in a special high-spatial-resolution mode are employed to address the above question in a systematical manner. The 3D gradient vectors as well as their horizontal and vertical components are estimated for the first time and analyzed statistically utilizing a large RISR-N data set. The vertical components of the gradient strength vectors are larger than their horizontal counterparts, especially in the lower portion of the F region (below 220 km). The sharpness of the density gradients reveals a significant increase around magnetic midnight due to a decreased effect of the solar smoothing. Further, sharp density gradients occur during magnetically quiet time, possibly because of the presence of the polar holes and reduced plasma precipitation. The peak of occurrence for the horizontal components of the gradient strength vectors occur at 0.5×10−6 m−1, whereas 15.5% of horizontal gradients exceed 10−5 m−1. These gradients are strong enough for a direct generation of GDI waves at decameter scale (i.e. in linear regime), which implies that nonlinear turbulent cascade is not necessarily required for at least some GDI waves.

C0.2-0031-18 IMAGING STUDY OF METEOR ECHOES USING VHF INTERFEROMETRIC RADAR

Jenn-Shyong Chen, james.chen@mail.cmu.edu.tw China Medical University, Taichung, Taiwan, China Chung-Li radar group

Combined observation with multifrequency and multireceiver techniques implemented in a VHF interferometric radar was made in this study to investigate the meteor echoes occurring often in the height interval of 70 and 110 km. The experiment was carried out by using the Middle and Upper atmosphere Radar (MUR) with twenty receivers and five frequencies (46.25, 46.375, 46.5, 46.625, 46.75 MHz). MUR is operated and maintained by the Kyoto University, Japan. Adaptive constrained methods based on the Capon method were used with these multireceiver and multifrequency echoes, respectively, to determine the angle of arrival of the echoes and the range distribution of meteor heads and trails. Preliminary results show that the range and angular distributions of the intensity, retrieved from the multifrequency and multireceiver radar echoes, can identify the fragmentation and bifurcate trails of the meteors.

C0.2-0032-18 A NEW TECHNIQUE FOR MEASURING THE LIFETIME OF BURSTS OF ELECTRON PRECIPITATION FROM SOUNDING ROCKET MEASUREMENTS

Computational Physics, INC., Springfield, Virginia, United States

Sounding rocket measurements of electron precipitation typically have an inherent uncertainty in distinguishing between spatial and temporal variability. For very short bursts of precipitation in the cusp region a new technique is presented that allows an estimate of the lifetime of these events using sounding rocket optical measurements. Specifically, ratios (and absolute brightness) of the auroral red and green lines will vary significantly as the lifetime of the precipitation becomes short, due to the long and different lifetimes of these emissions; 110s for the red line and 0.8s for the green line. Thus, at very high altitudes (above 250 km or so) where both emissions are excited predominantly by electron impact on O atoms, the ratio of these two emissions will vary dramatically as the lifetime of the electron precipitation changes from long timescales (minutes) to short time scales (fraction of a second). This technique is explored using data from the RENU2 mission which was launched north from Andoya Rocket Range on December 13, 2015, reached altitudes above 400 km, and encountered intense cusp aurora in the vicinity of Svalbard. For this study data are used from the near-zenith pointing photometers which measured the red and green emissions, and data from other instruments which measured the electron spectra, electron temperature, and neutral winds all at high temporal resolution. Using these data along with modeling it is shown that the optical data suggests that many bursts were observed with lifetimes well below one second.

These results will be compared to estimates from the electron spectrometer and electron temperature data. The implication for the spatial extent of these bursts will also be discussed.

C0.2-0033-18 GADANKI ACTIVE PHASED ARRAY MST RADAR SYSTEM WITH ENHANCED CAPABILITIES FOR HIGH RESOLUTION ATMOSPHERIC OBSERVATIONS: SYSTEM DESCRIPTION AND INITIAL RESULTS

High power VHF radar operated at around 50 MHz is a powerful tool to probe the atmosphere with high temporal and spatial resolutions. Such radars have been used extensively for studying atmospheric dynamics in the troposphere, lower stratosphere and mesosphere including short and long term wind variabilities with application to satellite launch missions and developing model, understanding convective and precipitation systems, and probing ionospheric plasma irregularities that are detrimental for satellite-based communication/navigation applications. Realizing the importance of the atmospheric dynamics and ionospheric parameters, a major project has been undertaken to develop a high power active array MST radar with incoherent scatter capability at NARL. This radar system, operating at 53 MHz, uses the existing antenna array of the Indian MST radar built in the

early nineties. The new system uses solid state transmitters each feeding one antenna and multiple receivers for implementing various radar techniques, such as Doppler beam swinging (DBS), spaced antenna (SA), post beam steering (PBS), spatial domain interferometery (SDI) and imaging techniques. Importantly, the system is highly scalable depending on the scientific application. The system is also designed to be functional as an incoherent scatter radar for measuring height profiles of ionospheric electron density, electric field, wind, composition, and electron and ion temperatures, which are not being measured in our country. This paper is meant to describe various subsystems and capabilities of the newly developed high power active array MST radar and some sample results obtained thus far. This scalability provides new insight on the optimization of such radar for wind profiler applications.

C0.2-0034-18 OBSERVATIONS OF PLASMA INSTABILITY CONDITIONS USING THE RESOLUTE BAY INCOHERENT SCATTER RADARS

Leslie Lamarche, leslie.lamarche@sri.com

SRI International, Menlo Park, California, United States Roger Varney, roger.varney@sri.com

SRI International, Menlo Park, California, United States

We consider plasma instability mechanisms in the polar cap F-region, using observations from both the North and Canada faces of the Resolute Bay Incoherent Scatter Radars (RISR-N and RISR-C). A volumetric interpolation algorithm is used to determine both plasma density and 3D gradients at all points within the combined RISR fields of view. Gradients and plasma drift velocity vectors, found with this technique, determine the susceptibility of the background ionosphere to various instability mechanisms in the polar cap. The results may lead to better understanding of plasma irregularity growth and regions of scintillation in the dynamic polar cap.

C0.2-0035-18 OBSERVATIONS OF THE DIURNAL CYCLE OF OUTGOING SHORTWAVE RADIATION FROM THE DEEP SPACE CLIMATE OBSERVATORY

Jing Huang, hjhyr@cug.edu.cn

Institute of Remote Sensing and Digital Earth, Chinese Academy of Sciences, Beijing, China Huadong Guo, hdguo@radi.ac.cn

Institute of Remote Sensing and Digital Earth, Chinese Academy of Sciences, Beijing, China Hanlin Ye, yehl@radi.ac.cn

Institute of Remote Sensing and Digital Earth, Chinese Academy of Sciences, Beijing, China

Outgoing shortwave radiation at top of atmosphere is a critical component of the Earth's energy budget (ERB). It's dependent on the solar energy which is reflected from objects on the surface, therefore the shortwave radiation can be measured only in the sunlit side. The Deep Space Climate Observatory (DSCOVR) is designed to continually monitor the sunlit side of the Earth at L1, so it provides a great opportunity to measure shortwave radiation from DSCOVR. Due to the enough distance from L1 and the Earth, it can measure the full disk. DSCOVR is equipped with two Earth-observing instruments: the National Institute of Standards and Technology Advanced Radiometer (NISTAR) and the Earth Polychromatic Imaging Camera (EPIC). NISTAR measures irradiance of sunlit face of the Earth and the data can be used to study changes in Earth's radiation budget caused by nature and human activities. The Instrument can measure total radiation and longwave radiation, thus, the shortwave radiation can be caculated by the former subsects the latter. EPIC generates full disk image in one picture and take images in 10 narrow spectral ranges. In this paper, we mainly discuss the shortwave radiation observations acquired by the DSCOVR. According to the holistic view of the DSCOVR, we simulate the outgoing shortwave radiation data. We make three contributions. First, we establish a new coordinate system that is suitable for the outgoing shortwave radiation onboard DSCOVR. Second, we proposed a method to simulate the data viewed from DSCOVR. Finally, the change of diurnal cycle of the outgoing shortwave radiation is discussed.

C0.2-0036-18 NEW STRATEGY FOR AUGMENTING IWV ESTIMATIONS USING REMOTE SENSING SATELLITES AND GPS TROPOSPHERIC PATH DELAYS

Yuval Reuveni, yuvalr@ariel.ac.il Ariel University, Israel, Ariel, Israel

Anton Leontiev, leont.anton@gmail.com Ariel University, Israel, Ariel, Israel

Water vapor (WV) is one of the greenhouse gases which plays a key role in global warming, and since it's the most variable component in the troposphere, investigation of its distribution and motion is of great importance in meteorology and climatology studies. One of the main difficulties for using WV for such studies is that it varies constantly across the lower part of the atmosphere, thus leading towards considerable amount of efforts been devoted for improving its spatial and temporal estimation. Radiosondes have long been the main observing platform for monitoring WV in the atmosphere and are still widely used to provide WV profiles, however their sparse distribution and limited temporal resolution makes it almost impossible to precisely detect the horizontal boundaries between moist and dry air. Consequently, several other approaches emerged for estimating the amount of WV in the troposphere. Currently, most of the related studies uses WV estimations derived from only one technique such as tropospheric GPS path delays or multi-spectral reflected measurements from different meteorological satellites such as the METEOSAT series. Constructing WV maps using only interpolated GPS zenith wet delay (ZWD) estimations has a main disadvantage due to the fact that it doesn't take into account clouds which are located outside the integrated GPS paths.

Here, we present a newly developed methodology for augmenting Integrated Water Vapor (IWV) estimations using both remote sensing satellites and GPS tropospheric path delays. The suggested strategy is based first on the ability to estimate METEOSAT-10 7.3 μm WV pixel values by extracting the mathematical dependency between the IWV amount calculated using GPS ZWD and the METEOSAT-10 data. For the second phase, the strategy combines these two approaches, using also METEOSAT-10 10.8 μm channel, in order to evaluate the WV amount at cloudy conditions when preforming the interpolation between adjusted GPS station inside the network. The suggested approach has the potential to improve the accuracy of the estimated regional WV maps and allows to obtain the total water amount at the atmosphere, both in the form of clouds and vapor.

C0.2-0037-18 INCOHERENT SCATTER RADAR STUDIES OF PHOTOELECTRON-ENHANCED LANGMUIR WAVES IN THE F REGION

Frank Djuth, fdjuth@geospace-research.com

Geospace Research, Inc., El Segundo, California, United States Herbert Carlson, herbert.c.carlson@gmail.com

Utah State University, Arlington, Virginia, United States Liwei Zhang, ldzhang@geospace-research.com

Geospace Research, Inc., El Segundo, California, United States

Photoelectron-enhanced Langmuir waves detected with a large incoherent scatter radar provide information about the photoelectrons that generated them. At Arecibo Observatory the determination of the Langmuir wave frequency versus altitude yields extremely accurate measurements of F region electron density profiles (0.1% to 0.03% error bars in 2 s with 150 m resolution). The first results from wideband (electron phase energies of 5 eV - 51 eV), highresolution (0.1 eV) spectral measurements of photoelectron-enhanced Langmuir waves made with the 430 MHz radar at Arecibo Observatory are presented. In the F region, photoelectrons produced by solar EUV line emissions (He II and Mg IX) give rise to Langmuir wave spectral peaks/valleys. These and other structures occur within an enhancement zone extending from electron phase energies of 14 eV to 27 eV in both the bottomside and topside ionosphere. However, photoelectron-thermal electron Coulomb energy losses can lead to a broadened spectral structure with no resolved peaks in the topside ionosphere. The Langmuir wave energy spectra obtained in the enhancement zone exhibit a unique relation in that phase energy is dependent on pitch angle; this relation does not exist in any other part of the energy spectrum. The pitch angle results do not impact the accuracy of the electron density profile measurements noted above. Finally, large fluctuations in the difference frequency between the upshifted and downshifted plasma lines are evident in the 14 eV to 27 eV energy interval. At high phase energies near 51 eV the absolute intensities of photoelectron-excited Langmuir waves are much larger than those predicted by existing theory. The new measurements call for a revision/improvement of photoelectron-enhanced Langmuir wave theory in several key areas.

C0.2-0038-18 RETRIEVING CHARACTERISTICS OF INERTIA GRAVITY WAVE PARAMETERS WITH LEAST UNCERTAINTIES USING HODOGRAPH METHOD

Gopa Dutta, gopadutta@yahoo.com

Vignana Bharathi Institute of Technology, Hyderabad, India Vinay Kumar Palla, vinaypalla@gmail.com

Vignana Bharathi Institute of Technology, Hyderabad, India Salauddin Mohammad, salauddin.physics@gmail.com

India

We have analyzed wind velocities measured with high resolution Global Positioning System (GPS) radiosondes which have been flown continuously for 120 h with an interval of 6 h from Hyderabad. Hodograph method has been used to retrieve the Inertia Gravity Waves (IGW) parameters. Background winds are removed from the time series by detrending whereas polynomials of different orders are removed to get the fluctuations from individual profiles. Butterworth filter is used to extract monochromatic IGW component. Another filter Finite Impulse Response (FIR1) is tried in a similar manner to test the effects of filters in estimating IGW characteristics. Results reveal that the fluctuation profiles differ with the change of polynomial orders, but the IGW parameters remain same when Butterworth filter is chosen to extract the monochromatic wave component. The FIR1 filter produces results with a broader range. The direction of wave propagation can be confirmed with additional temperature information.

C0.2-0039-18 HF RADIO OBSERVATIONS OF THE F-LAYER RESPONSE FROM THE 21 AUGUST 2017 TOTAL SOLAR ECLIPSE

Juha Vierinen, jvierine@gmail.com University of Tromsø, Tromsø, Norway

The transit of the moon between the sun and earth disrupts the flux of ionizing radiation that maintains the daytime ionosphere. This produces a large "hole" in the ionosphere that allows HF (3 to 30 MHz) radio waves penetration in regions where reflection would normally occur. The HF radar and communications links which normally would cover 10's of MHz are now completely eliminated or reduced to only a few MHz. The ability to understand and model this process is validated using ground-to-ground propagation tests and first principles models of the ionosphere.

On 21 August 2017 the Total Solar Eclipse over the United States on a path from Oregon to South Carolina removed the Solar Ionization Radiation that maintains the ionosphere during the day. The eclipse process, which is like sunset without the atmospheric attenuation at dusk, had a large-area, time-dependent impact on the F-Layer ionosphere. High Frequency

(HF) diagnostic experiments to measure the changes of the ionosphere were conducted using

(1) propagation from Virginia to the West Coast of Florida and to the Yucatan Peninsula of Mexico and (2) Idaho Falls, ID to the Canadian ePOP satellite. Interpretation of the one-way, oblique ionogram and trans-ionospheric data provide implications for operations of HF systems and testing of the propagation through models of the disturbed ionosphere.

Data have been collected software defined receivers (SDR's) located on the ground in nearly identical propagation azimuths from a ground HF transmitter. Existing ground transmitters are available to make oblique ionograms. The ground receiver sites were chosen to place HF ionospheric reflection points centered along the path of the total eclipse that occurred on 21 August 2017. The satellite propagation tests with the Canadian ePOP satellite used an HF transmitter beam the interested the ePOP satellite orbit. As predicted by the NRL SAMI3 Model, the electron densities in the F-layer were substantially reduced at the time of totality. Using this same model, the computed electron densities provided the plasma refraction model for HF raytracing between the observation transmitter and receiver points. Range and Doppler frequency observations for ground to satellite paths through the eclipse are nearly straight lines. The HF ray path computations clarify the modes that were available for point-to-point propagation in the modified plasma during the eclipse. Disagreements of theory and measurements for both the frequencies bands and the group paths for HF propagation through eclipse region ionosphere need to be examined with regard to improving the predictive model. Several changes in the SAMI3 model that could improve the agreement with observations include (1) using a different neutral atmosphere model, and (2) coupling eclipse zone neutral winds and electric fields.

The data and theory comparison presented here were focused on the time of total eclipse at the crossing time for the propagation paths. The oblique ionogram data is analyzed throughout the total eclipse event to estimate the decay and replenishment of the ionosphere. The impact of an eclipse-like event has be examined for affect on both HF radar and communications systems. Similarly, the HF beacon transmissions through the low-density ionosphere at total eclipse were received on the ePOP satellite radio receiver instrument (RRI) in low-earth-orbit.

The observation technique using existing HF chirp transmitters and inexpensive SDR's deployed on the other side of a totality zone at ground and satellite platforms may be applied and enhanced during future eclipses. The oblique sounder technique is sensitive to horizontal gradients in the bottom side ionosphere. Multiple HF ray paths in the 2 to 20 MHz band can help locate the progress of the eclipse driven disturbance in the ionosphere. The spatially resolved disturbances may include both electron density reductions and gravity-wave associated density fluctuations.

C0.2-0041-18 CONVECTIVE STRUCTURES OF SODIUM LAYER IN LOWER THERMOSPHERE AT LOW-LATITUDE REGION

Jing Jiao, jjiao@spaceweather.ac.cn

National Space Science Center, Chinese Academy of Sciences, Beijing, China Guotao Yang, gtyang@nssc.ac.cn

National Space Science Center, CAS, Beijing, China

The atmospheric sodium layer normally occurs in the mesopause (80-105 km) region, but rarely in the lower thermosphere region (>105 km) at low latitude. We observed a kind of peculiar sodium layer in lower thermosphere at Haikou (19.99°N, 110.34°E)-the thermospheric convective sodium layer (TCSL) in a lidargram. The TCSL's sodium density unstably developed over time and appeared as several discontinuous convective shapes vertically. It is the first time convective sodium layer observed in the lower thermosphere region (105-120 km). Based on Haikou lidar data, we obtained 14 TCSL events during 180 nights from March 2010 to August 2012. Most of the apogees of the TCSL events are higher than 108 km. A TCSL event lasts several hours and is composed of several convective structures, with each vertical shape lasting 5-30 min. All TCSL events occurred during spring and summer, and generally appear near midnight (22:00-00:00 LT). The TCSL has potential regional feature and appears to be related to the thermospheric sporadic E (Es) layers, winds, and field-aligned ionospheric irregularities (FAI).

C0.2-0042-18 STUDY OF TROPOPAUSE HEIGHT FROM UPPER AIR OBSERVATIONS USING GPS-RADIOSONDES OVER BENGALURU, INDIA

Nagaraja Kamsali, kamsalinagaraj@bub.ernet.in Bangalore University, Bengaluru, India

Indian Space Research Organization, Bangalore, India

The upper air observations such as temperature, relative humidity and wind are most important meteorological parameters and are used as initialization of the analyses of several numerical weather prediction models for operational weather forecasting. Accurate measurements of the vertical structure of temperature and water vapour fields in the troposphere are extremely important for all types of forecasting, especially regional, local forecasting and now-casting. Several experimental campaigns were made using indigenously developed GPS radiosonde by ISRO that were intended to make upper air observations. The observations were carried out at 00 and 12 UT from Bangalore University, Bengaluru, India about 8-10 days prior to satellite launch by ISRO from Satish Dhawan Space Centre (SDSC), India, about 350 km away from Bengaluru. The GPS radiosondes were used for observing the variation of pressure, temperature, relative humidity and wind with one second resolution, and transmitting data on real-time to SDSC to run the NWP model for studying the stability of atmosphere before launch of satellites. The results show the variation of temperature, relative humidity, wind and height of tropopause over Bengaluru with seasonal variability. The horizontal movement of balloons with wind were compared with trajectories of HYSPLIT and the detailed analysis of wind during different seasons over the station is discussed.

C0.2-0043-18 WIND RETRIEVAL OF MIDDLE AND UPPER ATMOSPHERE BASED ON NON-FULL CIRCULAR FRINGE OF FABRY-PEROT INTERFEROMETER (FPI)

Houmao Wang, hmwang@nssc.ac.cn national space science center, Chinese Academy of Science, Beijing, China

Fabry-Perot Interferometer (FPI) has been used widely for wind measurements of the middle and upper atmosphere. To date, most of FPIs have been based on full-closed circular fringe, which needs 15-25 min to obtain a group of wind velocity (zonal and meridional). A data processing method is proposed for non-full circular fringe of FPI, which can support CCD with enough area of observations in several directions simultaneously. The method is focused on the center determination of non-full fringe. It includes radial cross-section, peak coordinate determination, and center calculation. Based on the calculated center, the fringe is annular summed. Then its radius is determined subsequently using Gaussian fitting. Finally, the wind is retrieved from the fringe radius. For validation, fringes from two ground-based FPIs were used, which are deployed in Kelan (38.71 °N, 111.58 °E) and Xinglong (40.40 °N, 117.59 °E) in China. The results retrieved from non-full fringes of FPIs were compared with that from full-closed circular fringe. The averaged wind deviation between them demonstrates reasonable difference with 5.38 m s-1 for 892.0 nm airglow emission, 5.81 m s-1 for 630.0 nm emission, and 3.03 m s-1 for 557.7 nm emission. Besides, wind results of Xinglong FPI are compared roughly with measurements of meteor radar which is deployed in Ming Tombs of Beijing (40.3°N, 116.2°E).

C0.2-0044-18 ANALYZE ON THE ARCTIC TROPOPAUSE WITH GNSS RADIO OCCULTATION MEASUREMENTS

Xin Wang, wangx2003@mail.iap.ac.cn

Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing, China Qiang Sun, franklin_sun@tom.com

Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing, China Daren Lu, ludr@mail.iap.ac.cn

Chinese Academy of Sciences, Beijing, China

Based on the GNSS (Global Navigation Satellite System) radio occultation measurements from the COSMIC mission (Constellation Observing System for Meteorology, Ionosphere, and Climate mission), the tropopause characteristics over the Arctic including height, temperature and pressure are analyzed during 2008-2010.The spatiotemporal structure of the Arctic tropopause is examined with two thermal definitions, the lapse-rate tropopause and coldest point. And the seasonal and intra-seasonal cycle is comprehensively studied. It shows that the prominent feature, a thick and unstable layer exists over the Arctic in winter frequently within the upper troposphere and lower stratosphere region. The spatial pattern transform from the symmetrical in summer to asymmetrical in winter. As well, some potential physical mechanisms are discussed.

C0.2-0045-18 REGIONAL ELECTRON DENSITY MODELING USING VARIOUS SPACE GEODETIC DATA

M.Mahdi Alizadeh, alizadeh@kntu.ac.ir

K.N.Toosi University of Technology, Tehran, Iran Saeed Zare, eng. saeedzare@gmail.com

K.N.Toosi University of Technology, Tehran, Iran Harald Schuh, schuh@gfz-potsdam.de

GFZ German Research Centre for Geosciences, Potsdam, Germany

The ionospheric delay is one of the most significant error sources in positioning using Global Navigation Satellite Systems (GNSS) data. Investigation and elimination of this effect requires an understanding of the distribution of ionospheric electron density. In addition, the ionosphere electron density and the Total Electron Content (TEC) along the line of sight between satellite and receiver are two important parameters in many fields, including ionosphere physics and telecommunication. The use of base-functions is one of the possible approaches for multi-dimensional modeling of the ionosphere parameters. On global scale, spherical harmonic functions are used to model the ionosphere parameters. However, on regional scale, using these functions will result in great errors. Therefore, in this research, the capability of using B-spline base-function along with Chapman profile function is investigated for regional ionospheric modeling over Iran. B-spline base-functions describe the electron density distribution horizontally and the Chapman profile function illustrates the electron density distribution in vertical. Due to the nonlinearity of mathematical model, the outputs of the International Reference Ionosphere (IRI-2012) model are used as initial values. The National Cartographic Center of Iran (NCC) has established a network of one hundred GPS stations: the Iranian Permanent GPS Network for Geodynamics (IPGN). The main task of the GPS stations is to collect and store raw GPS data and send them to Tehran processing center on a daily basis for final processing. The required data for our investigation are ground based measurements of the IPGN network and ionospheric information obtained from Formosat-3/Cosmic Radio Occultation data. We expect to increase accuracy and reliability of the final model by integrating these two observation techniques.

C0.2-0046-18 TEC VARIABILITY IN EQUATORIAL IONOSPHERE BASED ON BDS-GEO DATA

Lomonosov Moscow State University, Moscow, Russia

With the development of GNSS systems, the coherent multi-frequency L band transmissions are now available from a number of geostationary satellites. These signals can be used for ionospheric TEC estimations in the same way as widely used GPS/GLONASS signals, taking the advantage of almost motionless ionospheric pierce points [1]. Among these geostationary satellites, Chinese BDS-GEO are of the peculiar interest, providing the best noise pattern in TEC estimations, which corresponds to those of GPS/GLONASS systems [2].

In this work we discuss the capabilities of BDS-GEO data for studying ionospheric variability driven by space weather and meteorological sources at different time scales. Analyzing data from a number of IGS receivers we present seasonal variations of geostationary TEC in near equatorial ionosphere and its relation to Solar activity, as well as day-to-day TEC variability driven by Solar flares, geomagnetic storms, SSWs and typhoon activity. We also discuss seasonal and diurnal variations of ROTI index constructed from geostationary TEC estimations and its relation to the EPB occurrence. Our results show large potential of geostationary TEC estimations with BDS-GEO signals for continuous monitoring of low-latitude and equatorial ionosphere.

C0.2-0047-18 COMMUNICATION PARAMETERS DERIVED FROM IONOLAB-RAY ALGORITHM

Esra Erdem, esraerdem@aselsan.com.tr ASELSAN INC., Ankara, Turkey

Feza Arikan, arikan@hacettepe.edu.tr HACETTEPE UNIVERSITY, ANKARA, Turkey

The performance of HF communication depends on the realistic representation of ionosphere and wave propagation. IONOLAB-RAY is an algorithm, models propagation in anisotropic, inhomogeneous and time dependent ionosphere. Propagation path is calculated based on ray tracing, applied on the spherical 3D grid model of ionosphere. Appleton-Hartree formula is used to calculate refractive index for each step. Electron cyclotron frequency, collision frequency and geomagnetic field are the inputs of Appleton-Hartree formula, so that anisotropicity is represented. The ionosphere parameters for given time and position of each voxel are obtained from IRI-Plas, which can be assimilated by Total Electron Density (TEC) data to bring a realistic modification. IONOLAB-RAY also calculates attenuation, phase velocity, group velocity and time delay. Multiple runs can be applied for each set of inputs, so that propagation paths and communication parameters can be obtained for each run. In order to perform a reliable long distance communication the wave parameters like frequency, azimuth and elevation of the transmitted wave, attenuation and time delay are needed to be predicted properly. By analyzing the outputs of multiple runs of IONOLAB-RAY, optimum values of input parameters which make attenuation and time delay minimum, can be decided. There are some models like International Telecommunication Union's REC 533, Ionospheric Communication Analysis and Prediction Program, Voice of America Communication Analysis and Prediction Program, Ionospheric Communication Enhanced Profile Analysis and Circuit Prediction Program, and Advanced Stand Alone Prediction System that can be used to assist in frequency management and related endeavors. All these are based on statistical models of ionosphere, but they cannot support the needs of user, when the ionosphere behaves different than statistical models, especially under storm. The ionosphere model in IONOLAB-RAY is supported by the assimilation of TEC data into IRI-Plas, which most recent data is obtained in 15 minutes. Thanks to the structure of the algorithm, parameters for each ray path are calculated and the best communication performance is picked out between the scenarios. This feature of IONOLAB-RAY will be an alternative to Real Time Channel Evaluation method and serves for remote sensing. This study is supported by TUBITAK 115E915 and joint TUBITAK 114E092 and AS CR 14/001. Keywords: Ionosphere, IRI-Plas, HF Communication, Ray Tracing, IONOLAB.

C0.2-0048-18 SPACEBORNE L-BAND SAR IMAGING OF HIGH LATITUDE PLASMA DENSITY IRREGULARITY UNDER PARTICLE PRECIPITATION

Hiroatsu Sato, hiroatsu.sato@dlr.de

German Aerospace Center (DLR), Neustrelitz, Germany Norbert Jakowski, norbert.jakowski@dlr.de

Deutsches Zentrum fuer Luft-und Raumfahrt (DLR), Neustrelitz, Germany Jun Su Kim, junsu.kim@dlr.de

German Aerospace Center (DLR), Weßling, Germany

We present coordinated observations of the high latitude ionosphere simultaneously performed by Lband SAR satellite and incoherent scatter radar techniques. Small scale plasma density irregularity is studied by the Advanced Land Observation Satellite 2 L-band Synthetic Aperture Radar (SAR) and the European Incoherent Scatter (EISCAT) radar at Tromsø, Norway. Fine scale SAR imaging captured the horizontal distribution of image azimuth shift caused by Total Electron Content (TEC) gradients at enhanced ionization up to about 300 km height observed by the EISCAT UHF radar. The irregular electron density structure is characterized by subkilometer patches to tens of kilometer structures aligned in east-west direction. TEC gradients can be estimated by using single image SAR sub-band data. Results suggest that these observed structures are likely associated with density irregularities caused by precipitating electrons that cascaded into smaller scales by plasma instability processes. This study suggests that spaceborne SAR may achieve mapping of small scale TEC disturbances as a new ionospheric observation tool especially when combined with other measurements.

C0.2-0049-18 SPACED-RECEIVER GPS SCINTILLATION EXPERIMENT ON HIGH LATITUDES.

Marcin Grzesiak, pajak@cbk.waw.pl

Space Research Centre of the Polish Academy of Sciences, Warsaw, Poland Mariusz Pozoga, pozoga@cbk.waw.pl

Radiophysical Research Institute (NIRFI), Nizhny Novgorod, Russia

The dependence of the polarization spectra of the background ULF noise (0.5-20 Hz) on the level of geomagnetic activity is investigated on the basis of analysis of the long-term monitoring data at two reception sites separated at a distance of about 120 Km (460 W, 560 N and 43.630 W, 55.660 N.). It was found a decreasing of the value of fb in the polarization parameter (eps) spectrum at the beginning of the magnetic storm, when the Kp index increases. fb is the boundary frequency which separates the regions of the spectrum with left and right polarization of the noise. Also it was found that the Q-factor of the sub-IAP resonator (an ionospheric resonator at altitudes of 80 -300 km [1]) decreased during periods of the main phase of strong magnetic storms when the value of Kp index exceeds 7. This was expressed in a decreasing of absolute value of the (eps) and in a increasing of the value fb. fb increased above the frequency of the first Schumann resonance during periods of complete disappearance of the spectral resonance structure. The lowest values of fb (0.5-1 Hz) are observed in the recovery phase due to the large optical thickness of the ionospheric layers at the sub-IAP resonator altitudes. It was shown that there are no significant variations in the model polarization spectra calculated using the IRI-2012 during strong magnetic storms, which are observed in the experimental data. Profiles of electron density Ne at altitudes of 80-300 km were corrected basing on a comparison of the calculated spectra with the experimental spectra and with the ionosonde data. As a result, the calculated spectra close to the observed ones were obtained. The effect of horizontally inhomogeneous sporadic Es-layers arising during the recovery phase of a magnetic storm on the ULF noise spectra was investigated. A comparative analysis of the features of the ULF noise spectra during periods of high geomagnetic activity at different latitudes was also performed. Work was financially supported by the RFBR the grant №№ 18-05-00108, 18-42-520035.

We have developed an algorithm for detecting various forms of TEC fluctuations obtained by processing GNSS data. This method was used to map isolated disturbances related to the Travelling Convection Vortex (TCV). To detect TCV event we used magnetometer data from the ground arrays CANMOS and CARISMA. TEC fluctuations were obtained by processing GNSS data from IGS and UNAVCO stations. The use of array of GPS receivers enables us to monitor the origin and dynamics of disturbance and also to obtain its physical parameters such as its amplitude and propagation speed along the ionosphere. For processing GPS data we used an algorithm that allows to detect isolated TEC fluctuations of specific duration and to find their location (and the corresponding time) on the map. In this way we successfully find a considerable agreement between data from ground-based magnetometers and ionospheric TEC data. The formation of TCV is observed almost simultaneously in both data time series and it is localized in a very small map region. We observed the related disturbances in a form of an isolated peak in a TEC data with a rather high amplitude. It reveals itself as a very fast TEC variation with a derivative up to 5 TECu/min and higher near a place of the TCV formation. Away from an «epicenter» of TCV-related disturbance its amplitude slowly decreases. We have also estimated the horizontal propagation speed of ionospheric disturbance. The calculated speed values (about some km per sec) are in agreement with expected velocities of the ionospheric projection of the solar wind flow around the magnetopause and with those calculated using magnetometer data. These results proved that GPS/TEC technique is sufficiently sensitive to monitor a formation and movement of relatively fast phenomena such as TCV.

C0.2-0053-18 INFLUENCE OF DIFFERENT IONOSPHERIC DISTURBANCES ON THE GPS SCINTILLATIONS AT HIGH LATITUDES

Vladimir Belakhovsky, belakhov@mail.ru

Polar Geophysical Institute, Russian Academy of Sciences, Apatity, Russia Yaqi Jin, yaqi.jin@fys.uio.no

University of Oslo, Oslo, Norway Wojciech Miloch, w.j.miloch@fys.uio.no University of Oslo, Oslo, Norway

In this work we compare the influence of auroral particle precipitation and polar cap patches (PCP) on scintillations of the GPS signals in the polar ionosphere. We use the GPS scintillation receivers at Ny-Ålesund and Skibotn, both operated by the University of Oslo. The presence of the auroral particle precipitation and polar cap patches was determined by using data from the EISCAT 42m radar on Svalbard. We analyzed more than 100 events for years 2010-2017, when simultaneous EISCAT 42m and GPS data were available. For some of the events, the optical aurora observations on Svalbard were also used. We consider the following types of the auroral precipitation: i) the dayside and morning precipitation, ii) precipitation on the nightside during substorms, iii) precipitation associated with the arrival of the interplanetary shock wave. All considered types of ionospheric disturbances lead to enhanced GPS phase scintillations. For the polar cap patches, the morning and daytime precipitation (i), and precipitation related to the shock wave (iii), the phase scintillations index reaches values less than 1 radian. We observe that auroral precipitation during substorms leads to the greatest enhancement of the phase scintillation index (up to 3 radians). Thus, the substorm precipitation has the strongest impact on the scintillation of GPS radio signals in the polar ionosphere.

C0.2-0054-18 REACTION OF THE IONOSPHERE ON THE SOLAR ECLIPSE MARCH 20, 2015 ACCORDING TO OBLIQUE SOUNDING

Valery Uryadov, uryadov.vp@nirfi.unn.ru

Nizhny Novgorod State University, Nizhny Novgorod, Russia Fedor Vybornov, vybornov@nirfi.unn.ru

Nizhny Novgorod State University, Nizhny Novgorod, Russia

The results of studies of the response of the ionosphere to the solar eclipse on March 20, 2015 according to data of oblique sounding on the paths in the Eurasian region are presented. Solar eclipse on March 20, 2015 took place in condition of very strong magnetic storm in the phase of its recovery. To detect the response of the ionosphere to the solar eclipse, oblique chirp sounding was carried out on paths with various lengths and orientations. During the eclipse there was an increase in the amplitude of signal, especially noticeable on long Pevek (68.77N, 170.12E) - Yoshkar-Ola (56.62N, 47.87E) path with large coverage phase of 0.75 ÷ 0.77, when amplitude growth was 3 ÷ 5 dB. On the paths with the maximum phase coverage of 0.62 ÷

0.66 (Vasil'sursk (56.1N, 46.1E) - Nizhny Novgorod (56.1N, 44.1E), Vasil'sursk - Yoshkar-Ola, Mikhnevo (54,95N, 37,75E) - Yoshkar-Ola) the decrease in 1FMOF was 8 ÷ 10%. On the paths with maximum phase coverage of 0.73 ÷ 0.79 (Lovozero (68N, 35E) - Nizhniy Novgorod, Norilsk (69.36N, 88.36E) - Nizhny Novgorod, Lovozero - Yoshkar-Ola), the decrease in 1FMOF and 1F LOF was 12-14% and 22-33% respectively. According to measurements of the variations of MOF and LOF for the Eand F-layers, as well as the variations in the group delay time of the radio signals within the eclipse interval, wave disturbances with period within the limits of 25-50 minutes are recorded, which we associate with generation of disturbances during motion of the lunar shadow in the atmosphere of the Earth. At the same time during the eclipse, quasiperiodic variations of these parameters were observed on a number of paths with a period of 50 ÷ 80 min, but with the onset of variations before the eclipse began. Probably, these variations were the result of a superposition of disturbances from two sources associated with the ionospheric effects of a magnetic storm and a solar eclipse.

The work was supported by the Ministry of Education and Science of the Russian Federation under contract 3.7939.2017/8.9.

C0.2-0055-18 HEIGHT-LATITUDE STRUCTURE OF THE HAYASHI WAVES IN THE NORTHERN STRATOSPHERE AND LOWER MESOSPHERE IN WINTER

Vladimir Guryanov, vv@kpfu.ru

Kazan Federal University, Kazan, Russia

By using the winter (from November to March) ERA-Interim reanalysis geopotential, temperature, zonal and meridional wind data in the troposphere, stratosphere and lower mesosphere (up to the 0.1 hPa isobaric level) for 1979-2016, an analysis of the Hayashi spectra for wave disturbances with zonal wave numbers 1 k 10 and with periods from 2 to 156 days is performed. In this, contributions of the eastward traveling (E), westward traveling (W), propagating (P), stationary (S) and total (T) waves are estimated. The climatological spatial-temporal distributions Hayashi waves are integrated by wave number and frequency. As a result, were received integrated height-latitude distributions of waves E, W, P, S and T. It has been established that magnitude of wave energy for geopotential, zonal and meridional wind has two peaks: in the upper stratosphere - lower mesosphere and in the area of the tropopause. For temperature one peak also occurs in the upper stratosphere, and the lower maximum divided by tropopause on two parts: above and below the tropopause. The resulting empirical model of the height-latitude distributions of wave characteristics can be a contribution to the COSPAR International Reference Atmosphere (CIRA).

C0.2-0056-18 MAPPING OF ELECTRICAL CONDUCTIVITY FROM GROUND SURFACE UP TO THE IONOSPHERE DURING SEISMICALLY ACTIVE PERIOD

Suman Chakraborty, suman.chakrabarty37@gmail.com Indian Centre for Space Physics, Kolkata, India Sudipta Sasmal, meet2ss25@gmail.com

Indian Centre for Space Physics, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

It has been well established through numerous works that small-scale perturbations of lithospheric origin can induce significant anomalies at tropospheric and ionospheric heights. One of the possible sources is the unusual perturbation of the near-ground vertical atmospheric electrostatic field Ez prior to earthquakes. There are numerous channels through which the seismo-ionospheric coupling can happen, the most effective being the electromagnetic channel whose effects can be identified as perturbations in received VLF signal amplitude/phase and in the ionospheric total electron content (TEC). Although from both ground based and satellite observations, we have gained sufficient knowledge about the nature of such possible perturbations associated with seismo-ionospheric anomalies, the right justification of such observations becomes very difficult because of the lack of concrete theory that can explain all the physical processes associated with such coupling mechanisms. In this paper, we aim to investigate deeper into the physical background of the electromagnetic channel and to develop a self-explanatory model that can corroborate this mode of coupling between the lithosphere and ionosphere. We start by calculating the atmospheric conductivity right from the ground surface up to ionospheric F-region altitudes. The atmospheric conductivity is dependent on numerous factors and thus it is further divided into several segments. The conductivity in each segment are then coupled to generate a single altitude profile. This conductivity is then used to calculate the electrostatic potential and the electric field. Because of this electric field, the electrons in the ionosphere experience a drift velocity and using a linear relation, we calculate the electron density distribution. This electron density profile is then incorporated into the Long Wavelength Propagation Capability (LWPC) code to determine the VLF signal amplitude. We found that under anomalous radon emanation (twice as normal), the conductivity at 10 km altitude increases by 20% which influences the overall conductivity profile and in turn the sub-ionospheric radio signal propagation.

SPACE STUDIES OF THE UPPER ATMOSPHERES OF THE EARTH AND PLANETS INCLUDING REFERENCE ATMOSPHERES (C)

IONOSPHERIC DISTURBANCES OBSERVED THROUGH VERY LOW FREQUENCY RADIO WAVES (C0.3)

C0.3-0001-18 IONOSPHERIC STUDIES USING VLF RADIO WAVES: ACTIVITIES OF ICSP NETWORK

Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

Indian Centre for Space Physics is monitoring several stations with several types of VLF receivers and antennas for about 15 years. It conducted Indiawide summer and winter campaigns, monitors solar flares, eclipses, gamma ray bursts, soft gamma-ray repeaters, lightning etc. By treating the Earths atmosphere as a gigantic detector, it has computed effects of these perturbations on the ionosphere and compared with the observed results. Our theoretical results agree with observations. We also solved the inverse problem, namely, prediction of injected spectrum from the VLF amplitudes. One of our major directions is the study of anomalies in VLF signal amplitude prior to major earthquakes. Similarly, we study the generation of Atmospheric Gravity waves, OLRs at every instances of perturbations. Our scientist's multiple visits to Antarctica yielded very exciting results. We were able to explain the signal shape and amplitude using LWPC code and also using other atmospheric models. We present a comprehensive review on our activities in this very vibrant field of research area.

C0.3-0002-18 RECENT ADVANCES IN THE STUDY OF SUBIONOSPHERIC VLF WAVE PROPAGATION ANOMALIES

Jean-Pierre Raulin, raulin@craam.mackenzie.br

Universidade Presbiteriana Mackenzie/CRAAM, São Paulo, Brazil

In this paper we report new advances on the detection of propagation anomalies within the Earth-Ionosphere Waveguide (EIW) produced by external perturbations. These anomalies reflect changes of the subionospheric propagation properties of Very Low Frequency waves within the EIW. We use VLF data provided by known instrumental networks localized in South America like SAVNET, LAVNET, to monitor indirectly the properties of the lower ionosphere D-region. This technique allows to study and discuss the D-region response and dynamics to disturbances caused by the entry of energetic photons and particles from the outer space, or by the upward propagation of waves from the Earth atmosphere. Perturbations responsible include the long-term and transient explosive changes of the solar activity as well as fast outbursts from remote cosmic sources. Solar eclipses are also known to trigger changes of the structure of the EIW, and therefore produce detectable propagation anomalies. We will also show how the VLF technique can be used to describe the quiescent lower ionosphere boundary over specific regions like the South Atlantic Magnetic Anomaly. Finally, we also discuss how the use of this technique was important in some cases to provide early warnings of seismic activity.

C0.3-0003-18 THE EFFECT OF ERUPTIVE AR LOCATION ON THE VLF SIGNAL PERTURBATION, IS THERE AN ASYMMETRY?

Yasmina Bouderba, yasminabdb@hotmail.com

Center of Research on Astronomy, Astrophysics and Geophysics (CRAAG), Algiers, Algeria Samir Nait Amor, naitamorsamir@hotmail.com

CRAAG, Algiers, Algeria Mouloud Tribeche Algeria

In terms of geomagnetic disturbances, some works demonstrate that the solar flares producing CMEs from the western side of the solar disk affect the Earth's environment more than those coming from the eastern side. In our study, we used the VLF signal, propagating along the NRK-ALG GCP, to probe the ionospheric D region (60-90 km) in order to show the existence of Est/West asymmetry in terms of solar flares disturbances efficiency. For this, we correlated the amplitude of the signal perturbation with the heliographic coordinates of the NOAA active region (AR) that produced flares. The considered data are recorded during the rising phase of the solar cycle 24 and happened at solar zenith angle SZA = -45 °. The results show that the heliographic location of the eruptive AR plays an important role on the perturbation amplitude of the VLF signal. Indeed, we found that the eruptive AR from the northwest quadrant produced an important perturbation amplitude than the northeast one. On the other hand, this effect appears reversed where the Southeast eruptive AR produced more important perturbation amplitude than the southwest one.

C0.3-0004-18 ATMOSPHERIC INFLUENCES ON THE D-REGION IONOSPHERE AS REVEALED BY VLF/LF RADIO SIGNALS

Sujay Pal, amisujaypal@gmail.com

Indian Centre for Space Physics, Kolkata, India Yasuhide Hobara, hobara@ee.uec.ac.jp

The University of Electro-Communications, Chofu, Japan Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

We investigate atmospheric influences on the D-region ionosphere and possible connection between stratosphere and the D-region ionosphere over a different time-scale ranging from few days to several months using the Very Low frequency (VLF) radio signals from three transmitters (namely, the NLK, NPM and NWC) observed at several receiving stations within Japan. Variations of nighttime VLF signal amplitudes, total column Ozone density and stratospheric temperature at 31 km altitude show a strong connection for some propagation paths that exists for several months. We have also found stratosphere-ionosphere connection that exists for several days corresponding to a Sudden Stratospheric Warming (SSW) event of 2009. An enhancement of the nighttime VLF signal amplitude during the SSW event is noted. The strength of quasi 16-day planetary waves is also found to increase during the SSW event consistent with stratospheric temperature enhancement.

C0.3-0005-18 IONOSPHERIC DISTURBANCES: GYROKINETIC SIMULATION OF ION-TEMPERAT GRADIENT MODE IN THE PRESENCE OF RADIO-FREQUENCY WAVES

S Sen, ssen01@wm.edu

NIA/W&M/BSU, Hampton, Virginia, United States

In our earlier work (REDS Plasma Science and Technology,171, 52 (2016)) the ion temperature driven modes was studied in the presence of radio frequency waves by the use of Gyro-Kinetic simulation Code. It was shown that the radio frequency waves through the ponderomotive force can stabilize the ion temperature gradient instabilities and contrary to the usual belief no radio frequency wave induced flow generation hypothesis was required. This might be a major way to explain many unknowns in the space plasma and can also help to create a transport barrier in the fusion energy generation. In this work we extend our earlier work to investigate the consequent transport and report the effect on the ion turbulent diffusivity.

C0.3-0006-18 MODULATION OF VLF RADIO WAVE PROPAGATION BY SGR X-RAY BURST: NUMERICAL RECONSTRUCTION WITH MONTE CARLO SIMULATION

Sourav Palit, souravspace@gmail.com

Universidade Presbiteriana Mackenzie/CRAAM, São Paulo, Brazil
Jean-Pierre Raulin, raulin@craam.mackenzie.br

Universidade Presbiteriana Mackenzie/CRAAM, São Paulo, Brazil

Sudden outburst of ionizing radiation in form of X-rays and γ rays from astrophysical transient sources, such as, X-ray bursts from Soft Gamma Repeaters (SGR), Gamma-ray bursts (GRB) etc., in spite of their large distance from earth, are quite capable of modifying the plasma properties in earth's lower ionosphere and middle atmosphere. One such series of bursts from SGR J1550-5418 on 22 January 2009, detected in Very Low Frequency (VLF) network across South America is investigated. A sincere effort has been made to reconstruct the observed modulation in VLF signal amplitude during the series of bursts using computer simulation, starting from observed spectra and lightcurve of the incident photons. A state of the art Monte Carlo simulation method using GEANT4 detector simulation program, an ion chemical evolution scheme and Long Wave Propagation Capability (LWPC) code, based on mode theory of VLF propagation in earth-ionosphere wave guide are used for the modeling of the VLF amplitude modulation detected in two distinct receiver points in South America. We gain some valuable insight in the modeling process on the chemical and dynamic evolution of lower ionosphere and part of the atmosphere below it under the ionizing influence of those extragalactic transient sources.

C0.3-0007-18 PROBING SOLAR FLARE AND GEOMAGNETIC STORM DRIVEN MAGNETOSPHER IONOSPHERE DYNAMICS IN D-REGION IONOSPHERE USING VLF SIGNAL PROPAGATION CHARACTERISTICS

Victor U.J. Nwankwo, victornwankwo@yahoo.com Anchor University, Lagos, Nigeria

Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

Manchester Metropolitan University, Manchester, United Kingdom

When propagating in the Earth-ionosphere waveguide, the amplitude and phase of VLF/LF radio signals are sensitive to changes in the electrical conductivity of the lower ionosphere. This characteristic makes it useful in studying sudden ionospheric disturbances, especially those related to prompt X-ray flux output from solar flares and gamma ray bursts (GRBs). However, strong geomagnetic disturbances and/or storm conditions are known to produce large and global ionospheric disturbances, which can significantly affect VLF radio propagation in the D region ionosphere. In this paper, using the data of three propagation paths (at latitudes 40-54°), we characterise and analyze the trend in variations of VLF radio signal under varying solar and geomagnetic space environmental conditions to identify flare and geomagnetic footprints on the D region ionosphere via the diurnal signature of the signal.

In this study we analyze sub-ionospheric very low and low frequency (VLF/LF) measurements related to solar flare disturbances. The x-ray flux measurements are NOAA GOES data. We show variations in VLF/LF amplitude and phase of eight radio paths for the time span 2009- 2017, in particular single X-class solar flare events and statistical results during this solar cycle 24 period.

The VLF/LF receiver is located in Graz, Austria, the mid-latitude station is part of a multistation network [1]. The main scientific objective of the facility is seismo-electromagnetic investigation in combination with lithosphere-atmosphere-ionosphere coupling (LAIC) mechanisms. To reach the goal non-seismic influences on the signals have to be considered, e.g. meteorological effects [2] or complementary results from satellite measurements [3]. For the upper boundary of the VLF waveguide, the Dand E-region, the electron densities of the semiempirical Faraday-IRI (FIRI) model are considered [4-6].

At the moment more than 400 VLF/LF amplitude and phase fluctuation events from C/M/Xclass flares are in the database and a reliable monitoring service is established. As outlook, we further investigate to disentangle natural and artificial VLF/LF amplitude and phase variations in order to characterize and classify various sources, among them possible modulations related to seismic events.

The variation of nonequilibrium two-temperature plasma parameters and the population of the orbital degenerate states of the Rydberg complexes, respectively, are observed in the D and E layers of the ionosphere during periods of increasing solar activity. This directly affects the operation of any of the systems based on the use of GPS radio signals passing through these layers. Since direct observation of the D and E ionospheric layer states is almost impossible, the question of using the GPS system for plasma diagnostics in these layers comes to the fore. First of all, we are talking about observations of changes in the concentration and temperature of electrons at an altitude of 110 km and the determination of their altitude profiles in the range of 60-110 km, where, as is known, GPS signals undergo the greatest distortions. To this end, it is possible to use the satellite radio occultation method, which is widely used for solving climatic problems. This method makes it possible to determine the altitude profiles of GPS signal propagation delays. However, the solution of the inverse problem will allow qualitatively, but not quantitatively, to obtain the altitude profiles of the considered quantities from relative measurements. Therefore, the obtained results should be supplemented with ground-based measurements of the power of the incoherent radiation flux at 1.4 and 5.0 GHz, which will ensure the reliability of the detected electron concentrations and temperatures. The control will be realized with the help of the code "Rydberg". Repeated GPS satellite measurements can provide information about the macroscopic dynamics of D and E layers containing Rydberg complexes and free electrons. In particular, we are talking about changing the thickness of the luminous layer in time, which leads to an additional contribution to the formation of GPS errors. In this connection, the obvious question arises about the dependence of the power of the incoherent radiation flux on time. It should also be noted that the influence of positioning errors on the passage of a satellite signal and the formation of microwave and infrared radiation is exerted by the entire luminous layer 80-110 km thick in the vertical direction and up to 1000 km and more when it propagates along, i.e. as a result of an integral contribution to the overall picture of the phenomenon. Therefore, certain details of the internal heterogeneities of the layer structure do not play an essential role here. Naturally, they are of interest for special questions of radiophysics and ionospheric dynamics, but do not have a noticeable effect on GPS signals received on Earth.
This work was supported by the Russian Foundation for Basic Research (grant no. 16-05-00052-a).

C0.3-0010-18 THE CONTRIBUTION OF THE D LAYER OF THE IONOSPHERE TO THE VALUE OF THE TEC DURING X-RAY FLARES

Iliya Ryakhovskiy, ryakhovskiy88@yandex.ru

Institute of Geospheres Dynamics RAS, Moscow, Russia Boris Gavrilov, gavrilov@idg.chph.ras.ru

Institute of Geospheres Dynamics RAS, Moscow, Russia Susanna Bekker, susanna.bekker@gmail.com

Institute of Geospheres Dynamics RAS, Moscow, Russia

The measurements of the total electronic content (TEC), carried out from the data of global navigation satellite systems, are an important parameter for studying the processes taking place in the ionosphere. At the same time, it is assumed that the F region of the ionosphere makes a significant contribution to the value of the TEC. However, the results of many studies have revealed that during powerful X-ray flares, the ionization of the D region can increase substantially, reaching values of 106 cm-3. In this paper, we analyze the changes in the parameters of the D region during flares of the M and X classes. At the same time, the ionization of the D layer is compared with the experimental values of the TEC obtained at the «Mikhnevo» geophysical observatory (54 ° 57’N, 37 ° 46’E). It is shown that a correct interpretation of TEC variations under powerful heliogeophysical perturbations requires taking into account the ionization of the lower ionosphere.

C0.3-0011-18 IONOSPHERIC GPS TOTAL ELECTRON CONTENT RESPONSE OVER INDIAN REGION TO THE SOLAR FLARES OF THE YEAR 2017

S.N. Bose National Centre for Basic Sciences, Kolkata, India

A solar flare is a sudden brightening in an active region usually near a complex group of sunspots of the photosphere, which produces immediate increases in the ionospheric ionization of varying degrees at different heights, together called the Sudden Ionospheric Disturbances (SIDs) or the ionospheric solar flare effects. The disturbances have important effects on radio communications and navigations over the entire radio spectrum reviewed that SIDs were generally recorded as the sudden increase in total electron content(TEC). The Total Electron Content

(TEC) is computed from Global Positing System (GPS) from Bangalore (13.02°N, 77.57°E) and

Hyderabad (17.417°N, 78.551°E) IGS station for the year 2017. We study the effect of solar flares on ionosphere during the year 2017 which is a high solar active year. We analysis the enhancement of TEC during the solar flare for Indian region. The magnitude of enhancement in ionospheric TEC to be dependent on the class of the flare. We compare the TEC variation with D-region electron density characteristics as obtained from theoretical simulation.

One of the important aspects of lightning phenomena at low altitudes is that the energy release is happening in highly localized regions of space leading to formation of spark channels with temperatures 25000K and plasma with electron densities exceeding 1017cm3 TLEs (sprites, jets, elves, halos) are associated with the electromagnetic connections and interactions between atmosphere, ionosphere and magnetosphere and with strong thunderstorm activity. DEMETER has clearly shown, that thunderstorms and sprites can affected the ionosphere even at altitude of its orbit (680km). The Swarm constellation comprises 3 identical satellites. Two of them are operating on the circular, polar orbits with initial altitude 460. Third one has also circular orbit, but with altitude 530. The orbits of the first 2 satellites are in almost the same plane, but third one is close to be perpendicular to the first two. The payload containing Vector Field Magnetometer, Absolute Scalar Magnetometer and Electric Field Instrument among other allows to study the effects in the ionosphere generated by thunderstorms. The discussion of the observation done by DEMETER and Swarm satellites will be given in the presentation. The discussion of the cross correlation between the ground based (WERA system) and Swarm registration of the ULF/ ELF waves related to the thunderstorm and TLE's will additionally be presented.

C0.3-0013-18 TOPSIDE IONOSPHERIC EFFECTS OF THE ANNULAR SOLAR ECLIPSE OF 15TH JANUARY 2010 AS OBSERVED BY DEMETER SATELLITE

Surya Kanta Maji, suryamaji@gmail.com Indian Centre for Space Physics, Kolkata, India

Sandip Kumar Chakrabarti, chakraba@bose.res.in

Indian Centre for Space Physics, Kolkata, India Sujay Pal, myselfsujay@gmail.com

Indian Centre for Space Physics, Kolkata, India

We studied effects of the annular solar eclipse of 15th January 2010 on the topside ionosphere using the DEMETER satellite data. Measurements of the electron-ion density and electron temperature by the ISL (Instrument Sonde de Langmuir) and IAP (Instrument Analyseur de Plasma) instruments on board the DEMETER satellite during the eclipse time over the low latitude (40) Indian ocean area are presented. We found decrease in electron density by about 25% and decrease in ion density by about 33% from the reference orbits at the altitude of the satellite (660 km). Electron and ion temperatures were also found to have decreased by 200- 300 K at the same altitude. Instead of simple decrease as in ion density, electron temperature showed a complex wave-like oscillation as solar eclipse progressed. Electron density decreased to a minimum value before the maximum obscuration and again started to increase before passing through another minimum at the time of maximum obscuration. Both the minima are located at the 10 degree geomagnetic latitude. Variations of electron and ion densities were found to follow the average solar illumination experienced by the satellite and its conjugate points at satellite altitude on the magnetic field lines connecting these two points, while the electron temperature showed no such correlation.

C0.3-0014-18 COORDINATED SATELLITE OBSERVATIONS OF THE VLF TRANSMISSION THROUGH THE LOW LATITUDE D-LAYER USING EMISSIONS FROM LIGHTNING

Robert Holzworth, bobholz@ess.washington.edu

University of Washington, Seattle, Washington, United States Abram Jacobson, abramj@u.washington.edu

University of Washington, Washington, United States Robert Pfaff, robert.f.pfaff@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States Roderick Heelis, heelis@utdallas.edu

University of Texas at Dallas, Richardson, Texas, United States

Both ray theory and full-wave models of Very Low Frequency transmission through the ionospheric D-layer predict that the transmission is greatly suppressed near the geomagnetic equator. We use data from the low-inclination Communication/Navigation Outage Forecast System satellite to test this semi-quantitatively, for broadband Very Low Frequency emissions from lightning. Approximate ground-truthing of the incident wavefields in the Earth Ionosphere Waveguide is provided by the World Wide Lightning Location Network. Observations of the wavefields at the satellite are provided by the Vector Electric Field Instrument aboard the satellite.

We find that in most broadband recordings of radio waves at the satellite, very few of the lightning strokes result in a detectable radio pulse at the satellite. However, in a minority of the recordings, there is enhanced transmission of Very Low Frequency lightning emissions through the D-layer, at a level exceeding model predictions by at least an order-of-magnitude. We show that kilometric-scale D-layer irregularities may be implicated in the enhanced transmission. This observation of sporadic enhancements at low magnetic latitude, made with broadband lightning emissions, is consistent with an earlier review of D-layer transmission for transmission from powerful man-made radio beacons.

C0.3-0015-18 ULF ELECTROMAGNETIC FIELD IN THE UPPER IONOSPHERE EXCITED BY LIGHTNING

Vyacheslav Pilipenko, pilipenk@augsburg.edu

(1) Space Research Institute (IKI) Russian Academy, Moscow, Russia Evgeniy Fedorov, enfedorov1@yandex.ru

Institute of Physics of the Earth Russian Academy of Sciences, Russia Nikolay Mazur, ngmazur@mail.ru

Institute of Physics of the Earth Russian Academy of Sciences, Russia

We have theoretically estimated ULF spectra on the ground and at ionospheric altitudes in the ULF frequency range 0.1-6.0 Hz excited by a lightning stroke in the lower atmosphere. This frequency band comprises typical frequencies of the ionospheric Alfven resonator and the ionospheric wavegude. The spectra of both horizontal magnetic and electric components are shown to reveal the spectral resonant structure in the upper ionosphere. The feasibility of the detection of ULF response in the upper ionosphere to isolated lightning stroke and stochastic thunderstorm activity by low-orbiting satellites with magnetic or electric sensors onboard is discussed.

C0.3-0016-18 MODELING OF DIURNAL VARIATION OF VLF SIGNAL OVER SIGNAL PROPAGATION PATHS OF VARIOUS CHARACTERISTICS

New Zealand

Characteristics of Very Low Frequency (VLF) signal depends on solar illumination profile across the propagation path. For a short path, the illumination range may not be so wide in general but for a longer or a medium path, the solar zenith angle varies widely over the path and this has a significant influence on the propagation characteristics. To study the effect, we monitor the diurnal variation of VLF narrow-band signal for a number of propagation paths, such as, NWC-IERC, NWC-Maitri (70.75°S, 11.67°E), NWC-Bharati (69.4°S, 76.17°E), NWCMaitri, VTX-IERC, VTX-Maitri, VTX-Bharati, VTX-Dunedin etc. The full illumination or full darkness over the path mostly occurs for shorter paths, where for longer paths partly illuminated conditions are there which influences the model interferences taking place in the propagating signal. To analyze and simulate those paths, first we categorize them according to their lengths. Then we reproduce the signal variations of VLF signal using solar zenith angle model coupled with Long Wavelength Propagation Capability (LWPC) code. We divided the whole path into several segments and computed the solar zenith angle (χ) profile. We assumed a linear relationship between the Wait's exponential model parameters, such as, effective reflection height (h1), steepness parameter (β), and χ. The h1 and β values were later used in the

LWPC code to obtain the VLF signal amplitude at a particular time. The same procedure was repeated to obtain the whole day signal. Nature of the whole day signal variation from the theoretical modeling is also found to match with our observation to some extent mainly for short propagation paths. For longer paths, the matching is moderate because of the limitations in the code.

C0.3-0017-18 MODELING OF THE LOWER IONOSPHERIC RESPONSE AND VLF SIGNAL MODULATION DURING A TOTAL SOLAR ECLIPSE USING IONOSPHERIC CHEMISTRY AND LWPC

S.N. Bose National Centre for Basic Sciences, Kolkata, India

The Earth is enveloped by a zone of ionized plasma known as the ionosphere that protects us from the outside hostile environment caused by several solar and extra-terrestrial phenomena. Solar eclipse is one such perturbing agent that exhibits a unique feature of controlled diminution and regain of the incoming solar radiation due to partial or total blocking of the Sun by the lunar disc for a definite period of time. It also provides an excellent opportunity to study such effects as we get to know its time of occurrence much prior to the actual event and thus can prepare ourselves accordingly. One such event (Total Solar Eclipse) took place in the Indian subcontinent on July 22, 2009. Indian Centre for Space Physics (ICSP) conducted a week long campaign to record Very Low Frequency (VLF) data transmitted from the VTX transmitter (18.2 kHz) before, during and after the eclipse from more than a dozen places. All the locations exhibited shifts in the received signal amplitude, either positive or negative depending on the propagation path-length. The interpretation of such effects on VLF signals require a better understanding of the D region ion chemistry which is not available till date. This paper is intended to use our previous knowledge of some of the parameters and explain the observations. We start from calculating the obscuration function and determination of the variation of ionizing radiation during the eclipse period. This information is then used in calculating the rate of ionization. We then incorporate a D-region ion chemistry model to determine the height profile of electron density. These electron densities are then used in the Long Wavelength Propagation Capability (LWPC) code to find the VLF signal modulations. In this process, we have been successful in two ways. First, we have been able to reproduce the trend of signal variation (both positive and negative) from a pure theoretical approach and second, we have been able to improve our knowledge of some of the D-region ion-chemistry parameters.

C0.3-0018-18 THE INFLUENCE OF SEISMIC ACTIVITY ON THE DEVELOPMENT OF THE FORMATION OF HETEROGENEITIES IN THE SPORADIC LAYER ES

Obid Alimov, alimov38@mail.ru

Institute of Astrophysics, Tajik Academy of Sciences, Dushanbe, Tajikistan Tatyana Kalashnikova, kruzhevnica_48@mail.ru

Institute of Astrophysics, Tajik Academy of Sciences, Dushanbe, Tajikistan

Based on the study of small-scale in homogeneities in the night sporadic layer of Es, which arose in the August 1986 earthquake preparation periods with a magnitude of 4.0 < M <5.5 and an epicentral distance of R < 250 km, criteria for large ranges of translucency of the sporadic layer Es - f0Es 2fbEs were developed. To detect seismo-ionospheric disturbances, the method of superposition of the epoch is used, since this method is more informative in the detection of seismo-ionospheric effects. It is shown that the duration of the existence of intense continuous small-scale irregularities of the sporadic Es layer in the seismically active period with the f0Es 2fbEs translucency criterion is from 2 to 6 hours 1-2 days before the earthquake. It is assumed that the duration of manifestation of seismo-ionospheric precursors can be associated with deformation processes in the earth's crust and various faults, that the duration of manifestation of seismo-ionospheric precursors can be as well as dissimilar properties of the environment of the epicentral zone.

C0.3-0019-18 IONOSPHERIC PERTURBATIONS IN D-LAYER DETECTED AT VLF RECEIVER IN TASHKENT

Bobomurat Ahmedov, bahmedov@yahoo.com

Ulugh Beg Astronomical Institute, Tashkent, Uzbekistan

Monitoring of the Dand F-layers of ionosphere over Central Asia territory is being performed on the permanent basis starting year 2008 when one Very Low Frequency (VLF) receiver and two SuperSID receivers. The results obtained at Tashkent VLF station are applied to earthquake electromagnetic precursors, lightning, and Solar flares and to ionospheric disturbances originating from gamma ray flares of Soft Gamma-Ray Repeaters connected with evolution of strongly magnetized neutron stars believed as magnetars. Several Solar events are observed and the analysis has shown that there is simultaneous correlation between the times of change of amplitude of the waves and the Solar flares. Features of the lightning discharge generated by radio atmospherics are studied and its effectiveness in D-region ionosphere diagnostics is examined.

C0.3-0020-18 NUMERICAL MODELING OF POSSIBLE LOWER IONOSPHERIC ANOMALIES ASSOCIATED WITH THE MAY 12, 2015 NEPAL EARTHQUAKE

Suman Chakraborty, suman.chakrabarty37@gmail.com Indian Centre for Space Physics, Kolkata, India Sudipta Sasmal, meet2ss25@gmail.com

Indian Centre for Space Physics, Kolkata, India Tamal Basak, tamalbasak@gmail.com

Gobardanga Hindu College, Gobardanga, India

We present the results obtained from numerical simulation of the anomalies in the sub-ionospheric Very Low Frequency (VLF) signal amplitude received at Ionospheric and Earthquake Research Centre and Optical Observatory (IERCOO under Indian Centre for Space Physics), India associated with a major earthquake on May 12, 2015. The signal is received from the JJI transmitter operating at 22.2 kHz before, during and after an earthquake of Richter scale magnitude M =

7.3 occurring at a depth of 18 km at southeast of Kodari, Nepal on May 12, 2015 at 12:50 PM local time. This earthquake was followed by numerous aftershocks, a major aftershock being on May 16 with magnitude M = 6.7. From the received signal, it is observed that the terminator times, both sunrise and sunset (SRT and SST) shifted towards nighttime, thereby increasing the overall day length. The maximum increase in day length is found to be 32 minutes. These shifts in terminator times is numerically reproduced using the Long Wavelength Propagation Capability (LWPC) code. The path under study (JJI-IERCOO) bears a special feature that it has a high longitudinal variation and thus the solar illumination is different at different points on the path. This is taken into account by varying the ionospheric parameters, namely, the effective reflection height (hi) and the steepness parameter (β) according to the true movement of the terminators over the path. In this way, the signal amplitudes on a normal non-seismic day is reproduced. Next, to generate the additional effects due to the seismo-ionospheric coupling processes, additional modifications are made for that portion of the propagation path that lie inside the seismically affected area. By doing this, we have been able to regenerate the observed increase in day length. The maximum shift obtained from simulation is 25 minutes. We also found that increase in the ionospheric parameters resulted in the observed night ward shifts of the terminator times. We further calculated the electron density profiles using the Waits formula and found the electron density to decrease significantly before the earthquake.

C0.3-0021-18 THERMAL ANOMALIES: AS LITHOSPHERIC - TROPOSPHERIC INTERACTION AND PRECURSORY EFFECT OF LARGE EARTHQUAKE

Soujan Ghosh, soujanghosh89@gmail.com Indian Centre for Space Physics, Kolkata, India

S.N. Bose National Centre for Basic Sciences, Kolkata, India

We present the effect of air ionization during and prior to large earthquakes. During and prior to large earthquakes, radon discharge from different cracks and faults is the primary source of air ionization. The newly formed ions coagulates with water molecules and drastic change in air temperature and relative humidity is observed. These changes extend up to the increment of surface latent heat flux also and can be observed though various remote sensing satellite as well as in many ground based measurements of surface air heat and other thermal parameters. We are presenting the change in air temperature, relative humidity and surface latent heat flux parameters as a precursory phenomenon of Nepal 2016 and Honsu 2011 Earthquakes. As the thermal excitation profile is different for land and sea, we compare the variation of pre-seismic thermal parameters for Nepal (land) and Honsu (near sea) earthquakes.

C0.3-0022-18 POSSIBLE CORRELATION OF VLF SIGNAL ANOMALIES WITH SEISMIC ACTIVITIES

Suman Ray, sumanray07@gmail.com Gobardanga Hindu College, Gobardanga, India

Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India Sudipta Sasmal, meet2ss25@gmail.com

Indian Centre for Space Physics, Kolkata, India

There are several types of natural disasters. Among them, earthquake is one of the greatest disasters which may cause loss of lives and property damages. The physical processes leading to seismic activities are very complex. The occurrence of earthquake is connected to Earth's crustal dynamics which involves in movements of tectonic plates. The conventional way for the prediction of earthquakes is related to monitoring of crustal structure movements, but this method has not yet yield satisfactory results. Furthermore, this method failed to provide any short-term predictions. In last few decades, scientists noticed that before any seismic event takes place, some disturbances in the ionosphere take place also. Thus, it is suggested that ionospheric disturbances may be used as precursors of earthquakes [e.g. Pulinets et al., 2004]. Since VLF radio waves propagate inside the wave-guide formed by lower ionosphere and Earth's surface, this signal may be used to identify ionospheric disturbances due to seismic activity. We have analyzed VLF signals to find out the correlations, if any, between the VLF signal anomalies and seismic activities. We have done both the case by case study and also the statistical analysis using a whole year data. In both the methods we found that the night time amplitude of VLF signals fluctuated anomalously three days before the seismic events. Also we found that the terminator time of the VLF signals shifted anomalously towards night time before few days of any major seismic events. We calculate the D-layer preparation time and D-layer disappearance time from the VLF signals. We have observed that this D-layer preparation time and D-layer disappearance time become anomalously high 1-2 days before seismic events. Also we found some strong evidences which indicate that it may possible to predict the location of epicentres of earthquakes in future by analyzing VLF signals for multiple propagation paths.

C0.3-0023-18 STUDY OF THE CHARACTERISTICS OF SMALL, INTERMEDIATE AND LONG VLF RADIO WAVE PROPAGATION PATHS BY USING LONG WAVELENGTH PROPAGATION CAPABILITY (LWPC) CODE

Sudipta Sasmal, meet2ss25@gmail.com

Indian Centre for Space Physics, Kolkata, India Tamal Basak, tamalbasak@gmail.com

Amity University, Kolkata, India

Suman Chakraborty, suman.chakrabarty37@gmail.com Indian Centre for Space Physics, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India James Brundell, jbrundell@gmail.com

New Zealand ropagation of Very Low Frequency (VLF) radio signal through the Earth-Ionosphere waveguide strongly depends on the plasma properties of the ionospheric D layer. Solar extreme ultraviolet radiation plays the central role in controlling physical and chemical properties of the lower ionospheric layers and hence determining the quality and propagation characteristics of a VLF signal. The nature of interference among different propagating modes varies widely with the length of the propagation path and also with the direction of propagation. The number of waveguide dominating modes, modal attenuation and mode conversion strongly differ from path to path. Also the ionospheric reflection parameters as prescribed by Wait's two component model (h' and) differ. Here we present a comparative studies of the modal attenuation and ionospheric parameters for three types of path lengths using Long Wavelength Propagation Capability (LWPC) code. We use (a) short path VTX-IERC (GCP < 2000 km), (b) intermediate paths NWC-IERC, NWC-Bharati and NWC-Dunedin (2000 km < GCP < 6000 km) and long paths VTX-Maitri, NWC-Maitri, VTX-Bharati and NWC-Bharati (GCP > 6000 km) for out study. By examining the path dependency of the waveguide modes, we also study the spatial distribution of VLF signal over the propagation path theoretically and compare the results with observed data.

C0.3-0024-18 SOME THOUGHTS OF CURRENT AND FUTURE PROBLEMS IN IONOSPHERIC PHYSICS

Bruce Tsurutani, bruce.tsurutani@jpl.nasa.gov JPL, Pasadena, California, United States

There are a considerable number of current and future problems in ionospheric physics. I will try to mention a few of them to stimulate discussion and thought about what they are and how to approach them. Besides the topics that I am able to mention, I suspect that the panel members and audience will be able to come up with many more.

C0.3-0025-18 OBSERVATION OF ANOMALOUS BEHAVIOUR OF THE D-LAYER PREPARATION OR DISAPPEARANCE TIME DUE TO EFFECT OF THE SOLAR FLARES BY ANALYZING VLF SIGNALS.

Suman Ray, sumanray07@gmail.com Gobardanga Hindu College, Gobardanga, India Sourav Palit, souravspace@gmail.com

Universidade Presbiteriana Mackenzie/CRAAM, São Paulo, Brazil Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

The ionosphere is a very important part of the Earth's upper atmosphere. Electrons are not distributed uniformly in the ionosphere and depending on this factor, ionosphere has different layers namely D, E and F. Different ionospheric layers generally exist during day and night time. During day-time when the main source of the ionization of the ionosphere is Sun, the lower most layer of ionosphere is D-layer. But during the night-time when Sun is absent and cosmic ray is the main source of the ionization of the ionosphere, this D-layer disappears and E-layer becomes the lower most region of the ionosphere. "Very Low Frequency" (VLF) is one of the bands of the Radio waves having frequency 3-30KHz, which propagates through the Earth-ionosphere wave-guide. In relation to propagation of radio waves through ionosphere, low mass and high mobility cause electrons to play a vital role. Normally, patterns of VLF signal depend on regular solar flux variations. However, during solar flares extra energetic particles are released from Sun, which makes the changes in the ionization of the ionosphere and these changes can perturb VLF signal amplitude. Usually if a solar flare occurs during any time of day, it only affects the amplitude and phase of the VLF signals. But in the present work, we found the if the flare occurs during D-layer preparation / disappearance time, then it will not only affect to amplitude and phase of the VLF signals but also to terminator times of VLF signals. We have observed that the sun set terminator time of the VLF signals shifted towards night time due to the effect of a M-class solar flare which occurred during the D-layer disappearance time. The shift is so high that it crossed 5σ level. To explain this observed effect, we are now trying to a make model using the ion-chemistry and LWPC code.

C0.3-0026-18 STUDY OF PRE AND CO-SEISMIC TROPOSPHERIC AND IONOSPHERIC ANOMALIES

Sudipta Sasmal, meet2ss25@gmail.com

Indian Centre for Space Physics, Kolkata, India Suman Chakraborty, suman.chakrabarty37@gmail.com Indian Centre for Space Physics, Kolkata, India

Gobardanga Hindu College, Gobardanga, India

Understanding of pre and co-seismic phenomena is extremely complicated as the physical mechanism behind this study is nonlinear and multiparametric. It is well established that the lithospheric change due to seismic hazards can be coupled with atmospheric and ionospheric perturbations by using various channels. These are mainly chemical, thermal, acoustics, and electromagnetic phenomena which act as link between the lithosphere, atmosphere and ionosphere and this is known to be the Lithosphere-Atmosphere-Ionosphere Coupling (LAIC) mechanism. We present the signature of such mechanism during and prior to various seismic events. We present both statistical and case-wise studies. We mainly emphasized the effects during the historical Honsu earthquake in March 2011 and Nepal earthquake in 2015 and simultaneously study all the possible thermal, acoustic and ionospheric anomalies associated with these to earthquakes. We also present a methodology proposed for LAIC mechanism and the intermediate results of the different stages of the coupling mechanism.

C0.3-0029-18 MAGNETOSPHERIC-IONOSPHERIC COUPLING DURING THUNDERSTORM LIGHTNING AS OBSERVED FROM ENERGETIC PARTICLE BURST

Sudipta Sasmal, meet2ss25@gmail.com

Indian Centre for Space Physics, Kolkata, India Suman Chakraborty, suman.chakrabarty37@gmail.com Indian Centre for Space Physics, Kolkata, India

Tamal Basak, tamalbasak@gmail.com Amity University, Kolkata, India

Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

Lightning discharge originates electromagnetic waves propagating in all directions through the earth-ionosphere waveguide. A small component of such wave enters into the earth magnetosphere and propagates along the magnetic field lines as a whistler mode wave. During this propagation, they interact with radiation belt electrons and due to this some of the electrons get trapped or precipitated in the ionosphere as a sporadic patch of excess ionization. The trapping electrons increase the count rate in the inner radiation belt and this particle count rate can be measured through satellite observation. Low Earth Orbital (LEO) satellite observes count rate of energetic particle burst in Van Allen Radiation Belt. We mainly use data from Medium Energy Proton and Electron Detector (MEPED) instrument associated with NOAA 15 satellite for this study. We use WWLLN network and global lightning data to get the lightning information. A significant increase of count rate is observed in MEPED data. We also corroborate our findings by the excess ionization due to lightning as observed from amplitude modulation of Very Low Frequency radio signal.

C0.3-0030-18 EVOLUTION OF VLF AND TEC IRREGULARITIES OBSERVED DURING THE BARDARBUNGA VOLCANO OF 2014/2015.

Karan Bhatta, karangeorgia@gmail.com

Nepalese Center for Research in Physical Sciences (NCRPS), Kathmandu, Nepal

In this work, we analyze the VLF/LF waves of 37453.125 Hz transmitted from Grindavik, Iceland and received in the Kiel Longwave Monitor, Germany for the year 2015. We did a graphical analysis of the variation of the intensity of the field associated with the VLF/LF of the respective frequency along with time. The comparison of sunrise and sunset terminator and D-layer formation times with the standard 2 lines was done. For several months of 2014 and 2015, several anomalies were observed in both the sunrise terminator times and D-layer formation times. We also calculated the trend, dispersion and night time fluctuations associated with VLF waves and found some irregularities. This gives us a possibility that the changes in these timings might be associated with intense volcanic activity which was observed in Iceland which stated off in Bardarbunga in August 2014 and ended only on 27th February 2015. In addition, we also analyzed the evolution of TEC during the volcano using the data of various GPS satellites in Iceland.

Equatorial ionosphere over the South American continent has been observed by ground-based GNSS receiver network (TEC maps and de-trended TEC), Ionosondes (foF2 and hF) and optical imagers (OI6300 and OH). Mesospheric gravity waves (MGW), medium scale ionospheric disturbances (MSTID), and equatorial plasma bubbles (EPB) were successfully monitored. Occurrence of MSTID and MGW in the afternoon to evening followed by EPB was observed in several cases in September 2015. We found that both MGW and MSTID were related to strong tropospheric convection activities. Also found was that the inter-bubble distances are approximately same to the horizontal wavelength of MSTID, suggesting that MSTIDs could be one of the possible forcing mechanism to generate EPBs.

Records of the standard ionospheric characteristics provided by ionosondes are analysed to detect distinct variations associated with the overpassing Large Scale Travelling Ionospheric Disturbances (LSTIDs). When observed in a sufficiently dense network of ionosondes, such as the one currently operating in the European region, coherency of the Fourier harmonics of these variations across different observatory sites can be inspected. If presence of such coherent variations is established in the time series, their cross-correlation analysis provides the horizontal phase velocity (azimuth and magnitude) of the LSTID propagation in the region, obtained under assumption of the planar wave propagation. Data analysis during periods of the geomagnetically disturbed conditions indicates presence of distinct LSTID signatures with dominant periods of 70-90 minutes and dominant southward velocities of 300 - 600 m/s. The agreement of the results deduced with independent data sources and technique confirms the presence of LSTIDs, potentially attributed to the auroral activity. These results confirm the potential of the correlation method for monitoring LSTID activity in support of the recently started TechTIDE research project and its practical applications.

C1.1-0003-18 ON THE ONSET CONDITIONS AND SEEDING OF EQUATORIAL PLASMA BUBBLE IN INDIAN SECTOR

Equatorial plasma bubbles (EPB) are highly detrimental for satellite based communication and navigation applications in the low latitude region. Identifications of the precursors and finding the onset conditions for the growth of the Rayleigh-Taylor instability are the key for developing successful prediction model for the occurrence of the equatorial plasma bubble. Attempts have been made to study the role of gravity waves initiation of equatorial plasma bubble using various radio optical and in-situ observations, which include large-scale wave structure (LSWS), satellite trace (ST), multi-reflected echoes (MREs) as the signature of seed perturbations. In the recent past using ionosonde observations it has been shown that temporal variability of the F-layer height can be used as seed perturbation of gravity wave origin for determining the onset of equatorial plasma bubble. Considering the likely potential of such observations in developing prediction capability of equatorial plasma bubble, we have examined ionosonde data from the Indian longitudinal sector. Results show that the occurrence/ non-occurrence of plasma bubble has any simple relation with the perturbation of the F layer height and the height of the F layer. The main finding is that the temporal variation of the F-layer height is not a reliable precursor of seed perturbation determining the onset of plasma bubble. Further analysis of ionosonde data in terms of satellite trace (ST) and multi-reflected echoes (MREs) has also not provided any conclusive results in determining the onset condition. In view of the above we have examined the spatial variations of Airglow observations made at 630nm to examine the seed structures in question, which provided more meaningful precursor so far as the seeding is concerned. These results are presented and discussed in the light of current understanding and developing forecast strategy of equatorial plasma bubble (EPB).

C1.1-0004-18 STUDIES ON IONIZATION DEPLETIONS OF EQUATORIAL PLASMA BUBBLES ON TRANSIONOSPHERIC RADIO SIGNALS USING GNSS DURING THE EQUINOCTIAL MONTHS OF 2011 - 2016.

Tanmay Das, stanmaydas@gmail.com University of Calcutta, Kolkata, India

This paper represents the studies on ionization depletions in form of TEC bite-outs of equatorial plasma bubbles on transionospheric radio signals received from Kolkata (latitude: 22.58oN, longitude: 88.38oE geographic; 32oN magnetic dip) is situated near the northern crest of the equatorial ionization anomaly (EIA) in the Indian longitude sector, using Global Navigation Satellite System (GNSS) during vernal and autumnal equinoxes of 2011 through 2016. It is observed that when a plasma bubble moves across a satellite link, scintillations and ionization are usually encountered. The apparent duration of the bite-outs may be different from the true east-west duration, as observed with geostationary links, because of the presence of a relative velocity between the irregularity cloud and the satellite. The trajectory of a GNSS(GPS/ GLONASS/GALILEO) satellite plays a vital role in observing the bubble characteristics. The distributions of amplitude and the parameters characterizing the ionization depletions, namely, the duration, depth and the leading and trailing edge slopes of the bubbles have been obtained during the same equinoctial months of 2011 through 2016. It is evident that the range error, extent of the bubble and ionization gradients measured in these equinoctial months of the equatorial region provides the worst case figures for system designers. The high range error (3-4 m) is observed during these equinoctial months. The statistical distribution of the TEC depletions showed some significant results. The maximum amplitude has been noted about 23.25 TECU (corresponding range error 3.7m at L1 frequency) with a median depletion of about 5.92 TECU during the vernal equinox of 2011. The majority of the bubbles were found to have Observed Duration (ObD) between 10-20 minutes with a maximum of 28.14 minutes with a median value of Actual Duration(AcD)of 2.37 minutes translates to nearly 150sec of possible satellite signal outage.Similar statistical distribution have been studied during the other equinoctial months of 2011-2016.

C1.1-0005-18 RADAR NETWORK IN THE EQUATORIAL IONOSPHERE FOR SPACE WEATHER CAPABILITIES: THE EQUADERN PROPOSED PROJECT

The Earth's equator is uniquely the region where the magnetic field lines lie approximately horizontal within the ionosphere. The morphology is thus entirely distinct from that at higher latitudes where the field threads more nearly vertically through the ionospheric layer. It is the most complex region of the Earth's ionosphere due to its interactions, instabilities and also hosts to the most complex phenomena in the upper atmosphere. There are several unresolved questions regarding the dynamics of the equatorial ionosphere, its electrodynamics and the physical processes that govern the region. The success of the Super Dual Auroral Radar Network (SuperDARN) in observing both the occurrence and important characteristics of ionospheric plasma irregularities in auroral latitudes, polar latitudes (PolarDARN) and midlatitudes (StormDARN) indicates that such a system may also be successful in the equatorial region. In this work, we examine the science questions such as equatorial plasma bubbles and spread F formation that the deployment of a SuperDARN style radar in the equatorial region would be able to address, both individually and in conjunction with other space-based and ground-based instrumentation. The proposed radar network is similar in style and technique to the SuperDARN radar network. The radar network will be used to study the equatorial ionosphere over a long interval of time, at least one solar cycle. The deployment of a radar network in the magnetic equator is called the Equatorial (Dual) Electroject Radar Network (EquaERN/EquaDERN). The proposed project will provide simultaneous observations of both electric and magnetic variations over the magnetic equator both individually and in conjunction with other space-based and ground-based instrumentation. The network of radars will clearly improve our understanding of the dynamics of the equatorial ionosphere and our understanding of its role in balancing the large-scale ionospheric current system, and will contribute to our ability to adequately model ionospheric and plasmaspheric densities and also enhance our understanding of global ionospheric processes which will improve the space weather capabilities of the International space science communities.

C1.1-0006-18 IMPACTS OF LOWER ATMOSPHERIC WAVES ON THE EQUATORIAL UPPER ATMOSPHERE

Vineeth Chandrasekharan Nair, cnvins@gmail.com

Indian Space Research Organization, Thiruvananthapuram, India

This paper deals with the influence of the lower atmospheric waves on the dip equatorial ionosphere in general, and the day-to-day variability of the Equatorial Electrojet (EEJ) in particular. The analysis carried out using the data from various optical and radio probing instruments over Trivandrum (8.5oN, 77oE, 0.5oN dip lat.), revealed that the equatorial upper atmosphere responds significantly to the forcings from the lower atmosphere. It has been found that the Planetary Waves (PWs) and Gravity Waves (GWs) play a major role in producing the variability on the quiet time equatorial upper atmosphere. While the PWs modulate most of the parameters of the equatorial ionosphere to their respective periodicity, the gravity waves play significant role in producing Counter Electrojet (CEJ) and Equatorial Spread F. Among the PWs, the quasi 16-day wave plays a major role in modulating the day-to-day variability of the EEJ. The PWs alter the strength, duration and time of the EEJ significantly. Another noteworthy observation is the periodic occurrence of CEJ during the northern hemispheric Stratospheric Sudden Warming events. The Planetary wave-tidal interactions and subsequent modification in the tidal components is found to be responsible for the observed variations. The paper discusses these aspects in detail.

C1.1-0007-18 EQUATORIAL EVENING PREREVERSAL VERTICAL DRIFT AND SPREAD F/ PLASMA BUBBLE IRREGULARITY DEVELOPMENTS UNDER DISTURBANCE TIME ELECTRIC FIELDS AND WINDS

Equatorial plasma bubble/spread F (EPB/ESF) irregularity development can suffer large variability on a day-to-day basis due to the highly variable dynamic state of the evening ionosphere. An important cause of the ESF variability lies in the prereversal enhancement in the F region vertical plasma drift (zonal electric field), that is subject to large modifications under forcing from magnetospheric disturbances, when penetrating inter-planetary electric fields, and disturbance dynamo electric field, cause large enhancement, or total suppression, of the PRE, and hence of the ESF development. Additionally the disturbance meridional/ trans-equatorial wind can cause total suppression of the ESF development independent of the modification of the PRE vertical drift. Many details regarding the nature of the impact of the penetration electric fields on the PRE vertical drift and that of the disturbance winds on ESF growth lack our understanding. In this paper we have analyzed data on F layer heights and vertical drifts obtained from Digisondes operated in Brazil, including from conjugate point observations, to investigate the connection between magnetic disturbances occurring during and preceding the sunset hours and the consequent variabilities in the PRE vertical drift and EPB/ESF development. The impact of the prompt penetration under-shielding eastward electric field and that of the over-shielding, and disturbance dynamo, westward electric field on the evolution of the evening PRE vertical drift, and that of disturbance meridional/trans-equatorial wind on EPB/ESF development are briefly examined.

The ability to perform data assimilation in the Whole Atmosphere Community Climate Model eXtended version (WACCMX) is implemented using the Data Assimilation Research Testbed (DART) ensemble adjustment Kalman filter. Results are presented demonstrating that WACCMX+DART analysis fields reproduce the middle and upper atmosphere variability during the 2009 major sudden stratospheric warming (SSW) event. Compared to specified dynamics WACCMX, which constrains the meteorology by nudging towards an external reanalysis, the large-scale dynamical variability of the stratosphere, mesosphere, and lower thermosphere are improved in WACCMX+DART. This leads to WACCMX+DART better representing the downward transport of chemical species from the mesosphere into the stratosphere following the SSW. WACCMX+DART also reproduces most aspects of the observed variability in ionosphere total electron content (TEC) and equatorial vertical plasma drift during the SSW. Hindcast experiments initialized on January 5, 10, 15, 20, and 25 are used to assess the middle and upper atmosphere predictability in WACCMX+DART. A SSW, along with the associated middle and upper atmosphere variability, is initially predicted in the hindcast initialized on January 15, which is 10 days prior to the warming. However, it is not until the hindcast initialized on January 20 that a major SSW is forecast to occur. The hindcast experiments reveal that dominant features of the TEC can be forecast 10-20 days in advance. This demonstrates that whole atmosphere models that properly account for variability in lower atmosphere forcing can potentially extend the ionosphere-thermosphere forecast range.

C1.1-0009-18 NUMERICAL SIMULATION OF TRAVELING IONOSPHERIC DISTURBANCES GENERATED BY UPWARD PROPAGATING GRAVITY WAVES

It has been recognized that gravity waves (GWs) play an important role on the momentum and energy budget in the thermosphere/ionosphere. In this study, using a whole atmosphereionosphere coupled model (GAIA) with a high horizontal resolution, behaviors of Traveling Ionospheric Disturbances (TIDs) generated by upward propagating GWs in the thermosphere are investigated. The horizontal resolution of GAIA is 1 degree longitude by 1 degree latitude, which is adequate to simulate large-scale GWs. The GAIA contains the region from the ground surface to the upper thermosphere, so that we can simulate excitation of gravity waves in the lower atmosphere, their upward propagation to the mesosphere and thermosphere, and their impacts on the thermosphere/ionosphere system. The GAIA can simulate TIDs because interaction processes between the ionosphere and neutral atmosphere are included. The equatorward (poleward) TIDs become dominant during the daytime (nighttime) due to the filtering effect of GWs by poleward (equatorward) thermospheric winds. The dominant horizontal wavelength and period of the simulated TIDs are 500-1500 km and 30-90 min, respectively. The dominant wavelength and period of TIDs are the same as those of GWs near 250-300 km height. We discuss seasonal and longitudinal variations of TIDs and their relation to GW activity in the thermosphere.

C1.1-0010-18 EFFECT OF SOLAR FLUX AND COMPOSITIONAL VARIATIONS ON THE VARIABILITY OF OXYGEN DAYTIME OPTICAL EMISSIONS OVER LOWAND MID-LATITUDES

Daytime oxygen airglow intensity variability provides us with a means of remote investigations of the upper atmospheric behaviour. The dayglow emissions typically show a diurnal pattern with a peak at around noontime, especially during geomagnetic quiet conditions. The photochemical and empirical models show that the emissions vary as a function of solar zenith angle and solar flux. Thus, both, larger solar flux magnitudes and smaller solar zenith angles, contribute to larger dayglow brightness as the yield of excited oxygen atoms is expected to be greater in those conditions. However, seasonal dayglow emission variability obtained from measurements at low-latitudes (Hyderabad, India; 170 N, 800 E; 8.70 N Mag. Lat.) and midlatitudes (Boston, USA; 42.20 N, 710 W; 48.30 N Mag. Lat.) show different behavior with regard to solar flux variation. While the low-latitude emission variability is dependent on solar flux variations, the variability over mid-latitudes is not. This paper will discuss the cause(s) of this discrepancy with regard to relative effects of variation of compositional versus solar flux on the daytime airglow emissions at the lowand mid-latitude locations.

C1.1-0011-18 THE ELECTRODYNAMICS OF THE EQUATORIAL LOWER IONOSPHERE

Bela Fejer, bela.fejer@usu.edu

Utah State University, Logan, Utah, United States Fabiano Rodrigues, fabiano@utdallas.edu

University of Texas at Dallas, Richardson, Texas, United States

Equatorial electrodynamic processes play fundamental roles on low latitude upper atmospheric dynamics and plasma density distribution, and on the occurrence of plasma structures and irregularities with a large range of scale sizes. The most complex equatorial electrodynamic processes occur in the lower ionosphere where there are large temporal changes in thermospheric neutral wind and plasma drift coupling. This is particularly the case in the evening and early night periods when rapid altitudinal variations in the plasma density significantly affect the occurrence of equatorial plasma irregularities. Over the last few years, numerous experimental, theoretical and modeling studies have examined the electrodynamics of the evening equatorial ionosphere. In this presentation, we initially examine recent experimental studies of these processes during geomagnetic quiet-times using mostly Jicamarca radar measurements. We also discuss recent modeling studies of the evening electrodynamic plasma drifts, and of their relationship to thermospheric neutral winds, and generation and the evolution of equatorial plasma irregularities. We also briefly examine storm time effects on lower ionospheric equatorial plasma drifts, their relationship to disturbance neutral winds and their season dependent effects on equatorial plasma waves. Finally, we suggest possible future experiments and numerical modeling studies necessary for the better understanding of this highly complex ionospheric region.

The present work shows the first results of the study about the seasonal variation of the Solar quiet (Sq) Earth's magnetic field based on magnetic measurements from the Embrace Magnetic Network (MagNet). This is made at several latitudes in South America, covering the equatorial and low latitudinal region. For this study, we used data covering the period from 2010 to 2016, during the ascending phase of the solar cycle 24. Besides being an integrating part of the process to deviate the South American K, known as Ksa, the Sq variations are discussed in terms of their signature in the Quiet Day Curve. In addition, the effect X-Ray solar flares observed in the magnetic data collected by the Embrace MagNet are used to estimate the southern focus of the Sq current system.

C1.1-0013-18 CHARACTERISTICS OF IONOSPHERIC STORMS IN EAST ASIA

Xiao Wang, wangx@nssc.ac.cn

State Key Laboratory of Space Weather,NSSC,CAS, Beijing, China Jiankui Shi, jkshi@nssc.ac.cn

State Key Laboratory of Space Weather,NSSC,CAS, Beijing, China

The ionosphere experiences intense response during the geomagnetic storm and it varies with latitude and longitude. The DPS-4 digisonde measurements and GPS-TEC data of ionospheric stations located at different latitudes in the longitudinal sector of 90-130°E during 2002 to 2016 were analyzed to investigate the ionospheric effects in the different latitude of East Asia during geomagnetic storm. Geomagnetic storm cases are selected according to the Dst index and available observed data, they are in different seasons and different solar activity levels. Results show that for the middle and high latitude, the short-lived positive disturbance associated with the initial phase of the every storm was observed in each season and then the disturbances were negative till the termination of storm. At the low latitude, storm-time disturbances of foF2 have obvious diurnal, seasonal and solar cycle characteristics. It's notable that geomagnetic activities occurred at local time nighttime can cause stronger and longer responses of foF2 at the low latitude. All in all, the obvious negative phase ionospheric storms often occurred at the low latitude. The differences of the responses of foF2 and TEC are also investigated.

C1.1-0014-18 MODELING THE LOWER PART OF THE TOPSIDE IONOSPHERIC VERTICAL ELECTRON DENSITY PROFILE OVER THE EUROPEAN REGION BY MEANS OF SWARM SATELLITES DATA AND IRI UP METHOD

Michael Pezzopane, michael.pezzopane@ingv.it

Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy Alessio Pignalberi, alessio.pignalberi2@unibo.it

University of Bologna, Bologna, Italy Rolando Rizzi, rolando.rizzi@unibo.it University of Bologna, Bologna, Italy

An empirical method to model the lower part of the ionospheric topside region from the F2- layer peak height to about 500-600 km of altitude over the European region, is proposed. The method is based on electron density values recorded from December 2013 to June 2016 by Swarm satellites, and on foF2 and hmF2 values provided by the IRI UP (International Reference Ionosphere UPdate) method recently proposed by Pignalberi et al. (2018), which is a method developed to update the IRI model relying on the assimilation of foF2 and M(3000)F2 data routinely recorded by a network of European ionosonde stations. Topside effective scale heights are calculated by fitting some definite analytical functions (-Chapman, -Chapman, Epstein and Exponential) through pair of values (N(hsat), hsat) recorded by Swarm and pair of values (NmF2, hmF2) output by IRI UP, with the assumption that the effective scale height is constant in the altitude range considered. Calculated effective scale heights are then modeled as a function of foF2 and hmF2, in order to be operationally applicable to both ionosonde measurements and ionospheric models. The method produces two-dimensional maps of the median effective scale height binned as a function of foF2 and hmF2, for each of the considered topside profiles. A statistical comparison with COSMIC/FORMOSAT-3 collected Radio Occultation profiles is carried out to assess the validity of the proposed method, and to investigate which of the considered topside profiles is the best one. The -Chapman topside function displays the best performance compared to the others. Anyway, the results shows also the possibility to use a two-layer profile consisting of a sum of -Chapman and Exponential functions to properly describe the topside region.

C1.1-0015-18 THE IONOSPHERIC AND THERMOSPHERIC RESPONSES TO GREAT SOLAR FLARES: OBSERVATIONS AND MODELING

A solar flare causes a sudden increase in solar irradiation including the X-ray wavelengths and the extreme ultraviolet (EUV). The sudden enhanced solar irradiation produces the extra ionization at all ionosphere heights from D region to F region. Then additional heating via ionneutral collision also causes some variations in thermosphere. The ionospheric responses to solar flares have been studied by many scientists. Compared to the ionospheric responses, the studies on the thermospheric responses to solar flares are much fewer due to the few high resolution thermosphere observation. The observations from CHAMP accelerometer show only the large enough solar flare (like X5 and larger flares) can cause thermosphere neutral density increase significantly. In this study, we further study what is the threshold value of solar flare for the significant thermosphere change. Furthermore, we studied the evolution of the thermosphere and ionosphere responses with increasing solar flare class. Both the ionosphere and thermosphere show an amplification effect. And also we studied the coupling responses of the ionosphere and thermosphere by modeling a super solar flare of X40. The results show the ionosphere responses can last more than 4 hours, which is mainly due to the great thermosphere changes. The quick expansion of the thermosphere results in an uplift of the ionosphere to higher heights where recommendation rate is less. In addition, we also investigated the electrodynamics variations of ionosphere by explore exploring the equatorial electric field and electrojet in the ionosphere at Jicamarca during some solar flares. It is verified that solar flares increase dayside equatorial eastward electrojet but decrease dayside eastward equatorial electric field, revealing a negative correlation between equatorial electrojet and equatorial electric field. The decreased equatorial electric field weakens the equatorial fountain effect and depresses the low-latitude electron density.A solar flare causes a sudden increase in solar irradiation including the X-ray wavelengths and the extreme ultraviolet (EUV). Germany

We present mid-latitude D-region disturbances during the northern hemispheric major Sudden Stratospheric Warming (SSW) events of 2009 and 2016, in different solar conditions, as sensed by sub-ionospheric VLF/LF radio signals. We have analysed VLF/LF radio signals from four transmitters (NAA, NRK, NPM, NLK) received at eight places in Europe, USA and Japan during these events. The 2009 event was the most intense SSW event in recent past, while the SSW of 2016 consisted of two warming events within months. Significant anomalies in nighttime and daytime VLF/LF amplitudes (3-10 dB) have been found for all propagation paths associated with stratospheric temperature rise at 10 hPa level during the SSW events. Modification of the lower ionospheric boundary conditions and corresponding modal interference effects between the different propagating waveguide modes are found responsible for the anomalous variation of VLF/LF amplitudes during the two SSW events. Simulation of VLF/LF diurnal variation are carried out using the well known Long Wave Propagating Capability (LWPC) code within the earth-ionosphere waveguide to quantify the ionospheric anomalies caused by the respective SSW events.

C1.1-0017-18 ON THE RESPONSE OF INDIAN EQUATORIAL AND LOW-LATITUDE IONOSPHERE TO SUDDEN STRATOSPHERIC WARMING DURING 2009 AND 2013

The vertical coupling between the lower and upper atmosphere is one of the major drivers of dayto-day variability of the ionosphere. The variability of low-latitude ionosphere is intricate as it is also coupled laterally to the high-latitude dynamical processes. Sudden stratospheric warming (SSW) is one such meteorological phenomenon which occur in polar winter stratosphere and causes large variations in the upper atmosphere. The present study investigates the variability of low-latitude ionosphere of the Indian region to the two major SSW events occurred during 2009 and 2013. The equatorial electrojet (EEJ) strength obtained from geomagnetic field variations and total electron content (TEC) derived from using Global Positioning Satellite (GPS) system at several stations in India have been in the present study. Results reveal a significant difference in the response of equatorial electrodynamics and low-latitude ionosphere during the two events. The National Center for Environmental Prediction (NCEP) wind data at 10hPa (30km) level and the meteor wind radar data installed at dip equatorial station, Trivandrum (8.5°N, 77.1°E, 0.5°N), have been used to identify any cause-effect relationship between observed variations in low-latitude ionosphere and stratospheric warming events. The results suggest the strong role of quasi-biennial oscillation (QBO) in modulating the effect of SSW over low-latitudes.

C1.1-0018-18 NEW RESULTS ON THE EFFECTS OF PROMPT PENETRATION ELECTRIC FIELD ON EQUATORIAL IONOSPHERE

D. Chakrabarty, dipu@prl.res.in

Physical Research Laboratory, Ahmedabad, India

In the last few years, a number of results obtained on the effects of prompt penetration electric field on the equatorial ionosphere have made significant impact on our understanding and raised new questions. First, it was found that long duration prompt penetration events may not constitute similar processes at a phenomenological level. This result has a direct bearing on the understanding of the shielding time constant which is taken to be around 30 min based on theoretical considerations. Second, it was also found that even small changes in the solar wind density only under northward IMF Bz condition can generate perceptible prompt electric field disturbances on the equatorial ionosphere. Third, it was shown that inductive electric field perturbations due to substorms during storms can be significantly high, additive or subtractive in nature and hence has the capacity to modify the prompt penetration electric field effects significantly. Fourth, it was also found that IMF By component can, on occasions, change the generally accepted polarity of prompt penetration electric field effects on equatorial ionosphere. In addition to the above results, it was also shown that geo-effectiveness of Co-rotation Interaction Region (CIR) events can be gauged based on prompt penetration electric field effects on equatorial ionosphere and CIRs are generally geo-effective as long as the solar wind azimuthal flow angle is within 6 degrees at the first Lagrangian Point (L1) of the Sun-Earth system. On the other hand, it is also found that even if the passage of an Interplanetary Coronal Mass Ejection (ICME) at 1 AU does not generate main phase of a storm, it can still be geo-effective in terms of prompt penetration electric field effects on equatorial ionosphere. The presentation will address these new aspects related to the effects of the prompt penetration electric field on equatorial ionosphere.

C1.1-0019-18 C/NOFS OBSERVATIONS BELOW THE EQUATORIAL IONOSPHERIC F-REGION LEDGE AT NIGHT

Robert Pfaff, robert.f.pfaff@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States

During the last year of the Air Force C/NOFS mission, the satellite had an opportunity to sample below the F-region bottomside ledge. This presented an opportunity to gather important new insight regarding the electrodynamics of these critical lower altitudes (< 350 km). Although the data are limited due to spacecraft constraints encountered during this time, plasma density and electric field data observed during the lower altitude portions of these orbits present an opportunity to extend our knowledge of the low latitude nighttime plasma density and its motions below F-region ledge. For example, as in cases where the F-peak was elevated near sunset, we sometimes observe evidence of reversed zonal plasma drifts – i.e., westward drifts at the lower altitudes – even at later local times after sunset. There are important longitude and local time signatures inherent in the measurements that we summarize in our overview of the data gathered by the Vector Electric Field Investigation during its last year of orbit.

C1.1-0020-18 THE ROLE OF PLASMA BUBBLES AND TRAVELING IONOSPHERIC DISTURBANCES IN THE CREATION OF PLASMA BLOBS

Hyosub Kil, hyosub.kil@jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, United States Larry Paxton, larry.paxton@jhuapl.edu

Applied Physics Laboratory, Laurel, Maryland, United States

Plasma blobs represent the plasma density enhancements relative to the background ionosphere. Their creation is understood in terms of either equatorial plasma bubbles or traveling ionospheric disturbances (TIDs). However, we do not yet clearly understand how often blobs occur in association with one of those phenomena. This study addresses this question by conducting case studies for each blob event and examining the occurrence climatology. Blob events are identified from the Swarm satellite observations in 2014-2017. The total electron content maps and all-sky images are used to monitor the occurrence of TIDs. The occurrence of bubbles is monitored using the observations of Special Sensor Ultraviolet Spectrographic Imager (SSUSI) on board the Defense Meteorological Satellite System (DMSP) F18. We identify the association of blobs with bubbles or TIDs by examining their simultaneous occurrence at the same magnetic meridian. The distributions of blobs, bubbles, TIDs are derived from Swarm observations, and these results are also used for the investigation of the role of bubbles and blobs in the creation of blobs.

C1.1-0021-18 ANOMALOUS PRE-EARTHQUAKE IONOSPHERIC SIGNATURES OBSERVED AT LOW-MID LATITUDE INDIAN STATION, DELHI, DURING THE YEAR 2015 TO EARLY 2016: PRELIMINARY RESULTS

Arun Kumar Upadhayaya, upadhayayaak@nplindia.org National Physical Laboratory India, New Delhi, India Sumedha Gupta, sumedha88@gmail.com

National Physical Laboratory India, New Delhi, India

Five major earthquake events measuring greater than six on Richter scale (M > 6) that occurred during the year 2015 to early 2016, affecting Indian region ionosphere, are analyzed using F2 layer critical parameters (foF2, hmF2) obtained using Digisonde from a low-mid latitude Indian station, Delhi (28.6°N, 77.2°E, 19.2°N geomagnetic latitude, 42.4°N dip). Normal day-to-day variability occurring in ionosphere is segregated by calculating F2 layer critical frequency and peak height variations (foF2, hmF2) from the normal quiet time behavior apart from computing interquartile range. By and large, significant perturbations are observed in the ionosphere F2 region across Delhi, 3-4 days prior to these earthquake events, resulting in a large peak electron density variation of 200%, indicating towards a possibility of seismo-ionospheric coupling as the solar and geomagnetic indices were normally quiet and stable during the period of these events. It was also observed that the precursory effect of earthquake was predominantly seen even outside the earthquake preparation zone, as given by Dobrovolsky et al. (1979). The thermosphere neutral composition (O/N2) as observed by Global Ultraviolet Imager, across Delhi, during these earthquake events does not show any marked variation. Further, the effect of earthquake events on ionospheric peak electron density is found to be comparable to those due to lower atmosphere meteorological phenomenon of 2015 sudden stratospheric warming event.

C1.1-0022-18 FOUNTAIN EFFECT SIGNATURES ON THE F3-LAYER CHARACTERISTICS FROM THE EQUATOR TO THE EIA CRESTS DURING THE GEOMAGNETIC STORM OF 17 MARCH 2015

The existence of an additional stratification of the equatorial ionospheric F region, the F3-layer, has been known since the1940s, and it has been explored in detailed for more than a decade. Adding to the large quiet time variability in the F region ionosphere, ionosondes have observed F3-layers during the occurrence of geomagnetic storm induced prompt penetration electric fields (PPEF). The St. Patrick's Day geomagnetic storm on 17 March 2015 is the strongest storm in the 24th solar cycle with the minimum Dst of -223 nT. During the main phase of this storm, two strong prompt penetration electric field phases took place: the first with the southward turning of IMF Bz around 1200 UT, and the second with the onset of a sub storm around 1725 UT leading to strong equatorial zonal electric field enhancements in the Brazilian sector, which was on the day side hemisphere. The F3-layer was observed over a large latitudinal extent of 45 degrees during the two strong PPEF phases that occurred in the main phase of the storm. The F3 is seen from the equator up to the equatorial ionization anomaly (EIA) crests in the northern and southern hemispheres along the Brazilian longitudes. Distinct latitudinal and hemispheric differences are noted in the occurrence characteristics of the F3-layer during both PPEF phases. The influence of the storm-induced super fountain effect on the evolution of the F3-layer over the equatorial and low latitudes is discussed.

C1.1-0023-18 SIMULATION OF THE LOW LATITUDE IONOSPHERE RESPONSE TO DISTURBED WINDS AND ELECTRIC FIELDS: BRAZILIAN REGION

Modeling the ionosphere during disturbed periods is one of the most challenging tasks due to the complexity of the phenomena that affect the electric fields and the thermosphere environment as a whole. It is well known that depending on the direction of the interplanetary magnetic field disturbance electric fields (undershielding or overshielding) can penetrate from high to low latitudes causing significant disturbances in the electron density distribution and in the equatorial ionization anomaly (EIA) development. Besides that, the large amount of energy deposited in the polar region during disturbed periods will be responsible for the generation of disturbed winds that will flow towards the equator where they produce a disturbance dynamo which also affects the EIA density distribution. The TIDs and TADs are also sources of disturbances that propagate at high velocity reaching the equator 2-3 hours after the beginning of the magnetic storm. In this work we use the Sheffield University Plasmasphere-Ionosphere Model at INPE (SUPIM-INPE), to simulate the drastic effects that were observed at the low latitude ionosphere in the Brazilian region during a very intense magnetic storm event. A few models are tested for the disturbed electric field and for the disturbed wind. The simulation results showed that the observations are better explained when considering a traveling waveform disturbance propagating from north to south at a velocity of the order of 200 m/s.

C1.1-0024-18 STUDY OF IONOSPHERIC PERTURBATIONS IN F-LAYER USING TASHKENTKITAB GPS STATIONS

Bobomurat Ahmedov, bahmedov@yahoo.com

Ulugh Beg Astronomical Institute, Tashkent, Uzbekistan

Monitoring of F-layer of ionosphere over GPS nodes in the Central Asia territory is being performed on the permanent basis and GPS derived TEC disturbances from two GPS stations located in Tashkent and Kitab are analyzed. The ionospheric anomalies observed during strong local earthquakes (M greater than 5.0) which occurred mostly in and around Uzbekistan in seismically active zones, during years 2010 to 2017 within 1000 km from the observing GPS stations located in Tashkent and Kitab. The solar and geomagnetic conditions were quiet during occurrence of the selected more than 30 earthquakes. We produced TEC time series over both sites and apply them to detect anomalous TEC signals preceding or accompanying the earthquakes. The results show the anomalies occurred 1-6 days before the earthquakes as ionospheric electromagnetic precursors. To identify the anomalous values of TEC we calculated differential TEC (dTEC). dTEC is obtained by subtracting 15 days backward running mean of vTEC from the values of observed vTEC at each epoch.

C1.1-0025-18 TOPSIDE IONOSPHERIC IRREGULARITIES AS DERIVED FROM SWARM SATELLITES OBSERVATIONS

Irina Zakharenkova, zakharenkovai@gmail.com

University of Warmia and Mazury in Olsztyn, Poland, Olsztyn, Poland Iurii Cherniak, tcherniak@ukr.net

Combination of ground-based GNSS and space-based low orbit multi-instrumental satellite observations can bring significant advances in our knowledge of physics near-Earth space in quiet conditions and during Space weather events. The present study is based on a joint analysis of the ground-based GPS/GLONASS observations as deduced from 6000 stations together with up-looking GPS measurements onboard the Swarm mission. The ESA's Swarm mission was launched on 22 November 2013 and consisted of three identical satellites - Swarm Alpha (A), Bravo (B) and Charlie (C) - two of them AC fly in a tandem separated by 1.4 degree in longitude at an orbit altitude of 460 km while the third satellite (B) - at an orbit altitude of 510 km. Each satellite is equipped with a zenith-looking antenna and 8-channel dual-frequency GPS receiver that delivered 1 Hz data for precise orbit determination (POD), as well as with a Langmuir Probe instrument for in situ electron density. We developed and sucessefully applied original approaches for detection topside ionospheric irregularities using in situ plasma probe measurements and GPS POD payload data from Swarm satellites. We demonstrate that LEO GPS observations are reliable data source for monitoring the topside ionospheric irregularities occurrence in both high-latitude and equatorial regions and it can essentially contribute to the multi-instrumental analysis of the in situ LEO measurements and ground-based data. In the present study we discuss features of the equatorial plasma irregularities detected by multisatellite observations in the topside ionosphere (above an altitude of 500 km) during main and recovery phases of severe geomagnetic storms in March and June of 2015. We demonstrate results with differences between the obtained climatological characteristics of the equatorial ionospheric irregularities occurrence probability derived from space-based GPS data and storm-induced equatorial irregularities observations (postsunset suppression, night/morningtime occurrence, expansion toward midlatitudes) with specific focus on the equatorial plasma bubbles occurrence in the topside ionosphere. The research is supported by the National Science

Centre, Poland, through grant No. 2017/25/B/ST10/00479.

C1.1-0026-18 ELECTRIC FIELDS IN A GEOMAGNETIC STORM

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

The ionosphere behaviors quite different from its normal state under geomagnetic active conditions, especially during geomagnetic storms. The ionospheric storm effects are always a research focus. An extreme space weather even occurring on 14-17 July 2012 manifests a geomagnetic storm. This event is characterized by a southward interplanetary geomagnetic field lasting for about 30 h below -10 nT. In this talk, multiple instrumental observations including electron density from ionosondes, total electron content (TEC) from Global Positioning System (GPS), Jason-2, and Gravity Recovery and Climate Experiment (GRACE), and the topside ion concentration observed by the Defense Meteorological Satellite Program (DMSP) spacecraft are used to comprehensively present the regional differences of the ionospheric response to this event and the electric field. We will show the intensive negative storm in the Asian-Australian sector and the difference between sectors. The evolution and role of the electric field in the storm will also be discussed. The storm-time zonal winds as indicated from the movement of composition disturbances region will help to understand the formation of disturbance dynamo processes.

Acknowledgments This research was supported by National Natural Science Foundation of China (41621063, 41774161) and by the Opening Funding of Chinese Academy of Sciences dedicated for the Chinese Meridian Project.

TechTIDE is a consortium of 13 research and applications organizations in Europe and South Africa formed in November 2017 under the European Union Horizon 2020 framework. Its overarching objectives are design and test of new viable mitigation strategies for the space weather impacts from Travelling Ionospheric Disturbances (TID). TechTIDE will propose near real-time warning services and mitigation technologies and demonstrate their added value for the systems that rely on high fidelity of trans-ionospheric propagation of radio signals, primarily for the purpose of precise navigation (e.g., EGNOS and N-RTK) and high frequency geolocation. TechTIDE is employing an ensemble of six different methodologies for automatic TID identification and tracking using

ionosonde, Doppler radar, and GNSS sensor networks in Europe and South Africa, and conducts its research and development in close collaboration with operators of the technologies affected by TIDs. Unique data products from TechTIDE aim at providing new understanding of the physical processes resulting in the formation of TIDs, and will consequently help to identify their drivers in the interplanetary medium, the magnetosphere, and the atmosphere. The paper discusses involved research methodologies in detail and outlines the strategies for their cross-validation and transition to operations.

C1.1-0028-18 RECENT RESULTS OBTAINED BY THE OPTICAL MESOSPHERE THERMOSPHERE IMAGERS (OMTIS) AT LOW AND MIDDLE LATITUDES

Kazuo Shiokawa, shiokawa@nagoya-u.jp

Institute for Space-Earth Environmental Research, Nagoya University, Nagoya, Aichi, Japan Yuichi Otsuka, otsuka@isee.nagoya-u.ac.jp

Institute for Space-Earth Environmental Research, Nagoya University, Nagoya, Japan

We review our recent progresses on the observation of the thermosphere and ionosphere using the Optical Mesosphere Thermosphere Imagers (OMTIs), which consist of 21 airglow imagers, 5 Fabry-Perot interferometers (FPIs), three airglow temperature photometers and 3 tilting photometers. They are in automatic operation at Canada, Russia, Finland, Iceland, Norway, Japan, Alaska, Indonesia, Thailand, Australia, and Nigeria. Statistical characteristics of plasma bubbles at Abuja, Nigeria were studied by Okoh et al. (JGR, 2017) with their relation to the GNSS scintillation statistics. Coordinated observations of post-midnight irregularities and thermospheric neutral winds and temperatures at low latitudes were reported by Dao et al. (JGR, 2017) to show the relation of the post-midnight irregularities with the midnight temperature maximum and associated thermospheric winds. Average thermospheric temperatures observed by four FPIs at Norway, Thailand, Indonesia, and Australia for 2-3 years are compared with those estimated by the GAIA model to investigate the validity of the model (Nakamura et al., EPS, 2017). The thermospheric winds obtained by the FPIs at geomagnetic conjugate stations in Japan and Australia are combined with the airglow imaging observations of nighttime medium-scale traveling ionospheric disturbances (MSTIDs) and ionosonde measurements to investigate MSTID generation mechanisms through E-F and hemispheric electromagnetic coupling processes.

C1.1-0029-18 VTEC VARIABILITY AT MIDNIGHT OVER MID-LATITUDES REGIONS USING PCA

Maria Paula Natali, mariapaula.natali@gmail.com

Facultad de Ciencias Astronómicas y Geofísicas, Universidad Nacional de La Plata, La Plata, Argentina

Amalia Meza, amalia.meza@gmail.com

Facultad de Ciencias Astronómicas y Geofísicas, Universidad Nacional de La Plata, La Plata, Argentina

The effect of the thermospheric vertical neutral wind on vertical total electron content (vTEC) variations including longitudinal anomaly, remaining winter anomaly, mid-latitude summer night anomaly, and semiannual anomaly is studied at mid-latitude regions around zero magnetic declination at midnight during high solar activity. This work studies the spatial and temporal variations of the ionosphere at midnight over mid-latitude regions during 2000-2002 using the Principal Component Analysis (PCA) numerical technique. PCA is applied to a time series of global vTEC maps produced by: the International Global Navigation Satellite System (GNSS) Service and the International Reference Ionosphere (IRI) 2012. Also, the Horizontal Wind Model 2007 (HWM07) is used to improve our climatology interpretation, by analyzing the relationship between vTEC and thermospheric wind, both quantitatively and qualitatively. At midnight, the behavior of mean vTEC values strongly responds to vertical wind variation showing a decrease of about 10-15% with the action of the positive vertical component of the field aligned neutral wind lasting for 2 hs. Remarkable results include: the mid-latitude summer night anomaly in South America and Asia regions, the remnant of the winter anomaly in North America and Oceania regions. Finally, the longitudinal east-west variation is also present. Our results show that at mid-latitudes regions, the IRI 2012 model represents midnight ionospheric mean values with a similar spatial distribution, but the values are always lower than those obtained by GNSS. There are also differences between IRI 2012 and GNSS in represent the different anomalies.

A coordinate campaign of observations was conducted in the northeast of Brazil during 21 August 2017 solar total eclipse. During this campaign neutral and ionic parameters of the mesosphere-thermosphere-ionosphere system were measured using airglow imagers, Fabry-Perot interferometer, ionosondes, coherent back-scatter radar, meteor radars and magnetometers. The main goal of this campaign was investigated secondary effect of the total solar eclipse in the dynamics and structure of the atmosphere over Brazil. From the airglow images, periodic gravity waves were observed in the mesopause (OH layer) and thermosphere (OI6300 layer). The waves had propagation directions and horizontal parameters compatible with waves that could be generated by the eclipse from the north part of the South America continent. Salient discussion will be present in this paper.

C1.1-0031-18 RECENT DEVELOPMENT ON E REGION IRREGULARITIES INDUCED BY THE FARLEY-BUNEMAN INSTABILITY

Jean-Pierre St-Maurice, jp.stmaurice@usask.ca University of Saskatchewan, Saskatoon, Canada Jorge Chau, chau@iap-kborn.org

Leibniz-Institute of Atmospheric Physics (IAP), Kühlungsborn, Germany

Observations from three closely located VHF radars in Northern Germany during the March 17 2015 storm have revealed several important features regarding the Farley-Buneman instability:

narrow fast echoes (formerly called Type IV) came from the top of the unstable region near 120 km while narrow slow echoes (formerly called Type III) came from below 100 km altitude. In the most unstable region near 110 km, the echoes were more normal, moving at the ion-acoustic speed in the plasma flow direction and decreasing steadily with flow angle. There was, however, an unexpected strong east-west asymmetry. It was determined that narrow fast echoes were generated when the ion drift was moving at a speed equal to the electron drift minus the threshold speed (roughly the ion-acoustic speed). The narrow slow echoes were also slowly growing modes generated, this time, when the electric field was very strong but the electron collision frequency was large. The more turbulent echoes near 110 km were consistent with a theoretical description involving a rotation and decrease of the electric field inside intermittent but elongated finite size structures. Their east-west asymmetry was the combined effect of a tilt in the direction of maximum growth and of a non-negligible ion Pedersen drift under strong electric field conditions. Additional features were revealed because the radars fortuitously acted both as Doppler and target radars, perhaps because of their low sensitivity (the radars having been built for more powerful meteor echoes). For instance, we observed slow narrow echoes from lower altitudes moving like discrete targets at a speed comparable to the ExB drift. This implied that the relativistic precipitation region that generated the low altitude plasma was localized but that it drifted at a speed comparable to the plasma ExB drift.

C1.1-0032-18 FEATURES OF OBSERVING FOR WEAK MSTIDS BY DENSE GNSS SATELLITES NETWORK

Ruslan Sherstyukov, sher-ksu@mail.ru Kazan Federal University, Kazan, Russia Adel Akchurin, adel.akchurin@kpfu.ru Kazan Federal University, Kazan, Russia Oleg Sherstyukov, oleg.sherstyukov@kpfu.ru Kazan Federal University, Russia

To analyze the weak midlatitude medium-scale travelling ionospheric disturbances we use the sufficiently dense network of GNSS receivers (more than 150 ground-based stations). We show the reason that the monitoring for MSTIDs by GNSS satellites is fragmented. We assume that this is the reason for the differences in the intensity of the appearance of MSTIDs by the data of GNSS and ionosonde. Comparing of satellites R18 and G18 data (at 9:40 UT on September 21, 2016) revealed that the LOS directed to ongoing MSTIDs phase front is preferred for MSTIDs observing. The characteristics of extremely weak MSTIDs with TECp values 0.2 TECU, wavelength 100 km and western direction of phase front moving are presented on two-dimensional TEC perturbation maps. We estimate these parameters as a threshold for monitoring the MSTIDs by GNSS network we used.

C1.1-0033-18 DECORRELATION OF MULTI-FREQUENCY GNSS SIGNALS OBSERVED FROM NORTHERN EQUATORIAL IONIZATION ANOMALY (EIA) CREST LOCATIONS

Ashik Paul, ashikpaul@aol.in University of Calcutta, Calcutta, India

Samiddha Goswami, samiddha.goswami@gmail.com University of Calcutta, Calcutta, India

Krishnendu Paul, krish6372@gmail.com University of Calcutta, Calcutta, India

Modern GNSS broadcast signals on more than one frequency so that a correction of the delay through the ionosphere can be determined. This could provide more advanced three-frequency correction schemes for which knowledge of correlation of different frequency pairs under conditions of ionospheric scintillations is desirable. A significant factor in decorrelating the signals arises from the different phase decorrelation effects due to diffraction of signals from local random inhomogeneities of the medium of propagation frequently found to develop in the equatorial region during post-sunset hours. Understanding the correlation of signal fades across multiple frequencies is important to assess their collective mitigation effectiveness. If signal fades at two frequencies are highly correlated, the actual aim of the frequency diversity scheme would be defeated. A GNSS receiver capable of tracking GPS, GLONASS and GALILEO at multiple frequencies (L1, L2, L5) is operated at Calcutta (22.58degN, 88.38degE geographic; magnetic dip: 32degN) since April 2013, situated in the anomaly crest region in the Indian longitude sector. In the present analyses, the equinoctial periods of February-April and August-October 2014 have been selected. To observe the effects of signal decorrelations at L1, L2 and L5 during periods of scintillations, correlations were measured between C/N0 deviations recorded at the three frequencies separately for samples of 3-minute interval for S40.2. In order to understand the impact of different nature of scattering at the three frequencies, three scattering coefficients were introduced in the analyses defined in terms of the ratio of difference and sum of C/N0 deviations for a pair of frequencies. Receiver position deviations were calculated at 50Hz sampling and expressed in terms of latitude and longitude in meters. It is found that during February through April 2014, low correlation coefficients between C/N0 deviations at L1, L2 and L5 were associated with high S4, high scattering coefficient and resulting large receiver position deviations for 39

C1.1-0034-18 NEUTRAL AND ELECTRODYNAMICAL VARIABILITY OF DIP EQUATORIAL UPPER ATMOSPHERE DURING SOLAR FLARES

Sumod S. G., sgsumodh@gmail.com

Space Physics Laboratory, Vikram Sarabhai Space Centre, TRIVANDRUM, India Pant Tarun Kumar, tkpant@yahoo.ca

Space Physics Laboratory, Vikram Sarabhai Space Centre, 695022, India

The present work comprehensively investigates the neutral and electrodynamical processes in the dip equatorial upper atmosphere over Indian longitudes during solar flare events of different ranks. The E and F regions of ionosphere are studied using the high cadence measurements of the Equatorial Electrojet (EEJ) and Total Electron Content (TEC) obtained from the ground based magnetometers and GPS receivers respectively. The thermospheric response in context of neutral-ion coupling is examined using the unique data set of the neutral OI 630.0 nm dayglow obtained from the Multiwavelength dayglow photometer (MWDPM) over Trivandrum in India (8.5° N, 77°E, dip 0.5°N). The study brought out a new finding that the Equatorial Ionization Anomaly (EIA) undergoes significant weakening associated with an X3.8 class flare, while no such changes has been noticed during the M class flares. In addition, it was understood that the response of OI 630.0 nm dayglow can be prompt or delayed depending on the class of the flare. The role of electrodynamics in modulating the flare induced changes in the OI 630.0 nm dayglow has been clearly delineated. The plausible mechanisms explaining these observations are presented in context of the present understanding of the equatorial electrodynamics and its imprint on this dayglow features. We believe that the high cadence ionospheric-thermospheric measurements of this sort during such transient events will help in quantifying the relative contributions of different mechanisms of this unique dayglow for the better understanding the energy budget of equatorial ionosphere-thermosphere system.

C1.1-0035-18 INVESTIGATION OF THE TRAVELLING IONOSPHERIC DISTURBANCES IN TURKEY USING IONOLAB-FAST FOURIER TRANSFORM (I-FFT)

Ali Cinar, alicinar@outlook.com.tr

Ionosphere is a layer of the atmosphere where significant numbers of free electrons and ions are present. The density of the free electrons in ionosphere cause the irregularities and disturbances in the in the VLF, LF and HF signals, magnetic field of the earth and in the local electric field. One of the main parameters of ionosphere, TEC (total electron content) is defined as the line integral of electron density along a ray path. Many researches would explain the mechanism and cause of the disturbances in the ionosphere. One of these disturbances, namely Travelling Ionospheric Disturbances (TIDs), is defined as the wave-like oscillations that are damped with the time. Atmospheric disturbances can propagate from the lower to the upper atmosphere where they may be responsible for the oscillations in the ionosphere in form of TIDs. TEC makes a convenient means for monitoring and detection of disturbances. In this study, the behavior of the IONOLABTotal Electron Content (TEC) estimates obtained from dual frequency groundbased GPS receivers are examined using IONOLAB-Fast Fourier Transform (I-FFT) method for geomagnetically disturbed and quiet conditions of the ionosphere over Turkey. It is observed that IONOLAB-FFT can estimate the frequency and the duration of TIDs with more than 80% accuracy. IONOLAB-FFT can also detect the duration and the frequency of medium scale TIDS and large scale TIDS that are defined in the literature. This study is supported by TUBITAK EEEAG 114E541 a part of the Scientific and Technological Research Projects Funding Program.

C1.1-0036-18 SEASONAL VARIATIONS AND AZIMUTHAL ASPECT SENSITIVITY OF 150- KM ECHOES OBSERVED BY THE EQUATORIAL ATMOSPHERE RADAR

We present long overdue statistical analysis of the 150-km echoes based on 12 years of observations made using the Equatorial Atmosphere Radar (EAR) located at Kototabang, Indonesia. Analysis shows that while the basic features of the echoes are very similar to those observed from other equatorial/low latitude stations, occurrence and SNR of the echoes have remarkable seasonal dependence. Occurrence rate and SNR of the echoes are much higher in the solstices than in the equinoxes. Notably, both occurrence rate and SNR in the December solstice are marginally lower than those of the June solstice and are remarkably higher than those of both equinoxes. The observed seasonal variations of the 150-km echoes are quite similar to that of Gadanki and are very different from that of Pohnpei, which indicate the potential role of neutral dynamics/electrodynamics in the echoing mechanism. EAR observations also display remarkable azimuthal aspect sensitivity of the echoes. These results are discussed in the light of recently proposed photo-electron induced plasma wave mechanism versus plasma instability mechanism in terms of the origin of the 150-km echoes.

C1.1-0038-18 EFFECTS OF SPACE WEATHER ON THE IONOSPHERE AND LEO SATELLITES' ORBITAL TRAJECTORY IN EQUATORIAL, LOW AND MIDDLE LATITUDE

Victor U.J. Nwankwo, victornwankwo@yahoo.com Anchor University, Lagos, Nigeria

Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

We study the effects of space weather on the ionosphere and low Earth orbit (LEO) satellites' orbital trajectory in equatorial, lowand mid-latitude (EQL, LLT and MLT) regions during (and around) the notable storms of October/November, 2003. We briefly review space weather effects on the thermosphere and ionosphere to demonstrate that such effects are also latitudedependent, and well established. Following the review we simulate the trend in variation of satellite's orbital radius (r), mean height (h) and orbit decay rate (ODR) during 15 October 14 November 2003 in EQL, LLT and MLT. Nominal atmospheric drag on LEO satellite is usually enhanced by space weather or solar-induced variations in thermospheric temperature and density profile. To separate nominal orbit decay from solar-induced (accelerated) orbit decay, we compute r, h and ODR in three regimes viz. (i) excluding solar indices (or effect), where r=r0, h=h0 and ODR=ODR0 (ii) with mean value of solar indices for the interval, where r=rm, h=hm and ODR=ODRm and (iii) with actual daily values of solar indices for the interval (r, h, and ODR). For a typical LEO satellite at h=450 km, we show that the total decay in r with respect to EQL, LLT and MLT during the period is about 4.20 km, 3.90 km and 3.20 km respectively; the respective nominal decay (r0) is 0.40 km, 0.34 km and 0.22 km, while solar-induced orbital decay (rm) is about 3.80 km, 3.55 km and 2.95 km. h also varied in like manner. Similarly, the respective nominal ODR0 is about 13.5 m/day, 11.2 m/day and 7.2 m/day, while solar-induced ODRm is about 124.3 m/day, 116.9 m/day and 97.3 m/day. We also show that severe geomagnetic storms can increase ODR by up to 117

C1.1-0039-18 SEASONAL/SOLAR ACTIVITY DEPENDENCE OF EQUATORIAL IONIZATION ANOMALY PARAMETERS

Oyedemi S. Oyekola, ooyekola@gmail.com Canada

In this study, we have used International Reference Ionosphere (IRI) maximum plasma density of F2 layer (NmF2) to gain a qualitative insight into the physical processes that accounts for the equatorial ionization anomaly (EIA) intensity parameters vary with season, phase of the solar activity cycle and magnetic activity level, and maximum value of post-sunset drift velocity (PRE) along longitude 358.48 degrees east for very low (F10.7 = 70 sfu), low (F10.7

= 80 sfu), moderate (F10.7 = 150 sfu), and high solar activity (F10.7 = 180 sfu) conditions at fixed local time (2100 LT) and fixed altitude (350 km) corresponding to bottomside F-region for months representing vernal equinox (March), summer solstice (June), autumnal equinox (September) and winter solstice (December). The results show that the southern crest location decreases with increasing levels of solar activity; whereas position of northern crest increases with increasing solar activity levels. When the anomaly is fully developed under high solar activity conditions, the structure of the monthly northern crest location reveals semi-annual variation (broad peaks during March-April, about 13.5 degrees and minimum value in July, around 5.6 degrees, while the pattern of monthly southern anomaly crest location exhibits winter anomaly (peak value in June, about -12.5 degrees, minimum value in October around -18 degrees) while The trough oscillates between about +/- 1 degree, a clear north-south asymmetry feature of EIA. The magnitude of the monthly northern crest shows semi-annual variation as well with broad maximum during February and March with a value of approximately 18.4×1011 el/m3 and minimum value show up in June and July with a value of 8.4×1011 el/m3. Similarly, the magnitude of the monthly southern anomaly crest demonstrates semi-annual variation with peak value in April, about 32.6 ×1011 el/m3 and minimum in July, 17.6×1011 el/m3. Moreover, maximum value of post-sunset drift velocity given by Scherliess/ Fejer (1999) /IRI equatorial model drift is fairly correlated with the magnitude of northern anomaly crest (NAC) (r = 0.38) and the magnitude of southern anomaly crest (SAC) (r = 0.44). Monthly values of NAC indicates correlation value of 0.44 with monthly values of F10.7, but the monthly values of SAC is poorly correlated with F10.7 (r = 0.12).

C1.1-0040-18 WINTER NIGHTTIME ENHANCEMENT AND SUMMER DUSK-TO-NIGHTTIME ENHANCEMENT OF NMF2 AND INTERHEMISPHERIC COUPLING

Yiding Chen, chenyd@mail.iggcas.ac.cn

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China Libo Liu, liul@mail.iggcas.ac.cn

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China Huijun Le, lehj@mail.iggcas.ac.cn

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China Weixing Wan, wanw@mail.iggcas.ac.cn

Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

The dusk-to-nighttime enhancement (DNE) of summer NmF2 and the nighttime enhancement (NE) of winter NmF2 were investigated using COSMIC radio occultation observations at solar minima. Summer DNE mainly occurs in three regions that depend on geomagnetic configuration and is more prominent in the southern than in the northern hemisphere owing to the particular geomagnetic configuration over the South Pacific (both the declination and inclination are important, neutral winds induce larger upward plasma drift around sunset thanks to this geomagnetic configuration) at higher geographic latitudes where photoionization is still significant at sunset and evening hours. Winter NE shows evident dependence on geomagnetic latitudes, the magnitude of winter NE reaches latitudinal peaks (troughs) at the geomagnetic latitudes of about 40°-50° (60°-70°); and the longitudinal variation of winter NE is also evident. The latitudinal variation of NE was suggested to be related to that of the plasma storage above F2-peak region, geomagnetic inclination, and background NmF2, and the longitudinal variation of NE was found to be related to the longitudinal differences in background NmF2, thermospheric density, and interhemispheric plasma transport. Moreover, the longitude variation of winter NE is dependent on that of summer DNE to some extent via interhemispheric plasma transport, implying that under the effect of geomagnetic configuration, neutral wind induced upward plasma transport in the summer hemisphere is important for the interhemispheric plasma transport from the summer to winter hemisphere.

C1.1-0041-18 PERFORMANCE OF IRI MODELLED TEC AND GROUND BASED MEASURING TEC AT LOW LATITUDE DURING THE ASCENDING PHASE OF SOLAR CYCLE 24

Vishnu Singh Rathore, vishnurathore1989@gmail.com Banaras Hindu University, Varanasi, India

Abhay Kumar Singh, abhay_s@rediffmail.com Banaras Hindu University, Varanasi, India

The widely used International Reference Ionosphere (IRI) model in simulation/modeling of ionospheric studies specifically at low latitudes require performance evaluation. To achieve this objective, we have compared total electron content (TEC) derived from the recent and earlier versions of IRI model (IRI-2016 and IRI-2012) over low latitude Indian station Varanasi (Geographic: 25°16N, 82°59E; Geomagnetic: 14°55N, 154°E) with TEC measured from the GPS receiver installed at Varanasi. The results are in good agreement with correlation coefficient 0.9, and root-mean-square deviations generally around 25-70 % for diurnal comparisons. The seasonal variability of TEC derived by using the different topside options of the IRI model (IRI-2001, NeQuick, and IRI01-corr) are studied and validated for the three seasons. IRI shows good agreement at other times instead of the equinox. Errors in TEC are likely due to peak height and density inaccuracies. IRI is a suitable model for specification of monthly averages of Total Electron Content and can be used to initialize a data assimilation process at times away from solar maximum.

C1.1-0042-18 EFFECT OF INTENSE GEOMAGNETIC STORMS ON LOW LATITUDE IONOSPHERE

Abhay Kumar Singh, abhay_s@rediffmail.com Banaras Hindu University, Varanasi, India Abha Singh, abhatdcnp

India

Sanjay Kumar, sanjay.skitvns@gmail.com Banaras Hindu University, Varanasi, India

Vishnu Singh Rathore, vishnurathore1989@gmail.com Banaras Hindu University, Varanasi, India

In this paper, we have analyzes the dual frequency signals from GPS satellites recorded at Varanasi (Geographic latitude 25 degree, 16 N, longitude 82 degree, 59 E) near the equatorial ionization anomaly (EIA) crest region in India, to study the effect of intense geomagnetic storms on the variation of total electron content (TEC), during the years 2010-2015. Three most intense storms having Dst-index < -100 nT observed during the above period have been analyzed, which occurred on 15th July 2012, 19th February 2014, and 20th December 2015. The storm induced features in the vertical TEC (VTEC) have been studied considering the monthly mean VTEC value of quiet days as reference level. The possible reasons for storm time effects on VTEC have been discussed in terms of local time dependence, storm wind effect as well as dawn-dusk component of interplanetary electric field (IEF) Ey intensity dependence.

C1.1-0043-18 A NEURAL NETWORK BASED MODEL FOR INFERRING DAYTIME VERTICAL EXB DRIFT FROM GROUND-BASED MAGNETOMETER OBSERVATIONS IN THE INDIAN LONGITUDE

PavanChaitanya Peddapati, pavanpeddapati@gmail.com National Atmopsheric Research Laboratory, Gadanki, India Amit Patra, akpatra@narl.gov.in

National Atmospheric Research Laboratory, Tirupati, India

Ionospheric vertical ExB drift plays an important role in the electrodynamics and plasma irregularities in the equatorial ionosphere. In this paper, we present an artificial neural network for inferring ionospheric daytime vertical ExB drift using ground based magnetometer observations in the Indian sector. For this purpose we have used daytime vertical ExB drift estimated using the mean Doppler shift of 150-km echoes observed using MST radar located at Gadanki (13.5oN, 79.2oE, dip latitude 6.5oN) and difference in magnetic fields (H) observed from Tirunelveli (8.7oN, 77.8oE, dip latitude 0.4oN), a magnetic equatorial location and Alibag (18.5oN, 72.9oE, dip latitude 13.0oN) a location well beyond the electrojet belt. The difference in magnetic fields provides a direct measure of electrojet current, and in turn, the vertical ExB drift velocity in the ionospheric F region. We have used a feed forward neural network with error back propagation to train the network. The network has been trained using 119 days of observations made during 2006-2011, when solar activity was characterized with F10.7 of 60-78 solar flux units. Results obtained on vertical ExB drift from the artificial neural network have been compared with the actual ExB drift measurements. The model successfully reproduces the vertical ExB drift with RMS error of 2.24 m s-1. The model results are also compared with the Scherliess and Fejer model. Remarkable difference between the neural network/actual observations and Scherliess and Fejer model has been noted. The usefulness of the neural network based estimates is presented and the discrepancy between the observations and standard models is discussed.

C1.1-0044-18 IMPACT OF SUDDEN STRATOSPHERIC WARMING OF 2009 ON THE EQUATORIAL AND LOW-LATITUDE IONOSPHERE OF THE INDIAN LONGITUDES: A CASE STUDY

Sudden stratospheric warming (SSW) is a large-scale meteorological phenomenon occur in the winter hemisphere which lasts several days or weeks. The effect of SSWs is not limited to high-latitude stratosphere alone but rather extends to other altitudes and latitudes. This paper presents the variability in the equatorial electrodynamics and low-latitude ionosphere over the Indian longitudes during a major SSW occurred in January 2009 during the low- solar activity conditions. Results indicate that the intensity of EEJ and the TEC over lowlatitudes (extending up to 30°N) exhibit significant perturbations during and after the SSW peak. One of the interesting features is the deviation of EEJ and TEC from the normal quiet time behaviour well before the onset of the SSW. This is found to be coincided with the beginning of enhanced planetary wave (PW) activity over high-latitudes. The substantial amplification of the semidiurnal perturbation after the SSW peak is seen to be coinciding with the onset of new and full moon. The response of TEC to SSW is found to be latitude dependent as the near-equatorial (NE) stations show the semidiurnal perturbation only after the SSW peak. Another notable feature is the presence of reduced ionization in the night sector over the NE and low-latitude regions, appearing as an 'ionization hole', well after the SSW peak. The investigation revealed the existence of a quasi-16 day wave in the TEC over low-latitudes similar to the one present in the EEJ strength. These results have been discussed in the light of changes in the dynamical background because of enhanced PW activity during SSW, which creates favourable conditions for the amplification of lunar tides, and their subsequent interaction with the lower thermospheric tidal fields.

C1.1-0045-18 IMPACT OF ASYMMETRY BETWEEN THE LEADING AND TRAILING WALLS OF PLASMA STRUCTURES OBSERVED FROM EQUATORIAL REGION OF INDIAN LONGITUDE SECTOR

Tanmay Das, stanmaydas@gmail.com University of Calcutta, Kolkata, India Ashish DasGupta, adg1bkpr@gmail.com University of Calcutta, Kolkata, India

This paper represents the impact of asymmetry between the two walls (leading and trailing edges) of the equatorial plasma bubbles observed through transionospheric satellite signals received from a station situated near the northern crest of the equatorial ionization anomaly (EIA) in the Indian longitude sector, using Global Positioning System (GPS) L1 frequency during the equinoctial months of February-April 2011, August-October, 2011 and FebruaryApril 2012. The observed bubbles showed notable asymmetry between the leading (eastern wall of the bubbles) and trailing (western wall of the bubbles) edges. It is observed that the trailing edge slope (the western wall) is much sharper than the leading edge slope (the eastern wall). The leading edge slope has a maximum value of 5.13 TECU/min with a median of about 2.1 TECU/min. The maximum value of the trailing edge slope of 9.8 TECU/min and median of 3.72 TECU/min validate the idea of asymmetric edges of the bubble. Such sharp gradients on the walls of the irregularities imply large pseudorange rates, nearly 157cm/min corresponding to the maximum value of the descending slope. It is evident that the range error, extent of the bubble and ionization gradients measured provides the worst case figures for system engineers. Similar results have been observed during the AugustOctober 2011 and February-April 2012.

C1.1-0046-18 ANALYSIS OF SECULAR VARIATIONS OF EARTH'S MAGNETIC DUE TO EQUATORIAL ELECTROJET FIELD MEASURED AT ECUADORIAN GEOMAGNETIC STATION.

Ericson Lopez, ericsonl@hotmail.com

Quito Astronomical Observatory, Quito, Ecuador Franklin Aldaz, franklin.aldas@epn.edu.ec

Quito Astronomical Observatory, Quito, Ecuador

In this study, we have used the Earth magnetic field (MG) data provided by the ground-based MAGDAS instrument at Jerusalem (JRS) station, located in Ecuador, above the geographic equatorial line. To study the variation of the declination angle, the variation the magnitude of Earth's magnetic field and the secular variation of the horizontal component of MG.

The variation of the declination of the magnetic field presents a linear tendency as function of time at JRS station with a variation of -0.1647 ° per year. The total Earth's magnetic field, from 06-2014 to 12-2016, shows a linear tendency as function of time weakening with a rate of 91 (nT) per year.

We found that the principal frequencies of the variation of horizontal field are f1=1,16*10(-5) [Hz], f2=2,31*10(-5) [Hz], f3=3,4722*10(-5) [Hz] and f4=4,6296*10(-5) [Hz]. Those frequencies are equivalent to periods of 24, 12, 8 and 6 hours respectively.

We found also the presence of a semiannual variation of Sq that is maximized during the months of the equinoxes and minimized during solstice months.

C1.1-0047-18 GEOMAGNETIC ACTIVITY INDEX AP AND THE OCCURRENCE RATES OF GEOMAGNETIC STORMS DURING 1996-2017

Oyedemi S. Oyekola, ooyekola@gmail.com Canada

Global geomagnetic activity disturbance index (Ap) and the occurrence rates of geomagnetic storms during the period 1996-2017, comprising solar cycle (SC) 23 (1996-2008) and SC 24 (2008-2017) have been investigated. Our results indicate that geomagnetic activity maximizes at equinoxes during both cycles. Overall annual mean value of Ap index is 13+/-4 nT for cycle 23 and 8+/-2 nT for cycle 24, a decline of 30%. The patterns of geomagnetic activity cycle fairly follow the sunspot number (SSN) cycle with a delay of 1-2 years during Ap index peak. Ap index and SSN are found to be reasonably correlated (r = 0.44) and somewhat significant (p-value = 0.0421). Moreover, analyses of the top 50 geomagnetic storms from minor to severe storms in each solar cycle are compared. Magnetic and solar variability effects with seasonal dependence are evident in the occurrence rates of geomagnetic storm distributions. Yearly occurrences of geomagnetic storms seem to be unsystematic with zero geomagnetic disturbances seen during 1996, 2007-2009 periods of exceptionally low geomagnetic activity and incredibly low solar activity conditions. The higher occurrence frequency of geomagnetic perturbation is likely to occur during geomagnetic cycle peak year than solar cycle peak period. The magnetic cycle peak years 2003 and 2015 indicate 16% and 36% occurrence rates, respectively. The seasonal distribution of geomagnetic storms is noted with equinoctial occurrence rates of 44% for SC 23 and 54% for SC 24. Also, the period 1996-2008 indicates 0% minor, 56% major and 44% severe storms; whereas 62% minor, 34% major and 4% severe storms are observed over the period 2008-2017. Using solar-wind data measured by Advanced Composition Explorer (ACE) satellite at L1 point in Geocentric Solar Ecliptic System (GSM) coordinates, we examine two geomagnetic disturbances scenarios: first, for superstorm that occurred on 31 March 2001 (year of solar activity maximum during SC 23), Ap = 192; second, for intense storm that happened on 8 September 2017 (declining phase during solar cycle 24), Ap =106. We demonstrate that duration and considerable strength of southwardly directed solar-magnetospheric northsouth component of the interplanetary magnetic field (IMF Bz) with associated dawn-dusk y-component of interplanetary electric field (IEF Ey), high solar-wind velocity, with strong solar-wind dynamic pressure associated with coronal mass ejection (CME) events are essential conditions to trigger severe geomagnetic storms with larger intensity as measured by the Dst index. Furthermore, estimates of geoelectric field are made from the first time rate of change in North-South (NS) and East-West (EW) components of interplanetary magnetic fields IMF-Bx and IMFBy, respectively. The results show that induced NS electric field (Ex) component presents larger fluctuations than induced EW electric field (Ey) component. In the first case, amplitude varies between about -0.111 to 0.0538 mV/m for Ex, and -0.179 to 0.0985 mV/m for East-West geoelectric voltages. In the second case, the amplitude of induced geoelectric field varies from approximately -0.0272 to 0.0225 mV/m for Ex and from -0.0454 to 0.0703 mV/m for Ey. The geoelectric fields are relevant for estimating geomagnetically induced currents (GIC) during enormously large geomagnetic disturbances, a threat to modern infrastructure.

C1.1-0049-18 HF RADAR OBSERVATIONS OF PERIODIC IONOSPHERIC IRREGULARITIES AT MIDDLE LATITUDES

La Trobe University, Bundoora, Australia

The ionosphere forms the lower boundary of the magnetosphere and couples to the thermosphere. The international SuperDARN consortium of high frequency over-the-horizon radars has been used for over three decades to investigate dynamics of the high latitude ionosphere. More recently a network of mid-latitude radars has been added to SuperDARN to provide extended coverage at times of enhanced magnetic activity. These include the TIGER and Unwin radars in Tasmania and New Zealand respectively, both located at -55°magnetic latitude. In 2014 a new design of HF mid-latitude radar was deployed at Buckland Park, near Adelaide, with a field of view overlapping TIGER and Unwin and extending from near the magnetic pole to around -40°magnetic latitude. The Buckland Park radar detects a range of ionospheric irregularities including MSTIDs and ionospheric perturbations driven by the electric fields of magnetospheric plasma waves. The TIDs may propagate equatorward away from a higher latitude source region and can also be detected with optical imagers and other radio sounders at lower latitudes. The plasma waves produce oscillation features with periods of a few minutes or less over a range of scale sizes. This presentation gives examples and discusses propagation properties and impacts for ionosphere users.

C1.1-0050-18 THE COOPERATION BETWEEN NSSC AND INPE TO INSTALL GROUND INSTRUMENTS FOR SPACE WEATHER OBSERVATION IN BRAZIL

The International Space Weather Meridian Circle Program (IMCP), which is the extension of Chinese Meridian Project, is proposed to connect ground-based monitoring devices around 120ºE and 60ºW meridian region, which will enhance the ability of worldwide space environment monitoring in a significant way. The IMCP has obtained extensive supports from those countries on the meridian circle. So far, some research institutes and universities, like Canadian Space Agency, Russian Institute of Solar-Terrestrial Physics, Massachusetts Institute of Technology, the University of Adelaide, have signed cooperation agreements with the Meridian Project. Up to now, MOST has highly valued IMCP, which is expected to be launched in the near future in consequence. As a significant observatory of International Space Weather Meridian Circle Program (ISWMCP), the China-Brazil Joint Laboratory for Space Weather, held by the National Space Science Center (NSSC) of Chinese Academy of Science (CAS) and National Institute of Space Weather (INPE) of Brazil, has completed the fundamental construction during the first period. A Na-K lidar was installed in SJ Compose in Dec. 2016, and the operation of lidar is good. Up to now, more than 600h data have been obtained. A Digisonde

(DPS4), a GPS-TEC and a magnetometer were installed in Santa Maria, a southernmost city in Brazil. And in the second period, the cooperation will be enlarged. Good achievements have been obtained under the efforts of both side of China and Brazil, which will deeply facilitate the regional space weather exploring and

obtaining the global space weather information, and show us a good prospect of further joint research and the bright future for the International Space Weather Meridian Circle Program .

C1.1-0051-18 GEOMAGNETIC CONJUGATE OBSERVATIONS OF NIGHTTIME ELECTRIFIED MEDIUM-SCALE TRAVELING IONOSPHERIC DISTURBANCES ALONG WITH THERMOSPHERIC WINDS AND IONOSPHERIC PARAMETERS: UNIQUE INSIGHTS

Viswanathan Lakshmi Narayanan, narayananvlwins@gmail.com National Atmopsheric Research Laboratory, Tirupati, India Kazuo Shiokawa, shiokawa@nagoya-u.jp

Institute for Space-Earth Environmental Research, Nagoya University, Nagoya, Aichi, Japan Yuichi Otsuka, otsuka@stelab.nagoya-u.ac.jp

IPS Radio and Space Services, Sydney, Australia

The electrified medium-scale traveling ionospheric disturbances (EMSTIDs) occurring as geomagnetically conjugate features in the nocturnal middle latitude F region ionosphere are studied using multi-instrument observations. Airglow imaging of OI 630 nm emission over Sata, Japan and Darwin, Australia are used to identify the occurrence of EMSTIDs. Thermospheric wind measurements made with the Fabry-Perot interferometer observations of OI 630 nm from Shigaraki, Japan and Darwin, Australia are used along with ionosonde observations over Yamagawa, Japan and Darwin, Australia to study the thermospheric and ionospheric characteristics. These are the first results from such multi-instrument observations simultaneously made from geomagnetic conjugate locations. EMSTIDs are generated only when there is significant sporadic E activity, at least in one of the hemispheres. The amplitudes of the EMSTIDs are found to be different between the hemispheres, particularly in the later hours of the night. Thermospheric meridional winds appear to control the EMSTID amplitudes in the respective hemisphere. These results conclusively indicate the importance of sporadic E layers in the generation of EMSTIDs. Further, it shows the significance of interhemispheric coupling between the E and F region ionospheres in the formation and evolution of EMSTIDs.

C1.1-0053-18 REVEALING THE POSSIBLE EARTHQUAKE PRECURSOR IN ULF GEOMAGNETIC FIELD BY WAVELET TRANSFORM MODULUS MAXIMA (WTMM) TECHNIQUE

Deepak Kumar Sondhiya, deepsondhiya@gmail.com

Lakshmi Narain College of Technology and Science, Bhopal, India, Bhopal, India

The short term Earthquake forecasting has primary significance for human beings in order to alleviate it's disasters. In the present work we have analyzed the geomagnetic field variations in Ultra Low Frequency (ULF) range prior to five strong Earthquakes (M > 6) occurred from 2005 to 2007. The Wavelet Transformation Modulus Maxima (WTMM) method has been used to analyze the data to reveal the short term (i.e. from few days to weeks) earthquake precursors. WTMM method allows calculation of anomalous variation in time-frequency sub-bands depend on sampling rate of the geomagnetic data. It was conclude that the WTMM analysis extract the irregular behavior in ULF data related to various stages of earthquake preparation process. The variation in ULF electromagnetic signal are causally bound with the preceding Earthquake via many sources, which are generated as a result of evolution of mode of deformation of rocks in the course of the earthquake preparation. The radon exhalation from the active faults is a primary source of ULF geomagnetic field variations.

Thermospheric winds play an important role in the dynamics of the mean behaviour of the midlatitude ionosphere especially during quiet conditions, which are dominant during low solar activity. This study will present equivalent meridional winds derived from ionospheric F2 peak parameters using the servo and Liu et al. (2003) methods during the solar minimum period of 2007-2009. Midlatitude ionosonde data over Grahamstown (33.3°S, 26.5°E), Hermanus (34.4°S,

19.2°E), and Madimbo (22.9°S, 30.9°E) are used to derive the winds. For the first time, local time and seasonal dependency of the derived winds over this region are explored and compared to global trends. The equivalent winds are compared to the winds predicted from the horizontal wind model 2014 (HWM14) and the coupled middle atmosphere thermosphere model (CMAT2) to test the validity of these methods.

In this paper we present the unusual behavior of critical frequency of ionospheric F2 layer during several large earthquakes in the western coast of South America from 2001 to 2005. We define a new parameter from Barbier's theorem and named it as Ionospheric Parameter (F). We consider five large earthquakes having Richter scale magnitudes greater than six ($M > 6.5$) and study temporal variation of this newly defined ionospheric parameter (F). Critical frequency and Virtual height are measured by ground based Ionosonde station at Jicamarca (lat. 11.95 S, long 76.87 W) in Chile which lies at a distance within a radius of 1000 km from the epicenter of the quakes under consideration. The critical frequency of F2 layer (denoted as f0F2) and virtual height of F layer (hF) are used to examine the ionospheric variation during earthquake at a span of ±15 days. We observe significant increase in the evaluated F parameter in 12 to 3 days prior to the earthquakes. The increment is over +3 from the normal variation. The f0F2 values also revealed significant anomaly is considered as a supporting evidence for our observed correlation. We also check geomagnetic indices in order to establish that these anomalies are indeed due to seismic events only.

C1.1-0057-18 SEASONAL VARIATION AND LONG-TERM TREND OF NITRIC OXIDE RADIATIVE EMISSION OVER INDIAN LONGITUDE SECTOR: TIMED-SABER OBSERVATION

Tikemani Bag, tiku.bag@gmail.com

Swedish Institute of Space Physics, Kiruna, Sweden

Nitric oxide (NO) density plays a significant role in the understanding of the structure, chemistry and dynamics of MLT region. The NO density in collision with atomic oxygen density produces nitric oxide raditive emission at 5.3µm. We study the seasonal variation and longterm trend of NO 5.3µm emission over Indian longitude sector using sixteen years of NO volume emission rate (VER) observations by TIMED-SABER satellite. The NO intensity is calculated by integrating NO VER over 100-155 km altitude region. The seasonal variation shows maximum NO VER and intensity during August. Whereas, minimum VER and intensity are observed during September. The FWHM for VER is found in the altitude region of 126-130 km. The long-term variation covers the time period from the depletion phase of 23rd solar cycle to the completion of 24th solar cycle. The NO VER and intensity show a clear correlation with solar cycle variation having minimum values observed during 2008-09. We performed cross-correlation analysis between NO intensity and sunspot number. Although the peak sunspot number doesn't correspond to the peak in NO VER/intensity, there is a strong correlation (correlation coefficient= 0.74) between them. Similar cross-correlation analyses between NO intensity and F10.7 solar index and Lyman-α are performed. These cross-correlation analyses show a strong correlation among NO intensity and F10.7 solar index and Lyman-α with correlation coefficient more than 0.7.

C1.1-0058-18 SOLAR AND CHEMICAL INFLUENCE ON TROPICAL (10°N-15°N) MESOPAUSE VARIABILITIES

Karanam Ramesh, karanamram@gmail.com

National Atmopsheric Research Laboratory, ANDHRA PRADESH, INDIA, India Sridharan Sundararajan, susridharan@narl.gov.in

ABSTRACT

Mesopause is the coldest region of the terrestrial atmosphere. It is the lowest altitude at which the molecular diffusion begins to play a dominant role. The mesopause is largely affected by radiative forcing associated with absorption of solar ultraviolet (UV) radiation by O2 and O3 and radiative cooling mainly due to CO2 infrared (IR) emissions. The exothermic reactions, O+O+M→O2+M+5.11eV and H+O3→OH+O2+3.34 eV could also affect the mesopause altitude and temperature. In the present study, the temperature and ozone volume mixing ratio (O3 vmr) obtained from Sounding of the Atmosphere using Broadband Emission Radiometry (SABER) instrument on board Thermosphere Ionosphere Mesosphere Energetics and Dynamics (TIMED) satellite for the years 2002-2012 (23-24 solar cycles) are used to investigate the solar cycle and chemical influence on tropical (10°N-15°N) mesopause variabilities. It is found that the mesopause temperature and O3 vmr are positively correlated with solar cycle. Though there is no specific seasonal variation found in mesopause temperature; it is higher in September (190K), slightly lower in May and July (185 K), and lowest (175-178 K) during other months. But the mesopause altitudes are comparatively higher (99-100 km) in April and lower (95 km) in September. The factors influencing these mesopause variabilities are investigated for the year 2011 as a case study as it resembles the long-term mean seasonal variation. Further the net heating rates due to (i) solar heating by O2 and O3, (ii) chemical heating due to seven major exothermic reactions among H, O, O3, OH, HO2, (iii) O3 long-wave radiative heating, and (iv) CO2 cooling obtained from TIMED-SABER are used to investigate the mesopause variabilities.

C1.1-0059-18 QUANTIFYING THE SOURCES OF IONOSPHERE DAY-TO-DAY VARIABILITY

Tzu-Wei Fang, tzu-wei.fang@noaa.gov

University of Colorado, Boulder, Colorado, United States Tim Fuller-Rowell, tim.fuller-rowell@noaa.gov

University of Colorado, Boulder, Colorado, United States Tomoko Matsuo, tomoko.matsuo@colorado.edu University of Colorado, Boulder, Colorado, United States Valery Yudin, valery.yudin@noaa.gov

University of Colorado, Boulder, Colorado, United States Rodney Viereck, rodney.viereck@noaa.gov

Space Weather Prediction Center, Boulder, United States

Simulation using the coupled Whole Atmosphere Model (WAM) and Global Ionosphere Plasmasphere (GIP) show significant day-to-day variations in the ionospheric parameters. In the simulation, the auroral precipitation patterns inferred from Television Infrared Observation Satellite (TIROS/NOAA), daily solar irradiance measurements derived from the NOAA GOES X-ray Sensor (XRS), NASA TIMED Solar EUV Experiment (SEE), and NASA SDO EUV Variability Experiment (EVE), and 5-min IMF/solar wind parameters are used to drive WAMGIP during June and July 2012. Overall, simulation is capable of capturing most of variability compared to observations. Results also show that the variability is much larger in the nighttime than in the daytime due to much lower background density in the night and the magnitudes of these variabilities strongly depend on their locations and local times. To quantify the sources of these variability, two more sets of WAM-GIP simulations are carried out intend to separate the impact from the solar activity, geomagnetic activity, and lower atmospheric perturbations. Results show that the lower atmosphere perturbation and geomagnetic activity are the main contributors to the NmF2 variability. For TEC variability, the solar activity, geomagnetic activity and lower atmosphere perturbation contribute almost equally. Our simulation further demonstrates that the TEC variability at low latitudes are largely dominated by lower atmosphere perturbation and solar activity. At the midand high-latitude region, the solar activity, geomagnetic activity and lower atmosphere perturbation all contribute to the TEC variability.

C1.1-0060-18 CLIMATOLOGY AND CHARACTERISTICS OF MEDIUM-SCALE F-REGION IONOSPHERIC PLASMA IRREGULARITIES OBSERVED BY COSMIC RADIO OCCULTATION RECEIVERS

Chris Watson, watsonc@ucar.edu

UCAR, Boulder, Colorado, United States

Medium-scale ionospheric plasma irregularities are a persistent global feature of the earth's Fregion ionosphere. Constellation Observing System for Meteorology, Ionosphere, and Climate (COSMIC) radio occultation measurements are well suited to address the incomplete global observational picture of irregularities, including the global climatology in both bottomside and topside F-region layers, as well as the irregularity structure in the vertical dimension. A climatological database of F-region ionospheric irregularities and their characteristics has been developed through detection of total electron content (TEC) perturbations by Global Positioning System (GPS) receivers onboard COSMIC satellites. Vertical scale sizes ranging from 2 to 50 km were resolved from 1 Hz TEC measurements. This paper presents the global occurrence and equatorial to mid-latitude characteristics of medium-scale irregularities under quiet geomagnetic conditions. The study covers four years, two during solar minimum (2008-2009) and two during the ascending phase of solar cycle 24 (2012-2013). Irregularities were commonly observed at high latitudes, and during nighttime in equatorial to mid-latitude regions in both bottom and topside F-region layers. Geographical and seasonal occurrence trends at equatorial and mid-latitudes are consistent with previous irregularity climatology, which reaffirms that localized irregularity occurrence is possibly linked to localized enhancements in plasma instability growth rates. Seasonal occurrence patterns also indicate a high occurrence of irregularities in regions corresponding to the solar terminator, confined primarily to altitudes below 300 km. The local time and altitude distributions of equatorial and mid-latitude irregularity occurrence, amplitude, and scale size provide further insight into irregularity generation mechanisms, and include features consistent with "spread-F" irregularities and travelling ionospheric disturbances (TIDs).

C1.1-0061-18 ANALYSIS OF THE IONOSPHERIC IRREGULARITY EVENTS OVER EAST ASIA LOW LATITUDE REGION BASED ON VARIOUS OBSERVATIONS

Based on various ground-based and space-based observational instruments at Hainan station (19.5ºN, 109.1ºE, dip: 13.6ºN) and magnetic equatorial region, we analyzed the temporal and spatial variation and the relevant physical processes of low-latitude F region irregularity events observed during the night of November 20, 2011. The comprehensive observation of VHF radar, ionospheric scintillation and digisonde at Hainan station shows that the observed ionospheric irregularities mainly occurred near sunset and near midnight, and there were two distinctly different morphologies, which reflected that the different generation and development processes of low latitude ionospheric irregularities. Combined with the magnetic equatorial GPS and the C/NOFS satellite observations, it is found that the radar plume and strong scintillation over Hainan region near the sunset are obviously related to the primary EPB/ESF caused by the sudden increase of ionospheric velocity and height in the magnetic equatorial region of the South China Sea. The weak spread F and weak scintillation over Hainan region near midnight may associate with the secondary ESF/EPB caused by the lower ionospheric height in the magnetic equatorial region on the west of Hainan after sunset.

C1.1-0062-18 TEMPORAL AND SPATIAL CORRELATIONS OF THERMOSPHERIC VERTICAL DENSITY PROFILES IN QUIET AND STORMY CONDITIONS

James Gilmore, james.gilmore@unsw.edu.au

University of New South Wales Canberra, Campbell, Australia

Modelling thermospheric density with high accuracy has proved to be a great challenge. With density predictions playing a crucial role in satellite tracking and orbital propagation calculations, there is a strong need to improve currently employed modelling techniques. In situ thermospheric density measurements are limited, leaving predictions reliant on the skill of density models developed with past observations, such as JB-2008 or DTM 2013.

Many density models demonstrate a reduction in skill in stormy conditions, including minor and moderate geomagnetic storms, which are frequent. Although improvements in density models are being made, the underlying reasons for this skill reduction can be difficult to diagnose from sparse observational density data. Parameterized vertical density profiles are commonly used in these models and are one known source of model uncertainty.

To develop a greater understanding of vertical density profiles we study quiet and stormy conditions in two thermosphere-ionosphere global circulation models: TIE-GCM and GITM. Thermospheric density profiles are examined under different conditions. To inform thermospheric density modelling we also examine spatial and temporal correlations of the profiles. The differences and similarities between TIE-GCM and GITM profiles are examined and the limitations of employing global circulation models for this work are discussed. The implications of this work to future modelling efforts of thermospheric density are highlighted.

C1.1-0063-18 RESPONSES OF GLOBAL OCEANIC EQUATORIAL/LOW-LATITUDE IONOSPHERIC IRREGULARITIES TO 2015 ST. PATRICK'S DAY AND SEPTEMBER, 2017 GEOMAGNETIC STORMS

Andrew Akala, akalaovie2004@yahoo.com University of Lagos, LAGOS, Nigeria Elijah Oyeyemi, e_oyeyemi@yahoo.co.uk University of Lagos, Lagos, Nigeria

Paul Amaechi, poloobiaks University of Lagos, Lagos, Nigeria

This study presents the responses of global oceanic equatorial/low-latitude ionospheric irregularities to 17th March, 2015 (St. Patrick's day) and 8th September, 2017 geomagnetic storms. We used total electron content (TEC) data from 15 International Global Navigation Satellite System (GNSS) Stations (IGS), distributed on the Pacific (7 stations), Atlantic (5 stations) and Indian (3 stations) Oceans. Rate of change index (ROTI) was used as the index to measure irregularities generation over the study sites. The study carefully diagnosed the interplanetary origins of the geomagnetic storms. The two storms, which occurred at the G4 and G3 levels, respectively were induced by corona mass ejection transients. We characterized the irregularities alongside with the geomagnetic storms, with five days before and after the days of occurrence of the two geomagnetic storms. During the main phases of the storms, an enhancement was observed on the irregularities generation over the Pacific Ocean, while irregularities were inhibited by the geomagnetic storms over the Indian and Atlantic Oceans. However, enhancement in irregularities occurrences were observed over the Atlantic Ocean during the Sudden Commencement phases of the geomagnetic storms.

C1.1-0064-18 ON THE ROLE OF IONOGRAM SIGNATURES OF LSWS (SATELLITE TRACES) AND LOW LATITUDE ESB LAYERS IN CAUSING THE VARIABILITIES OF ESF IRREGULARITIES OVER INDIAN SECTOR

Sreeba Sreekumar, sreeba90@gmail.com

Indian Institute of Geomagnetism, New Panvel(W), Navi Mumbai, India Sripathi Samireddipalle, ssripathi.iig@gmail.com

Indian Institute of Geomagnetism, Navi Mumbai, India

We investigate the role of ionogram signatures of LSWS (satellite traces) and low latitude Esb layers in causing the variabilities of ESF irregularities, in addition, to post-sunset vertical drift for the year 2015 using ground-based ionosondes located at Tirunelveli (8.71° N, 77.75°E, Geomag. Lat 0.21°N) and Hyderabad (17.38°N, 78.48°E, Geomag. Lat 8.74°N). Results show, statistically, that the presence/absence of STs is higher/lower than the absence/presence of Esb prior to occurrence/non-occurrence of ESF during all the seasons. This implies the importance of ST/LSWS in the ESF occurrence. Results of weak correlation of low latitude Esb layers with ESF possibly indicate its coupling to higher apex altitude than the base of the F-layer. Significant equinoctial asymmetry is also observed in both the ESF and ST occurrences wherein vernal is dominant than autumn equinox. Band-pass filtered h'F oscillations of 1-1.5 hour reveal significant wave amplification during the PRE on ESF than non-ESF days and also during vernal than autumn equinox. Further investigations suggest that the height oscillations of early ESF and delayed ESF are amplified according to their onset time of ESF. The study suggests that post-sunset height rise of F-layer together with the presence of LSWS provide suitable conditions for the ESF development. Further, the presence of downward phase propagation on ESF days than other days indicate the presence of upward propagating Gravity Waves (GWs) in the initiation of these wave structures

There is growing concern about the effect of solar flares and Coronal Mass ejections (CMEs) on the terrestrial ionosphere and upper atmosphere system mainly due to the possible deterioration or damage in our communication and navigation applications. The solar flares release a burst of radiation into interplanetary space, especially in the bands of X-ray, UV, and EUV. The X-ray and UV-EUV will be absorbed in lower ionosphere (D and E regions) and F-region, respectively. Therefore, there is a sudden increase of electron density in the D, E, and F regions, called sudden ionospheric disturbances (SIDs). The SIDs in the D region can cause a total or partial blackout of short radio-wave propagation through the ionospheric region. The equatorial electrojet (EEJ) increases its intensity (E region) and at the F region the Total Electron Content (TEC) increases as well. In addition, the ionograms recorded by ionosondes show total or partial black-out, which means that the radio wave pulses transmitted by ionosonde get absorbed by D-region and there is no echo traces during flare hours. On September 6, 2017 the solar active region AR 2673 emitted two solar flares and they were powerful enough to black-out high and low radio waves. The first flare took place at 09:10 (X2.2) and the second one at 12:02 UT (X9.2). The X9.2 was the strongest solar flare event in a decade and disturbed the ionosphere on the sunlit side of the Earth. In this study we will take advantage of these two extreme flare events X2.2 and X9.2 to investigate the effects

on ionosphere using ionosonde data and TEC inferred using GPS dual frequency receivers. During the solar flares events of X2.2 (09:00 UT) and X9.2 (12:00 UT) the European and African sectors and European, African, and Brazilian sectors were exposed to the solar flare radiation, respectively. It was noticed that during the X2.2 flare there was an ionosonde blackout duration of about 45 minutes and during the X2.9 flare there was an ionosonde blackout of about 1 hour and 30 minutes. In addition it was noticed that the GPS-TEC showed a positive phase during these events.

C1.1-0066-18 LONG TERM PARAMETERIZATION OF THE OCCURRENCE RATE OF HF BACKSCATTER AS A FUNCTION OF THE UPSTREAM DRIVERS AND MAGNETIC INDICES

Hammed Lawal, hadelawal@yahoo.co.uk

Olabisi Onabanjo University, AGO-IWOYE, Nigeria Mark Lester, mle@ion.le.ac.uk

University of Leicester, Leicester, United Kingdom Tim Yeoman, yxo@ion.le.ac.uk

University of Leicester, Leicester, United Kingdom

The study presents the statistical analysis of the impacts of the upstream solar wind drivers and magnetic indices on the occurrence of ionospheric backscatter from 1996-2016. The data used in our analysis were obtained from the two eastern-most Super Dual Auroral Network (SuperDARN) radars located at Hankasalmi (Finland) and Pykkvibaer (Iceland). We investigate the occurrence of ionospheric backscatter seen during the four seasons in four different sectors of magnetic local time. The solar cycle and local time variations of the occurrence of ionospheric scatter as a function of the drivers in the four sectors of the magnetic local time and during the four season's shows a remarkable result. The goal of the study is to identify which of the parameters, seasonal and local time for which such a parameterization can be used as a predictive tool for now-cast and forecast purposes of the occurrence of ionospheric scatter. The study shows that the occurrence of backscatter was low in summer than during winter which might be due to density gradients suppression by photo-ionization.

C1.1-0067-18 CHARACTERIZATION OF EQUATORIAL AND LOW-LATITUDE MAIN GEOMAGNETIC FIELD ELEMENTS IN AFRICA

Oyedemi S. Oyekola, ooyekola@gmail.com Canada

We use 3 ground-based magnetic observatories annual means time series of geomagnetic field elements, namely D (magnetic declination) and I (magnetic inclination), X (geographic northsouth), Y (geographic east-west), Z (vertically down-vertically up), H (horizontal), and F (total field intensity) to investigate regional features, long-term changes, and the dynamics of the main geomagnetic field over equatorial and low-latitude in Africa. The magnetometer observations were obtained from East Africa: Addis-Ababa, Ethiopia (AAE: 9.2oN, 38.46oE, +0.5o dip latitude) for the period 1958.5-1995.5; West Africa: Ibadan, Nigeria (IBD: 7.26oN, 3.54oE,

-4.38o dip latitude) for the interval 1956.5 to 1975.5; and North Africa: Tamanrasset, Algeria (TAM: 22.48oN, 5.32oE, +14.73o dip latitude) over the period 1951.5 to 2015.5. Our results indicate complicated spatial/temporal distribution of geomagnetic field elements. Addis-Ababa Yand Z-components exhibit reversal from the westward to the eastward direction and from upward to downward direction around 1972.5 and 1989.5, respectively. The observed variability of the magnetic field intensities at TAM is exceptionally larger in value than those seen at Addis-Ababa and Ibadan by a factor of up to 7 and 12, respectively. The trends of magnetic field intensities at Ibadan and Tamanrasset are predominately positive except for Z-component which indicates negative trend at both sites. The overall strength of the equatorial dipole field is found to be declining at a rate of 6.2 nT/year. Conversely, we found evidence of a positive trend of order 13.2 nT/year at Ibadan and 15.8 nT/year at Tamanrasset. The first-order, time derivative of X-, Yand Z-components follow similar behavior at each station apart from Tamanrasset north-south and east-west components. Prominent geomagnetic jerks observed in the secular variation (SV) seem to be apparent in all the three orthogonal components of Earth's magnetic field intensities for the three stations with higher occurrences in equatorial dipole field at Addis-Ababa. We found significantly larger magnetic declination mean drift rate of roughly 1.51 degree/year (eastward) for Addis-Ababa, 0.88 degree/year (eastward) for Ibadan, and -0.85 degree/year (westward) for Tamanrasset; whereas the magnitude of magnetic inclination average drift rate is approximately comparable at the three observatories with a value of 0.36 degree/year for Addis-Ababa, 0.43 degree/year for Ibadan, and -0.37 degree/year for Tamanrasset.

C1.1-0068-18 IONOSPHERIC RESPONSE TO NEAR-EARTH CONDITION OBSERVED OVER MAITRI STATION 70.76 DEGREE S, 11.74 DEGREE E: A PRELIMINARY STUDY

James Arokiasamy Baskaradas, jamesbaskaradas@gmail.com SASTRA DEEMED TO BE UNVERSITY, Thanjavur, India

Veera Kumar Maheswaran, mveerakumarkvb@sastra.ac.in SASTRA DEEMED TO BE UNVERSITY, Thanjavur, India

Rupesh M. Das, rupesh@mail.nplindia.org National Physical Laboratory India, India

Near-Earth space environment system is a major driving force which controls the Earth's ionospheric condition. The near earth space environment system is very complex where the dynamics of the electric and magnetic fields are influenced by the high energy particles associated with solar wind. The present study is an attempt to study the influence of the solar flux on the high latitudinal ionosphere and the plasma drift. The GPS data recorded at Indian permanent research base "Maitri", (70.76°S; 11.74°E) during astral summer and equinox disturbed days were considered. The results reveals that the high latitudinal background geophysical conditions are very much modulated by slight variation in the solar condition which further significantly affects the Phase and Amplitude of GPS signal due to change in the state of ionosphere. The results suggested that the high latitude ionospheric response to the adverse space weather condition are different for different seasons i.e. a positive effect for summer and negative effect has been observed for equinox. Such positive and negative effects are mainly depending upon the combination of high latitudinal electro-dynamic conditions and neutral wind direction. The combination of equator-ward plasma transportation along with ionospheric compositional changes causes a negative ionospheric impact during summer and equinox seasons. However, the combination of pole-ward contraction of the oval region along with particle precipitation may lead to exhibit positive ionospheric response. The overall results suggested that the changing near-earth space environmental condition modifies the high latitudinal electrodynamic processes. The modifications of electro-dynamic processes are mainly due to injection of high energy particle up to the lower ionospheric altitudes which further modifies the E x B drift velocity. The combined effect of E x B drift velocity and direction of neutral wind decides the nature of ionospheric response over the considered region.

The ionospheric radio tomography methods (RT) are actively developing at present. These methods are suitable for reconstructing spatial distributions of electron density based on ra- dio signals transmitted from the navigational satellite systems and recorded by the receiv- ing networks on the ground. The RT systems working with the signals of low-orbiting (LO) (Parus/Transit) navigational systems have been in operation since the early 1990s. Recently, the RT methods employing the signals from the high-orbiting (HO) satellite navigational systems such as GPS/GLONASS have come into play. In our presentation, we discuss the accuracies, advantages, and limitations of LORT and HORT as well as the possibilities of their combined use for reconstructing the structure of the ionosphere in a studied region during a given time interval on the different spatiotemporal scales. LORT reconstructions provide practically instantaneous (spanning 5-10 min) 2D snapshots of the ionosphere within an interval of up to a few thousand km. Vertical resolution of LORT is 25-30 km and horizontal resolution is 15-25 km. HORT methods are capable of reconstructing the 4D structure of the ionosphere (three spatial coordinates and time). The spatial resolution of HORT is, generally, at best 100 km, and the interval between successive reconstructions is 30-60 min. In the regions with dense receiving networks, the spatial resolution can be increased to 30-50 km and time step reduced to 10-30 min. In California and Japan which are covered by extremely dense receiving networks, even higher spatial resolution (10-30 km) and shorter interval between the neighboring (up to 2 min) can be achieved. We discuss the LORT and HORT reconstructions of the ionosphere during different periods of the 23rd and 24th solar cycles in the different regions of the world. We analyze the spatiotemporal features and dynamics of the ionosphere depending on solar and geophysical conditions. Particular attention is focused on the periods of the strong geomagnetic disturbances. The storm-time ionosphere is characterized by extremely complicated rapidly varying structure. Under the action of a variety of the perturbing factors, the ionospheric parameters experience striking variations which can be traced by the RT methods. The RT reconstructions revealed multi-extremum plasma distributions, ionization troughs, steep wall-like gradients of electron density, spots of enhanced ionization, etc. A complicated structure of the main ionization trough with polar wall moving equatorwards was observed. The methods for constructing the RT indices of ionospheric perturbation which take into account the peculiar features of the HORT and LORT data are discussed. The results of comparing these RT indices to the indices of geomagnetic activity are presented. The work was supported by the Russian Foundation for Basic Research (projects nos. 16-05-01024 and 17-05-01250).

Multifrequency and multi-satellite occurrences of scintillations of tranionospheric signals at unexplored S (2492.08 MHz) band and L5 (1176.45 MHz) band from satellite constellation of the Indian Regional Navigation Satellite System(IRNSS) along with scintillations at L1(1575.42 MHz) and VHF (250.650 MHz) bands are investigated in the context of failsafe navigation. Observation are made during April 2015 to April 2017 from Raja Peary Mohan College(22.660 N, 88.40 E) located near the northern crest of EIA. Analysis indicates occurrence of severe scintillations exceeding dynamic range in the VHF to lower microwave L bands during equinoctial months of high solar activity years but the S band scintillations are mostly limited to 6-10dB fluctuations.Fast fading 30 fade/minutes at VHF,6-18 fade/minute at L band distinguished slowest fading(5/6 fades/minutes) at S band.The most probable fade duration irrespective of depth and locations of IPSs is estimated 2-3 sec at L5 and S bands while 10dB fades at L5 are separated by 6-10sec. While multiple scattering, signatures of dual slope, lowest coherence length characterize the VHF to L band scintilations, single scattering dominates S band.A study of CDF leads to fade margin of 14dB at L5 and 6dB at S band for faithful navigation.There are periods when multi-satellite links located within the 10o span of IPPs (satellites stationed between 55oE (IRNSS) and 145oE (MTSAT)) exhibit scintillations simultaneously and different GNSS links are disturbed by losses of lock.During the period availability of GNSS links (GPS, GLONASS etc) attains a value of less than minimum requirement of 4 for faithful navigations. Analysis of TEC data on the various GNSS tracks reveals severe depletions along with high value of ROTI, evolution and shifting of wavelet pattern in detrended TEC during multisatellite scintillations.The result may be discussed in terms of post sunset evolution of cluster of equatorial plasma bubbles with embedded multi-scale irregularity structures and corresponding dynamics.

C1.1-0071-18 RELATIVE ROBUSTNESS OF TRIPLE FREQUENCY GPS SIGNALS OBSERVED FROM ANOMALY CREST LOCATIONS DURING PERIODS OF IONOSPHERIC SCINTILLATIONS

Trisani Biswas, trisani77@gmail.com University of Calcutta, Kolkata, India Somrita Sarkar, somu.chaity@gmail.com University of Calcutta, Kolkata, India Ashik Paul, ashikpaul@aol.in

University of Calcutta, Calcutta, India

GPS modernization program includes addition of new civilian frequencies, L2C and L5 (1176.45MHz) to augment the already existing L1 and semi-codeless L2 frequencies. The basic objective behind this exercise is to provide improved multi-frequency ionospheric corrections to the civilian user community. Relative robustness of these new signals during periods of deep signal fading frequently encountered at equatorial and low latitude regions need to be examined. A multi-frequency and multi-constellation GNSS receiver capable of tracking GPS, GLONASS and GALILEO signals at L1, L2C and L5 frequencies is operational at Institute of Radio Physics and Electronics, University of Calcutta (22.58N, 88.38E, magnetic dip: 32N) and Department of Physics, North Bengal University (88.26E, 26.42N, magnetic dip: 39.85N) around the northern crest of the Equatorial Ionization Anomaly (EIA) in the geophysically sensitive Indian longitude sector.

During the present solar cycle, frequent and intense amplitude scintillations at L-band were observed from Calcutta and Siliguri. Cycle slips were calculated at L1, L2C and L5 on the same satellite link to understand the effect of equatorial ionospheric scintillations at different frequencies. During March 2014, a number of cases of cycle slips with duration exceeding 10s were noted, these values being higher than that specified by International Civil Aviation Organization (ICAO) for aircraft approach with vertical guidance (APV). It is interesting to note that cycle slips were found to be more frequent at L5 compared to L1, and L2C compared to L5, the latter result indicating less robustness of L2C signal. This exercise was repeated during 2016-2017 from Calcutta and Siliguri. Differences in occurrence of cycle slips at Calcutta and Siliguri may indicate enhanced randomness in the medium of propagation during these periods of signal fades.

C1.1-0072-18 STUDY OF SOLAR ACTIVITY EFFECT ON TEC VARIATION AT LOW-LATITUDES

Olatunbosun Lilian, lilianola@yahoo.com

Federal Polytechnic, Ado-Ekiti, Ekiti State, Nigeria, Ado-Ekiti, Nigeria Ayomide Olabode, a.labode@live.com

Department of Physics, Obafemi Awolowo University, Ile-Ife, Nigeria Emmanuel Ariyibi, eariyibi@oauife.edu.ng

Department of Physics, Obafemi Awolowo University, Ile - Ife, Nigeria

The dual frequency signals from the GPS satellites recorded at Ile-Ife, Nigeria (Geomagnetic Lat 7.52oN and Long 4.28oE); Addis Ababa, Ethiopia (Geomagnetic Lat 9.04oN, Long 38.77oE) and Bangalore, India (Geomagnetic Lat 13.03oE, Long 77.57 oE) have been analysed to study the effects of geomagnetic and solar activities on Total Electron Content (TEC). In the study, we described the geomagnetic and solar activity dependence of TEC. TEC shows a positive ionospheric storm effect, with increased geomagnetic activity corresponding to higher TEC values. The variations of TEC at maximum and minimum solar radio flux (F10.7) and sunspot number (SSN) for the two years revealed that the magnitude of TEC are influenced by solar activity, with maximum solar indices corresponding to maximum TEC values and was dependent on season and geographic location. The best correlation was found between TEC and F10.7, with a highest value of 0.851 at Addis Ababa in 2011.

Keywords. Low latitude Ionosphere, Equatorial Ionisation Anomaly, Total Electron Content, Solar activity.

C1.1-0073-18 STUDYING THE REALISTIC IONOSPHERIC PRECURSORS FROM EARTHQUAKE

Sanjay Kumar, sanjay.skitvns@gmail.com Banaras Hindu University, Varanasi, India Abhay Kumar Singh, abhay_s@rediffmail.com Banaras Hindu University, Varanasi, India

Wu Chen, lswuchen@polyu.edu.hk

Abstract: Spectral analysis as well as statistical analysis of total electron contents (TEC) derived from ground based GPS have been applied to study the earthquake's signature in the ionosphere. The anomalous perturbations in the TEC were observed from few days to few hours prior to the main shock of the earthquake. Perturbation depends on distance as well as direction of observation point from the epicenter. In addition to ionospheric perturbations, the wave-like features in detrended TEC (DTEC) were also identified. The spectral analysis of DTEC data showed an efficient tool to distinguish the perturbation between seismic induced perturbations from other sources. In addition to ionospheric perturbations, the wave-like features in DTEC were also identified. The wave like oscillation occurs few days to few hours before the main shock and associated periodicities in DTEC data varies from 20 min to more than 100 min. Keywords: Earthquake, GPS, Gravity Waves, Plasma Bubbles

Introduction: Earthquakes (EQs) are the most destructive phenomena which have killed thousands of people and destroyed several cities. Researchers around the world reported the seismic events and ionospheric perturbations anomalies observed in relation of EQs from almost two decades (Hayakawa et al, 1996; Pulinets 1998; Liu et al. 2000, 2001; Singh et al. 2004; Dutta et al. 2007; Hayakawa et al. 2010; Priyadarshi et al. 2011; Pulinets and Davidenko 2014; Kumar and Singh, 2017). These anomalies termed as seismo-ionospheric anomalies are detected through different ionospheric parameters as subionospheric fixed frequency transmitter signals, total electron content (TEC) etc. Gokhberg et al. (1989) reported first time the effect of the VLF radio sounding, and Molchonov and Hayakawa (2008) discussed in detail the electromagnetic phenomena associated with EQs.

Space Physics Laboratory, VSSC, Trivandrum, India

Solar flare effect over Ionosphere has always fascinated ionosphere plasma physicists to understand the behavior of Ionosphere during the flare event. In the present study we are discussing the effect of M1.4 class long duration flare during night time over Indian region emanating from sunspot region 0808 during 7th September 2005. Ionosphere response due to this flare can be observed in terms of reduction of Equatorial Electro-jet strength, maximum height of F2 layer (hmF2) and Total electron content derived by Global Navigation Satellite System over equatorial station (Trivandrum) and at low latitude station, Hyderabad and Equatorial Ionization Anomaly zone, Bhopal. Since Equatorial Ionization anomaly (EIA) is the unique phenomenon of equatorial ionosphere which lead to the diffusion of plasma from equatorial region to low latitude region under the effect of pressure gradient and gravity. EIA proxy has been calculated to confirm the flare induced EIA inhibition during the event day. In order to address the reason for the suppression of EEJ electric field, the observations are compared with quasi two dimensional first principle Ionospheric model calculations. The electron density profile are calculated at non flare and flare conditions. Hall and Pederson conductivities are calculated from these electron density profiles under two conditions and was able to explain the observed variation in the EEJ, hmF2 and TEC over different stations. Since during flare time, Ionosonde measurements are hampered because of enhanced electron density, we are no longer dependent over these observations as the electron density simulated by our model is to the close approximation of real time electron density measurements in Ionosphere.

C1.1-0075-18 ESTIMATION OF THE HEIGHT OF IONOSPHERIC INHOMOGENEITIES BASED ON TEC VARIATIONS MAPS OBTAINED FROM GPS OBSERVATIONS

Regional maps of total electron content (TEC) variations, obtained from the near zenith satellites observations of global navigation satellite systems (GNSS), make it possible to classify ionospheric heterogeneities and to evaluate their parameters. The analysis of the characteristic features of the spatial autocorrelation function allows to detect moving ionospheric inhomogeneities associated with atmospheric gravity waves and thermospheric winds. The direction of motion, speed, period and spatial distribution, as well as the lifetime, describe the characteristics of inhomogeneities in 3D space - latitude, longitude and time. In this presentation, we focus on the determination of the height of heterogeneity to create their 4D models. To calculate the height of the localization of ionospheric irregularities, the TEC variations maps, obtained from the signals of two or more GNSS satellites observed near zenith by the dual-frequency receivers of a dense regional network are used. Our research shows that the network area should not be less than 500x500 km with an average distance between stations about 50 km or less. The principle of determining the height is similar to the principle of determining the distance to the subject for focusing on the sharpness in modern photo cameras. The authors proposed and verified two techniques of the height estimation. Firstly, the sequence of the TEC variation maps for different heights of the ionospheric layer is constructed using the data of two or more simultaneously observed satellites. The localization height of inhomogeneities corresponds to the map with the greatest contrast. Secondly, the sequences of TEC variation maps for different heights of the ionospheric layer are constructed for each satellite separately. For each height the cross correlation functions between maps corresponding to different satellites are calculated. The biggest cross-correlation coefficient value determines the height of ionospheric irregularities. Numerical experiments on model inhomogeneities made it possible to estimate the optimal parameters and correlation characteristics of inhomogeneities, the height of which can be determined by the proposed techniques. It turned out that these are isotropic inhomogeneities with characteristic dimensions of around 100 km. Isotropy is

desirable because the mutual angular position of satellites can be arbitrary. Consequently, the cross-correlation characteristics of the inhomogeneities in the direction perpendicular to the plane formed by the two satellites and the reception point are essential to determine the height. The proposed techniques were tested for several events that took place in March 2013 and 2015 during the week when powerful geomagnetic storm on St. Patrick's Day occurred. At first, the time intervals for observing of more than one GPS satellites near the zenith were determined. For each day examined this condition was satisfied only for two fragments during the day and two satellites, that demonstrate the potential limitation of the proposed method. Nevertheless, even in two fragments during a day it was possible to study the behavior of ionospheric inhomogeneities. It was founded that in quiet geomagnetic conditions the ionospheric irregularities are localized predominantly within the interval 180-220 km near the maximum of the ionospheric F2 layer. In disturbed geomagnetic conditions, the height of their localization increased up to several hundreds of kilometers. These estimations correspond to the result from previous research. During the initial phases, on March 15 2013 and March 16 2015, of two powerful geomagnetic storms, both the significant growth of the height of inhomogeneities and a modification of their structure were detected. Namely, the traces of horizontally elongated quasiwaves structures in the ionosphere associated with moving irregularities, on the maps have been replaced by striped traces of structures elongated in the vertical direction and localized at altitudes of up to several thousand kilometers. These structures may be associated with streams of energetic electrons, emanating from the radiation belt along the lines of the geomagnetic field - Birkeland currents.

Different type of MSTIDs has been observed at Cachoeira Paulista (22.4°S; 45.0°W), Brazil, from June 2013 to December 2015 using airglow OI 630.0 nm images. During the period, 58 MSTIDs were identified and classified as: MSTIDs dark band (around 10 events), and periodic MSTIDs (48 events). Dark band MSTIDs present phase velocity between 50 and 200 m/s and propagation direction to northwestward. On the other hand, periodic MSTIDs have a horizontal wavelength of 80 to 160 km, a period ranging between 5 and 45 minutes, the phase velocity of 50 to 200 m/s, and propagation directions are mainly north-northeastward. The waves parameters indicate that the periodic MSTIDs have different characteristics compared to the dark band MSTIDs, suggesting that the periodic MSTIDs are not generated through the well-known Perkins instability. In addition to it, the present study indicates that the spectral characteristics found in Brazil are different from other regions such as Japan and Indonesia. Therefore, we intend to investigate the generation mechanisms of the periodic MSTIDs. Furthermore, the anisotropy observed in the periodic MSTID propagation direction can be explained by the wind filtering mechanism.

C1.1-0077-18 EQUATORIAL IONOSPHERIC RESPONSE TO THE MAIN PHASE OF INTENSE GEOMAGNETIC ACTIVITIES AT ILE-IFE, NIGERIA

Ayomide Olabode, aolabode@oauife.edu.ng Obafemi Awolowo University, 220005, Nigeria Emmanuel Ariyibi, eariyibi@oauife.edu.ng

Department of Physics, Obafemi Awolowo University, Ile - Ife, Nigeria

The effect of the main phase of two intense geomagnetic storm events which occurred on August 5-6 and September 26-27, 2011 on the equatorial ionosphere have been investigated using Global Positioning System (GPS) data obtained from an Ile-Ife station (geomagnetic lat. 9.84N, long. 77.25E). Total Electron Content (TEC) profiles during the main phase of the two geomagnetically disturbed days were obtained and compared with quiet time average profiles to examine the response of the equatorial ionosphere. International Reference Ionosphere (IRI) 2012 TEC model was also obtained from Virtual Ionosphere, Thermosphere, Mesosphere Observatory (VITMO) and the extents of deviation from measured GPS-derived TEC were examined for the main phase of the storm events. The results showed that the intensity of both storm events during the main phase which occurred at night-time correlated well with a strong southward direction of the z-component of the Interplanetary Magnetic Field (IMF-Bz) and Solar Wind Speed (Vsw), with the Disturbance storm time (Dst) profile showing multiple step development. TEC depletion was observed during the main phase of the August 5-6, 2011 storm event with TEC recording a maximum value of 9.31 TECU. A maximum TEC value of 55.8 TECU was recorded during the main phase of the September 26-27, 2011 storm event depicting TEC enhancement. Significant scintillation index value of 0.57 was observed when the main phase started on August 5-6, 2011 followed by a prolonged suppression while there was less significant scintillation impact on September 26-27, 2011 with a maximum value of 0.33. The present study show that remarkable energy input from solar wind during geomagnetic storm events have remarkable impact on the equatorial ionosphere over Ile-Ife, Nigeria.

C1.1-0078-18 THE MORPHOLOGY AND DRIVER OF THE TROPICAL IONIZATION TROUGH

Woo Kyoung Lee, wklee@kasi.re.kr

Korea Astronomy and Space Science Institute, Daejeon, Korea Hyosub Kil, hyosub.kil@jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, United States Larry Paxton, larry.paxton@jhuapl.edu

Applied Physics Laboratory, Laurel, Maryland, United States

A new type of ionization trough, the “tropical ionization trough”, is identified in the tropical F region from the satellite observations. The trough is formed around midnight near ±25° magnetic latitudes in the winter hemisphere. The formation of the trough in the winter hemisphere is explained in terms of the convergence of meridional winds in the tropics in the winter hemisphere. Troughs are pronounced around 330°E in the Southern Hemisphere during the June solstices and around 210°E in the Northern Hemisphere during the December solstices. This phenomenon is explained by the magnetic declination control of the zonal wind effect; an intense trough develops at the location where zonal winds enhance the poleward (or downward) plasma motion along with summer-to-winter winds. We investigate the variability of the trough morphology with height and solar cycle by analyzing the CHAMP and Swarm satellite observations. The physical processes underlying the trough formation are investigated using the ionosphere and thermosphere data provide by TIEGCM.

C1.1-0079-18 THE IMPORTANCE OF THE THREE-DIMENSIONAL GEOMETRY OF SOLAR ECLIPSES FOR ANALYSIS OF THE IMPACT ON THE IONOSPHERE

Tobias Verhulst, tobias.verhulst@oma.be

Royal Meteorological Institute (RMI), Brussels, Belgium Stanimir Stankov, s.stankov@meteo.be

Royal Meteorological Institute (RMI), Brussels, Belgium

Solar eclipses are well known to cause major disturbances in the ionosphere. Even an eclipse that does not reach totality anywhere can have a significant impact on the total electron density, the peak height and density, and other ionospheric characteristics all along its path. Additionally, travelling ionospheric disturbances can be generated in the path of the eclipse and travel well outside the region of obscuration. An extensive catalogue exist of all solar eclipses from 2000 BC to 3000 AD, with detailed information on the timing of the eclipse and the obscurations observable from different locations on the earth. However, investigations of the effects of the total eclipses visible in Europe in 2015 and in North-America in 2017 on the ionosphere have indicated that not only the latitude and longitude should be considered when calculating the obscuration levels and timing during a solar eclipse, but the altitude as well. Various effects have been observed that can only be explained by taking into account the three-dimensional nature of the shadow of the moon during an eclipse. We present theoretical calculations considering the full, three-dimensional geometry of solar eclipses, and show some examples of the importance of the height dependency of the eclipses' effects on the ionosphere.

C1.1-0080-18 DEVELOPMENT AND VALIDATION OF A NEURAL NETWORK BASED MODEL TO OBSERVE THE IMPACT OF GEOMAGNETIC STORM ON TEC AT LUCKNOW DURING 2015-2016

Dibyendu Sur, dibyendumalay@ieee.org University of Calcutta, KOLKATA, India Ashik Paul, ashikpaul@aol.in

University of Calcutta, Calcutta, India

The effects of strong geomagnetic storms over Total Electron Content (TEC) in Indian longitude sector have been reported in this paper. Geomagnetic storms during December 20-21, 2015; January 20-21, 2016; October 13-14, 2016 have been used to inspect the effects over TEC from Lucknow (26.91°N, 80.96°E, magnetic dip 41.90°). During December 20-21, 2015, an enhancement of TEC is observed over this station during and just after the storm period. The maximum enhancement observed during December 22, 2015 was 21.76 TEC Unit (TECU) during 11:02UT. TEC enhancement is also noticed before diurnal peak on December 21, 2015. The enhancement of TEC maximizes on December 22, 2015. Similar TEC enhancement during geomagnetic disturbed conditions are observed during January 20-21, 2016; October 13-14, 2016. An Artificial Neural Network (ANN) based TEC model is developed at Lucknow to predict Vertical TEC (VTEC) during geomagnetic quiet as well as disturbed conditions. The model is developed using International GNSS Service (IGS) TEC data from Lucknow. The model uses geomagnetic, solar indices as well as neutral wind inputs to generate VTEC by one minute resolution. The model is compared with standard ionospheric models such as International Reference Ionosphere (IRI) and Parameterized Ionospheric Model (PIM) to analyze its applicability in equatorial region.

C1.1-0081-18 VARIATIONS IN THE METEOR RADAR WINDS AT 22.7°S DURING GEOMAGNETIC STORMS ON JULY 2004

Luciana Rodrigues De Araujo, lucianarodrigues@uepb.edu.br UEPB, Campina Grande, Brazil

Lourivaldo Lima, lourivaldo_mota@yahoo.com.br Universidade Estadual da Paraíba, Campina Grande, Brazil Paulo Batista, paulo.batista@inpe.br

National Institute for Space Research (INPE), Sao Jose Dos Campos, Brazil

The interactions between the solar wind and the magnetosphere-thermosphere-ionosphere system produce variations on upper atmospheric dynamic to different spatial and temporal scales. The episodic increases in energy during geomagnetic storms results in additional variations in dynamics, chemistry as well as in the composition of the atmosphere. In this paper we have used winds from meteor radar at Cachoeira Paulista (22.7°S, 45°W) to investigate a possible relationship between variations in the dynamics of the upper mesosphere and lower themosphere (MLT) region and geomagnetic storm events on July 2004. The wind behavior presented a different pattern from those observed before and after the period of the geomagnetic storms, mainly in the meridional component. The possible relationship between diurnal tide variations and the geomagnetic storm events are discussed.

C1.1-0082-18 MITIGATION OF SYSTEMATIC ERRORS FROM IONOSPHERIC DISTURBANCES IN GOCE GPS DATA FOR GRAVITY FIELD DETERMINATION

Veerle Sterken, veerle.sterken@aiub.unibe.ch

Astronomical Institute, University of Bern, Bern, Switzerland Daniel Arnold, daniel.arnold@aiub.unibe.ch

Astronomical Institute, University of Bern, Bern, Switzerland Lucas Schreiter, lucas.schreiter@aiub.unibe.ch

University of Bern, Bern, Switzerland Adrian Jäggi, adrian.jaeggi@aiub.unibe.ch

Astronomical Institute, University of Bern, Bern, Switzerland

The ESA Gravity field and steady-state Ocean Circulation Explorer (GOCE) mission was operated from 2009 until 2013 in a Low Earth Orbit at an altitude between ca. 280 and 225 km. It provided gravity fields of the Earth with an accuracy 1 mGal, and with a spatial resolution of less than 100 km, using its gradiometers. Kinematic precise orbits were also determined using the GPS-data of GOCE, especially for long-wavelength gravity field determination.

However, gravity fields based on the kinematic orbit determination suffer from systematic GPS data errors in two latitudinal zones north and south of the Earth's geomagnetic equator that are likely caused by equatorial ionospheric plasma bubbles, especially at high solar activity.

In this talk, we give an overview of the activities undertaken at AIUB for empirically reducing the anomaly in the gravity fields as determined from kinematic orbits. We demonstrate that using the second derivative of the geometry-free GPS carrier phase observations (plain difference of L1 minus L2) as a screening criterion leads to slightly improved gravity fields.

C1.1-0083-18 DEPENDENCE OF LUNAR TIDE OF THE EQUATORIAL ELECTROJET ON THE WINTERTIME POLAR VORTEX, SOLAR FLUX AND QBO

University of Colorado, Boulder, United States

The lower atmospheric forcing effects on the ionosphere are particularly evident during extreme meteorological events known as sudden stratospheric warmings (SSWs). During SSWs the polar stratosphere and ionosphere, two distant atmospheric regions, are coupled through the SSW induced modulation of atmospheric migrating and non-migrating tides. The changes in the migrating semidiurnal solar and lunar tides are the major source of ionospheric variations during SSWs. In this study, we use 55 years of ground-magnetometer observations at Huancayo, Peru to investigate the composite characteristics of the lunar tide of the equatorial electrojet (EEJ) during SSWs. These long-term observations allow us to capture the EEJ lunar tidal response to the SSWs in a statistical sense. We examine the EEJ lunar tidal response during vortex-split and vortex-displaced SSWs and find that larger lunar tidal enhancements are observed during the vortex-split events. Further, we examine the influence of solar flux conditions and the phases of Quasi-Biennial Oscillation (QBO) on the lunar tide and find that the QBO phases and solar flux conditions modulate the EEJ lunar tidal response during SSWs in a similar way as they modulate the wintertime Arctic polar vortex. This work provides first evidence of modulation of the EEJ lunar tide due to the QBO phase.

C1.1-0085-18 SEASONAL VARIATION OF GEOMAGNETIC FIELD AND TEC AT MID LATITUDES

Amalia Meza, amalia.meza@gmail.com

Facultad de Ciencias Astronómicas y Geofísicas, Universidad Nacional de La Plata, La Plata, Argentina

Maria Paula Natali, mariapaula.natali@gmail.com

Facultad de Ciencias Astronómicas y Geofísicas, Universidad Nacional de La Plata, La Plata, Argentina

Our study is focused on the analysis of the geomagnetic variability of the H and Z components at different local times and at midlatitude during high solar activity. The variations of geomagnetic field can be from scale of seconds to millions of years and they can be periodic or random and its strength can vary from few to thousands of nT. It is divided in two main groups: long and short time variations. The first ones are mainly related with the dynamics of the Earth interior, primarily fluid motion in the core, and are on scale of few years to millions of years. The short time variations come predominantly from an external origin and are produced by currents in ionosphere and magnetosphere and by induced current in Earth's crust and ocean; they are on a scale of seconds up to a year. However these two types of variations could be overlapped particularly on the solar cycle effects and on secular variation impulses, known as jerks.

In this work, the data sample were carefully chosen, to isolate certain geomagnetic variabilities characteristic, which are clearly related to primary and secondary current systems of the magnetosphere and the ionospheric region. In this way, the overlap of the events that are not physically orthogonal, is minimized and a numerical technique based on principal component analysis (PCA's technique) will be useful to explain about the causes that produce these variabilities. In order to link these variabilities with the total electron (TEC) content and the thermospheric winds, the same numerical analysis was performed on vTEC obtained from observations of Global Navigation Satellite System network and thermostheric vertical wind from HWM07 model. Some remarkable results are the nighttime variation of the geomagnetic field measure from the ground that show an strong annual variation, with the superposition of a smaller semiannual component, the numerical technique applied over the selected sample, isolate the ring current variability as the main effect. From the Z component, the effect of the F layer currents variabilities could be identify. For midday variations (subtracting the nighttime period) a strong relationship between the TEC variability (spatial and temporal) and the magnetic field was found. The thermospheric wind describe a variability linked to the magnetic field variation. Therefore, in our analysis is clearly observed the effect of the variability in the conductivity and of the thermospheric wind that causes a current variation that finally induces the variability in the magnetic field.

C1.1-0086-18 QUIET-TIME MODERATE MIDLATITUDE L-BAND SCINTILLATION IN ASSOCIATION WITH PLASMA BUBBLES OVER NICOSIA

Haris Haralambous, eng.hh@fit.ac.cy Frederick Research Center, Nicosia, Cyprus

Despite the fact that scintillation events are infrequent phenomena over mid-latitude regions moderate night time amplitude scintillation on the GPS L1C/A signal was recorded at the midlatitude station of Nicosia (35.18N, 33.38E ; geomagnetic latitude 31.79N), Cyprus, on a geomagnetically quiet day. Slant total electron content (STEC) variations and amplitude scintillation index (S4) on the night of June 12, 2014 indicated the presence of electron density depletions in conjunction to scintillation occurrence. The apparent horizontal drift velocity estimated by digisonde drift measurements and the propagation direction of the plasma depletions are consistent with those observed for the equatorial plasma bubbles, thus indicating that the moderate amplitude L-band scintillation observed over Nicosia may be associated with the extension of such plasma bubbles. The L-band scintillation occurrence was concurrent with the observations of range spread F (RSF) on Nicosia digisonde ionograms. The Height Time Intensity (HTI) plot generated using the ionogram data also showed features indicative of off-angle reflections from electron density depletions, therefore corroborating the STEC observations. This event suggests that the midlatitude ionosphere is more active even during geomagnetically quiet days than previously thought and that further studies are necessary. This is particularly relevant for the GNSS user community and related applications.

C1.1-0087-18 GPS TEC SCINTILLATIONS AND TEC DEPLETION AS SEEN FROM HETAUDA AND NAST, NEPAL FOR 2016

Karan Bhatta, karangeorgia@gmail.com

Nepalese Center for Research in Physical Sciences (NCRPS), Kathmandu, Nepal

We analyzed the data of TEC from two GPS stations Hetauda and NAST, Nepal which are a part of UNAVCO. We obtained the variation of ROTI and S4 index throughout the year 2016 for the two stations involved for the 32 all the PRN numbers barring PRN number 4 which was inactive throughout the year. We also correlated the value of ROTI index with ROTI index and S4 index with S4 index for the two stations and found that the ROTI index of Hetauda was well correlated with ROTI index of NAST with the highest being 94% for PRN 10 and the lowest being -13% for PRN 1. Extremely low correlation between S4 index of Hetauda and S4 index of NAST was observed with the highest correlation being 8% in PRN 3, 32 and the lowest correlation of -15% in PRN 12.

C1.1-0088-18 CHARACTERISTICS OF EQUATORIAL PLASMA BUBBLES OBSERVED BY TEC MAP OVER SOUTH AMERICA AND NUMERICAL SIMULATION OF ITS DEVELOPMENT

Universidad de Los Andes, Venezuela

Ground-based network of GNSS receivers have been used to monitor Equatorial Plasma Bubbles (EPBs) by mapping the Total Electron Content (TEC map). Large coverage of the TEC map allowed us to monitor several EPBs simultaneously and get characteristics of the dynamics, extension and longitudinal distributions of the EPBs from the onset time until their disappearance. These characteristics were obtained by using TEC map analysis and keogram technique by using the data obtained during the period between November/2012 and January/2016. The zonal drift velocities of the EPBs showed a clear latitudinal gradient varying from 123 m/s at the equator to 65 m/s for 35°S of latitude. Consequently, observed EPBs are inclined against the geomagnetic field lines. Both zonal drift velocity and the inclination of the EPBs were compared with the thermospheric neutral wind, which showed a good agreement. Moreover, large coverage of TEC maps permit to study periodic EPBs with a wide longitudinal distance. This averaged values observed for the inter-bubbles distances also presented a clear latitudinal gradient varying from 920 km at the equator to 640 km at 30°S. On several occasions, the distances reached more than 2000 km. Inter-bubbles distances greater than 1000 km have not been reported in literature. Numerical model calculations, using different latitudinal gradients in zonal wind, showed a good agreement with the latitudinal gradient in the EPBs zonal drift observed by TEC map. Comparison of the observational results with the theoretical model calculations confirms that the EPB inclination against the geomagnetic field lines and the latitudinal gradient of inter-bubbles distances were originated due to a latitudinal gradient in the

EPBs zonal drift.

C1.1-0089-18 THE EMBRACE MAGNETOMETER NETWORK FOR SOUTH AMERICA: FIRST SCIENTIFIC RESULTS

Clezio Marcos Denardini, clezio.denardin@inpe.br INPE, Sao Jose Dos Campos, Brazil

Embrace MagNet

Clezio M. Denardini, Sony S. Chen, Laysa C. A. Resende, Juliano Moro, Andreos V. Bilibio, Paulo R. Fagundes, Mauricio A. Gende, Miguel A. Cabrera, Mauricio J. A. Bolzan, Antonio L. Padilha, Nelson J. Schuch, Jose L. Hormaechea, Livia R. Alves, Paulo F. Barbosa Neto, Paulo

A. B. Nogueira, Giorgio A. S. Picanço, Thaina O. Bertollotto

The present work is the second of a two-part paper on the Embrace Magnetometer Network. In this part, we provide some of the first scientific findings that we have already achieved with this network. We identified the diurnal and the seasonal natural variations of the H component. We provided the precise determination of SSC and SI. We showed that the H amplitudes derived from the Embrace MagNet during intense magnetic storm are in very good agreement with the Dst index. We showed that it is possible to investigate of the effects of the Sq systems response to the X-class solar flares occurring during daytime under magnetically quiet conditions.

C1.1-0090-18 A STUDY ON THE METEORIC PERIODIC ACTIVITY ON THE TRIGGER OF INFRASOUND WAVE PRODUCTION IN THE EQUATORIAL REGION OF INDONESIA

Mario Batubara, batubaramario@gmail.com

Indonesia National Institute of Aeronautics and Space (LAPAN), West Java, Indonesia Masa-yuki Yamamoto, yamamoto.masa-yuki@kochi-tech.ac.jp

Kochi University of Technology, Kami, Japan

The infrasonic region of the sonic wave spectrum in the Earth's atmosphere is filled with a wide variety of natural sources. One of the more unusual, but constant, sources of natural infrasound is that of interplanetary debris, or meteoroids, colliding with the Earth's atmosphere at hypersonic velocities, in a process commonly referred to as a meteor. Many meteors can be detected by radio, generating shock waves during the lower transition flow regime and before their terminal stages in the Mesosphere-Lower Thermosphere (MLT) region of the atmosphere, at altitudes range between 75 km and 100 km. The shock wave strength generated by the meteor depends on meteoroid atmospheric velocities in a given region. However, practical detection and determination of the altitude of formation of these shock waves (i.e. over dense meteors) have not been possible up to this point. Moreover, a good estimate of the direction and speed of infrasound propagation in the atmosphere at equatorial latitudes, remains elusive. To solve this, we investigated the relevant meteor parameters observed by Meteor Wind Radar (MWR) in Kototabang (0.20o S, 100.32o E) and Biak (1.17o S, 136.10o E) in Indonesia. Here, we present the observed periods of meteors which generated infrasound as a function of observed meteor velocity as an initial investigation for further study. On the other side, we plan to install the infrasound sensor network around equatorial Indonesia that can be used as a reasonably accurate indicator of the infrasound sources.

C1.1-0091-18 GRAVITY WAVES PROPAGATION FROM TROPOSPHERE UP TO THERMOSPHERE OVER BRAZIL

Diego Barros Silva, bar_diego@hotmail.com

INPE - Instituto Nacional de Pesquisas Espaciais, São Paulo, Brazil

Gravity wave structures were observed in the troposphere in southern Brazil on September 16th, 2015. Temperature profiles were obtained from COSMIC radio occultation technique. On the same day, wave structures were observed on dTEC (detrended Total Electron Content) maps in the ionosphere over the southeast region of Brazil, with a horizontal wavelength of 345 km, a 26-minute period and a phase velocity of 221 m / s, propagating to North. Airglow observations in the same region also show several types of gravity waves with horizontal wavelengths ranging from 14 to 34 km and periods between 5 and 8 minutes spreading to northeast. Using the reverse and forward mode of the ray tracing technique we investigate the wave sources in the troposphere and the wave propagation up to the thermosphere

C1.1-0092-18 MORPHOLOGY OF THE IONOSPHERIC SCINTILLATIONS OVER LOW LATITUDE REGION DURING GEOMAGNETICALLY QUIET AND DISTURBED PERIODS

Marcelo Henrique Duarte Silva, mhduartemantec@hotmail.com
Univap, Sao Jose Dos Campos, Brazil

Marcio Muella, mmuella@univap.br

Universidade do Vale do Paraíba - UNIVAP, Sao Jose Dos Campos, Brazil

This study aims look into the long-term ionospheric scintillations activities during quiet and disturbed geomagnetically periods over the low latitude region in the Brazilian sector. The research was carried out from single-frequency GPS receivers acquired during 17 years on the amplitude scintillation data through Global Positioning System satellite. At first, it was analyzed the climatology of ionospheric scintillations at Cachoeira Paulista site (22.4ºS, 45.0ºW) during quiet geomagnetically periods from 1997 to 2014. The results reveal that the nocturnal occurrence of scintillation follows the seasonal distribution of plasma bubble irregularities. In addition to the solar cycle dependence, the results suggested that the occurrence climatology of scintillations is also modulated by the secular variation in the dip latitude of Cachoeira Paulista. The analysis was complemented by an unpublished study of statistical characterization of scintillations using the - distribution model. The results show that for different levels of solar cycle activity the α-μ model fit quite well with the experimental data and with the temporal characteristics when the S4 < 0,8. Meanwhile, in terms of higher-order statistics the parameter did not vary along the solar cycle. Then, it was analyzed the morphology of scintillations owing to magnetosphere-ionosphere coupling for storm time disturbance electric field propagation to equatorial latitudes through the processes of direct penetration (PPEF) and disturbance wind dynamo (DDEF), so that caused drastic changes on the electrodynamics of the equatorial ionosphere, especially, in terms of their impact on plasma bubble irregularity development conditions. The scintillation activities during geomagnetically periods were analyzed from 303 events of geomagnetic storms (SYM-H -50 nT) since 2000 until 2014 over the equatorial station of São Luís (2.3°S; 44.2°W) and a low latitude station of São José dos Campos (23.1°S; 45.8°W), located under the southern crest of the EIA. The geomagnetic storm events were classified according to their diferente types, intensities and solar wind drivers, so that a statistical study of scintillations was noticed over the both stations. In general, the results reveal that the a progressive increase of magnetic activity resulted in inhibition of irregularities causing scintillations, especially for S4 > 0.5. In the end, five diferentt events of storm were selected with the aim study on the equatorial ionospheric scintillation response to the disturbance electric field, since the in two events, where the maximum SYM-H excursion occurred close to the dawn or dusk terminators the results diverge from what was expected. However, the results that emerge from these observations indicate that the effects the ring current and the local time when the ring curent changes from injection to recovery appears to play a leading role in establishing the conditions necessary for equatorial F layer irregularity generation and inhibition.

C1.1-0093-18 GRAVITY WAVE PARAMETERS AND THEIR SEASONAL VARIATIONS STUDY NEAR 120OE CHINA BASED ON NA LIDAR OBSERVATIONS

Xu Zou, christian5022@163.com

National Space Science Center, CAS, Beijing, China Guotao Yang, gtyang@spaceweather.ac.cn

Center for Space Science and Applied Research, Chinese Academy of Sciences, Beijing, China Jihong Wang, jhwang@nssc.ac.cn

National Space Science Center, CAS, Beijing, China

Based on the newly established lidar chain at meridian 120oE China, the gravity wave (GW) activity between 80 and 105km and the seasonal behavior of temporal and spatial spectra at Beijing, Hefei and Hainan were studied with continue accumulated data based on the 3 years observations. The GW induced atmospheric density perturbations and their spectra were analyzed at the three observation site. The averaged RMS atmospheric density perturbations over three sites are near 6 %, which in summer are obviously larger than that in winter and the maxima occur near the solstice. Besides, as a disparity, the density perturbation of GW is still active considerably in winter of low latitude in China at Hainan. The spectra of vertical wave number (m) with special value as 2π/8 km, 2π/4 km, 2π/2 km 2π/1 km and observed frequency spectra as =2π/60min, 2π/25min, 2π/15min exhibit the similar seasonal behavior with the semiannual maxima emerging around the solstice. The m spectra and spectra show power law shapes, of which the average are near -3 and -1.7, respectively. The GW spectra seasonal variation shows the similar regulation as density perturbations at different latitudes. The wave source was calculated by LIDAR observation at a distance of about 1100km westward to the 120oE observing chain which are located at the bounder of Tibetan Plateau, and it could be concluded that this behavior may be caused by effect of Tibet Plateau wind shear.

C1.1-0094-18 STUDY OF EFFECTS OF SOLAR ZENITH ANGLE PROFILE ON SUB-IONOSPHERIC VLF RADIO WAVE PROPAGATION CHARACTERISTICS

Sudipta Sasmal, meet2ss25@gmail.com

Indian Centre for Space Physics, Kolkata, India Tamal Basak, tamalbasak@gmail.com

Amity University, Kolkata, India

Suman Chakraborty, suman.chakrabarty37@gmail.com Indian Centre for Space Physics, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

The ionization of the lowermost D-layer of the ionosphere highly depends on the solar zenith angle profile (). The electron density profile of D-layer plays the key role for modulation of Very Low Frequency (VLF) radio signal propagated through earth-ionosphere waveguide. This implies that the VLF signal characteristics strongly depends on the solar zenith angle profile over the entire propagation path. As for a particular location, the solar zenith angle variation depends upon the day of the year, the diurnal and seasonal signal profile will follow the same trend of if no extra ionization takes place due to other source. Depending upon the time of the day, the propagation path may be uniformly or non-uniformly illuminated. Here we compute the zenith angle profile over different VLF propagation paths for different times of the day. We use Wait's exponential model to compute the electron density profile of lower ionosphere and we assume a linear relationship between the Wait's parameters effective reflection height (h), steepness parameter (????), and solar zenith angle. We fed these parameters to Long Wavelength Propagation Capability (LWPC) code to simulate the signal amplitude profile for various propagation paths and compare them with observed signal.

C1.1-0095-18 EFFECT OF SOLAR ACTIVITY ON NIGHT-TIME F-LAYER HEIGHT PROFILE AT THE MAGNETIC EQUATOR IN WEST AFRICA DURING THE SOLAR MINIMUM PERIOD 1995 - 1997

Komenan Zacharie Zaka, komzach@yahoo.fr

LAPA-MF, SSMT, University FHB of Cocody, Abidjan, Abidjan, Cote D'Ivoire

The night-time equatorial F-layer height behavior at Korhogo (9.2° N, 5° W; 2.4°S dip lat), Cote d'Ivoire, in west African sector is investigated in this paper. The focus of this paper is to study the effect of solar activity on the night-time F-layer height. The period of study take place during the solar minimum (1995 - 1997), where data from quarter-hourly ionogram of an Ionospheric Prediction Service (IPS) 42-type vertical sounder is available at the station of Korhogo. The statistical analysis of the occurrence of night-time F-layer profiles through-out the solar minimum period (1995 - 1997) recently evidenced at Korhogo by Tanoh et al. (2015) revealed two main F-layer height patterns with specific characteristics associated with seasons. The one with the post-sunset height peak (Type-1) due to the evening E×B drift, associated with the northern winter period and the other with the midnight height peak (Type-2), observed during the northern summer period. The transition process from the pattern Type-1 to the pattern Type-2 was found to last only a few weeks during the equinox period. In order to evaluate the effect of solar activity on night-time F-layer height profiles Type-1 and Type-2, the average value of the F-layer all the time, on the duration of every period is calculated and the variations of the temporal profiles of average height obtained, as a function of year, are analyzed. During the consecutive years, the same F-layer profile Type-1 appears in the winter period with a peak the amplitude of which grows. In summer, the profile changes morphology from one year to another, passing gradually from the pattern Type-1, in 1995 at the solar minimum to relatively modified pattern Type-2 as a function to the increasing solar activity. However the amplitude of the peak increases. These results show that an important effect of the solar activity on the F-layer height is to lift the peak when the solar activity increases. However on the seasonal morphology, there is no influence of solar activity on the winter pattern Type-1. But on summer pattern Type-2, the relative change in the profile can be due to the method of data processing. Thus other investigations turn out to be necessary. A quantitative study of the variations of the post-sunset peak height and the midnight peak height, as a function of solar activity during the various seasons finds that the height of the peak grows linearly with the solar activity. The post-sunset peak rises of 1 km when the number of sunspots increases by a unit whereas the midnight peak grows twice less fast for the same variation of the solar activity.

C1.1-0097-18 HIGHLIGHTS OF THE ARECIBO OBSERVATORY REMOTE OPTICAL FACILITY (AO-ROF) DATABASE AND FUTURE PROJECTS.

Pedrina Santos, pterra@naic.edu

Arecibo Observatory, Arecibo, Puerto Rico, United States Christiano Brum, cgmbsjc@hotmail.com

Arecibo Observatory, Arecibo, Puerto Rico Eva Robles, erobles@naic.edu

Arecibo Observatory, Arecibo, Puerto Rico

The Arecibo Observatory Remote Optical Facility (AO-ROF) was established in the island of Culebra since November 2015 and has been successful on its operation.The AO-ROF is located 95miles East from AO (18,3°N; 65,3°W) in a recluse and secure area and provides an economical opportunity to offer a superior data product to our scientific clients and users. Given Culebra Island's favorable geographical and climatological characteristics as its low elevation and geographic location, it has more steady weather conditions than Arecibo, so therefore it provides more availability for optical observations. The AO-ROF instrumentation includes: all-sky imager systems, GPS, High Frequency receivers and cloud sensor. The capability of the optical instruments placed at AO-ROF in to observe the same thermospheric volume over AO sampled by the Incoherent Scatter Radar (ISR) is especially relevant during the High Frequency (HF) campaigns, which are ran by the AO new heating facility. This work presents highlights of the database acquired at the ROF, as well a discussion of the current status of the facility and future projects.

C1.1-0098-18 METEOR RADAR TEMPERATURES AT 7.4°S AND 22.7°S

Lourivaldo Lima, lourivaldo_mota@yahoo.com.br Universidade Estadual da Paraíba, Campina Grande, Brazil Paulo Batista, paulo.batista@inpe.br

National Institute for Space Research (INPE), Sao Jose Dos Campos, Brazil Ana Roberta Paulino, arspaulino@gmail.com

UEPB, Campina Grande, Brazil

Mesospheric temperatures at 90 km height have been estimated from meteor radar measurements obtained at Cachoeira Paulista (22.7°S, 45°W) and São João do Cariri (7.4°S, 36.5°W). The temperatures were estimated using local models for temperature gradient and pressure and showed a good agreement with temperatures from Sounding of the Atmosphere by Broadband Emission Radiometry (SABER) over both sites. The temperatures by gradient technique show larger day to day variations than those estimated by pressure method and from SABER data. Spectral analysis have revealed the presence of annual (AO), semiannual (SAO) and quadrennial (QAO) periods on temperatures estimated by two techniques and from SABER data at both sites. The amplitude of the SAO over Cachoeira Paulista on temperatures by pressure method exceeds those estimated by gradient technique as well as the SABER temperatures. Over São João do Cariri, the SAO amplitude on temperature by pressure method also exceeds those derived by gradient technique and from SABER data. The SAO temperatures are in phase with each other, with maximums around equinoxes, just when the phase of SAO on mean zonal winds around 81 km is westward over both sites, however, the maximums in the westward winds happens before the maximum temperatures.

C1.1-0099-18 IONOSPHERIC DISTURBANCES: HYBRID SIMULATION OF KELVIN-HELMHOLTZ INSTABILITIES IN THE PRESENCE OF RADIALLY VARYING FLOW

S Sen, ssen01@wm.edu

NIA/W&M/BSU, Hampton, Virginia, United States

This paper summarizes the hybrid simulation results of plasma flow curvature effects on the growth of the Kelvin-Helmholtz instability (KHI). It is found that KHI growth rate is higher when the shear flow has a negative initial curvature than linearly sheared initial flow. The growth rate is lower when the initial shear flow has a positive curvature. The growth rate under positive curvature decreases with increasing positive curvature.

C1.1-0100-18 STUDY OF THE CHARACTERISTIC OF THE GROWTH OF MSTID OBSERVED BY GNSS

Takafumi Ikeda, ikeda@kugi.kyoto-u.ac.jp Kyoto University, 222, Japan

Akinori Saito, saitoua@kugi.kyoto-u.ac.jp Kyoto University, Kyoto, Japan

Takuya Tsugawa, tsugawa@nict.go.jp

National Institute of Information and Communications Technology, Tokyo, Japan

Medium scale traveling ionospheric disturbance is one of phenomenon in ionosphere and has been long studied. Nighttime MSTID will be caused by Perkins instability, but linear growth time(e folding time) of Perkins instability is very slow as growth time from random thermal noise. For this problem, we could solve by the geomagnetic connection between E-region and Fregion, and inserting the sporadic E layer's polarized electric field as the energy source of growth. However, we have few examples of observational verification whether E-region is connected to Fregion when a disturbance occurred. And Perkins instability's growth rate is independent from wavelength, but we observe more MSTID events which wavelength is 200km - 400km. Sporadic E layer has less than 100km periodic structure, which contradicts observation. Therefore we think it is difficult to claim E-region and F-region connection as growth mechanism. To verify this idea, we studied the character of growth of nighttime MSTID. Using this method, we statistically estimated growth rates of nighttime MSTID in japan in summer 2014 observed by GNSS. We applied three-dimensional spectral method for total electron content grid data ,and estimated propagation velocity. Using this velocity, we tracked movement of one wavefront of MSTID, and estimated the fastest growth time of each event by using wavenumber spectra when tracking. As a result, growth time is slower than 16 minutes. Propagation direction when growth time is fastest is southwestward(205 deg - 245 deg). Growth time is even faster when 240 degrees. This time is too slow as growth time of MSTID, and is within the range of one perkins instability expects. We will show the detail about the relation between this growth time and both mechanisms, and also present the wavelength dependence of growth.

C1.1-0101-18 TRANSIENT ES-LAYERS PROPERTIES AT MID-LATITUDES OF NORTH HEMISPHERE.

Kamil Yusupov, kamil.usupov@kpfu.ru Kazan Federal University, Kazan, Russia Takashi Maruyama, tmaru@nict.go.jp

Natl. Inst. of Info. and Comm. Tech., Tokyo, Japan Adel Akchurin, adel.akchurin@kpfu.ru

Kazan Federal University, Kazan, Russia Oleg Sherstyukov, oleg.sherstyukov@kpfu.ru Kazan Federal University, Russia

At present, there are many methods for studying the ionosphere: rocket, radar, satellite, optical, vertical and inclined soundings with ionosondes, etc. Therefore, in recent years, the number of phenomena occurring in the ionosphere is becoming more and more known and obtain theoretical explanations. With the development of methods for studying the ionosphere, the phenomena of the lower part of the ionosphere the sporadic E-layer (Es) gets increasing interest. The greatest information about these layers is collected using ionosondes. To study Es-layers, other methods of observation either have a weak sensitivity (for example, GPS) or short duration (radar methods). In addition, an important parameter is the time and speed of observation or sounding, therefore, in order to study the fast processes of the ionosphere in Kazan the ionosonde «Cyclone» was modernized. Modernization consisted in increasing the sounding period from 15 to 1 minute. This ionosonde mode allowed to finde statistical features and heights appearance range of transit sporadic Eslayers at mid-latitudes. Possible mechanisms of the transit Es-layer formation are discussed.

C1.1-0102-18 ANALYSIS OF THE LOW AND EQUATORIAL IONOSPHERIC RESPONSE TO A SUPER STORM – OBSERVATIONS AND NUMERICAL SIMULATIONS

Liang Xu, lix0413@whu.edu.cn Wuhan University, Wuhan, China

We present both observations and numerical simulations of the low and equatorial ionospheric response to a super magnetic storm during 9-10 Nov. 2004. Observations include GPS-TEC, E×B drift obtained by the Incoherent Scatter Radar at Jicamarca Radio Observatory (JRO), hmF2 and foF2 obtained by the ionosonde at JRO. Both observations and simulations show super plasma fountains during the daytime and nighttime respectivelycaused by the strong eastward penetrate electric field. And then the super fountains are suppressed by the westward disturbed dynamo electric filed occurring subsequently. During the daytime, the F3 appears as a result of the super plasma fountain. The simulation reproduces the generation, development, and suppression of the equatorial F3, which is well consistent with the ionogram. During the nighttime, because of the lack of photochemical effect, there appears huge depletion at the low and equatorial ionosphere after the lifting of the ionosphere. The numerical simulations are consistent with the observations without consideration of the neutral wind effect, which implies that the electrodynamic effects might play a major role in controlling the ionosphere for this storm event.

C1.1-0104-18 CLIMATOLOGY OF THE NIGHTTIME IONOSPHERIC TROUGH

Facultad de Ciencias Astronómicas y Geofísicas, Universidad Nacional de La Plata, La Plata, Argentina

Global vertical Total Electron Content (vTEC) maps produced by the International Global Navigation Satellite System (GNSS) Service are used to study the seasonal variation of the mid-latitud ionospheric trough (MIT). MIT shows a structure in longitude and latitude in the F2 region. The shape and behavior of the trough is different and its related with the spatial-temporal ocurrence. Some authors showed that the trough prevail during evening and night-times hours. Several physical mechanisms have been proposed to explain it formation which include plasma stagnation, periods of increasing geomagnetic activity, enhanced of the electric field between others. Also, the horizontal neutral wind was proposed as a possible cause in deepest MIT formation.

By using the principal component analysis (PCA) numerical technique, this work studies the spatial and temporal variations of the MIT at nigth for the period 1999-2017 during differents hours: 22, 00 and 02 LT. The vTEC maps series are carefully choosen taken into account the Kp index to associate the MIT formation with the geomagnetic activity. Also, vTEC maps from the International Reference Ionosphere (IRI) 2012 and the Horizontal Wind Model 2007 (HWM07) are used to improve our climatology interpretation, by analyzing the relationship between vTEC and the horizontal neutral wind.

C1.1-0105-18 OCCURRENCE AND AMPLITUDES OF EQUATORIAL PLASMA DEPLETION AS OBSERVED BY SWARM SATELLITES

Xin Wan, iml_wobscene@whu.edu.cn Wuhan University, Wuhan, China Chao Xiong, bear@gfz-potsdam.de

GeoForschungsZentrum Potsdam, Potsdam, Germany Juan Rodriguez-Zuluaga, juanrz@gfz-potsdam.de

Wuhan University, Wuhan, China

An auto-detection technique is developed to find equatorial plasma depletions (EPDs) and their amplitudes base on the in situ electron density profiles measured by Swarm satellites, which can also be applied to the measurements of other spacecraft. For the first time, three different parameters derived from Swarm satellites, the GPS receiver signal loss events, the Ionospheric Bubble Index (IBI) of L2 product, and the occurrence and amplitudes of EPDs are taken in comparison. The EPDs are found with largest occurrence rate between 2200-0000 magnetic local time (MLT) and show a similar pattern with IBI but with a larger magnitude, while largest depletion amplitudes of EPDs appear earlier between 1900-2100 MLT correspond to higher background electron density and stronger effects on the Swarm GPS receivers. Similar features are also identified from a longitudinal perspective. The occurrence rate of post-midnight EPDs is generally reduced compare to pre-midnight; however, during June solstice months even more post-midnight EPDs are observed at African longitudes. CHAMP observations confirm this point regardless to high or low solar activity conditions. Besides, evidence also shows that solar minimum is preferred for the occurrence of post-midnight EPDs over Pacific region, especially for southeast Pacific during Dec. S. months. Further by comparing with the plasma vertical drift velocity from ROCSAT-1, we suggest that the F-region vertical plasma drift plays a key role in dominating the occurrence of EPDs during pre-midnight hours, while the postmidnight EPDs are the combined results from the continuing of former EPDs and newborn EPDs, especially during June solstice. And these newborn EPDs during post-midnight hours seem less related to the plasma vertical drift.

C1.1-0107-18 NIGHTTIME ENHANCEMENT OF MIDLATITUDE IONOSPHERE AND ITS CONNECTION TO THE PLASMASPHERE

Yongqiang Hao, hao@pku.edu.cn Peking University, Beijing, China Quanhan Li, liquanhan@pku.edu.cn Peking University, Beijing, China Donghe Zhang, zhangdh@pku.edu.cn

Department of Geophysics, Peking Uinversity, Beijing, China Zuo Xiao, zxiao@pku.edu.cn

Peking University, Beijing, China

Midlatitude Arcs (MLA) have been found in the TIMED/GUVI OI 135.6nm nightglow observation previously. The glow arcs are supposed to be the phenomenon of nightside enhancements of the ionosphere at 20º-45º magnetic latitudes in both hemispheres. Using ionospheric observations we search for plasma enhancement structure counterpart to the nightglow MLA. The topside TEC observations from LEO satellites reveal longitudinal plasma distribution of the plasmasphere, interestingly showing some correlation with the ionospheric MLA structure. The plasmaspheric TEC concentrates near the equatorial plane, while the geomagnetic field lines connect the plasmasphere and midlatitude ionosphere. We therefore suggest that the plasmaspheric downward flux possibly feeds the midlatitude ionospheric structures during nighttime.

C1.1-0108-18 ANALYSIS OF GPS IONOSPHERIC SCINTILLATION FADING UNDER LOW LATITUDE REGIONS

Instituto Tecnológico de Aeronáutica - ITA, São José Dos Campos, Brazil Waldecir Perrella, waldecir@ita.br

Instituto Tecnológico de Aeronáutica - ITA, São José Dos Campos, Brazil

Global Navigation Satellite Systems are widely used by the aeronautic community to increase safety and reduce costs. These systems allow the use of procedures that increase airport efficiency, increasing flight availability, reducing flight delay, saving fuel and increasing safety. However, quick variations in the signal amplitude and carrier phase shift due to the ionosphere scintillation may cause the degradation or loss of the GNSS related services. Equatorial regions, such as most of the Brazilian territory, present great ionospheric scintillation because of the development of instabilities and the Equatorial Ionospheric Anomaly. The objective of this work is to perform a statistical analysis of the ionospheric effects on the GPS signals, with signal data from monitoring stations in the Brazilian territory to assess the fading in signal amplitude for the civilian GPS signals L1, L2C and L5. The analysis will include approximations for the amplitude fading for the GPS signals in similar geophysical conditions. The analysis of these equations will show how the new civil signals L2C and L5 perform in scenarios with ionospheric scintillation in comparison with the current L1 signal. The used amplitude distribution model used in this work is the α -μ distribution. The data used in this work belong to four different stations with dips of 8.86°, 16.01°, 19.28° and 22.32°. The stations belong to CIGALA/CALIBRA network. The data were collected from November 2014 to March 2015, during the summer equinox in the peak of the current solar cycle, period of great ionospheric scintillation occurrence. The results show that GPS users of new frequencies L2C and L5 are significantly more susceptible to the effects of ionospheric irregularities, in particular the stations located near the crest of Equatorial Ionospheric Anomaly.

C1.1-0109-18 EXTRACTION OF SOLAR RADIATION EFFECT FROM TEC BASED ON NONLINEAR DATA PROCESSING TECHNIQUE FOR SEISMO-IONOSPHERIC ANOMALY DURING THE PERIOD OF EARTHQUAKES

Kunvar Yadav, kunvar.yadav@gmail.com

Indian institute of teacher education (IITE), Gandhinagar, India

The study of ionospheric precursors of the earthquake has gained interest among many researchers, especially the precursor obtained in terms of anomalous variation in total electron content (TEC). If an earthquake occurs during a period of moderate to high solar activity, the TEC derived using global positioning system (GPS) measurements requires the elimination of solar effect so as to identify the precursory signature. This paper includes multi-resolution time series technique to remove the nonlinear effect from solar radiation on GPS-based TEC. The technique is based on wavelet transform applicable to RINEX TEC data. This technique is used to remove nonlinear background solar effect from TEC prior to four different earthquakes (M > 6.0). Further, in order to evaluate the extracted TEC, we obtain the correlation between the decomposed TEC A6 and measured solar index (F10.7) and extreme ultraviolet (EUV). A good correlation is obtained between decomposed TEC A6 and EUV for all the cases. This suggests that this technique is useful for the removal of background solar effect for identifying earthquake precursor in TEC.

C1.1-0110-18 STUDY ON ZONAL DRIFT VELOCITIES OF THE IONOSPHERIC PLASMA BUBBLES USING A SINGLE GPS SCINTILLATION MONITOR

Matheus Henrique Monteiro De Oliveira, matheus.hm@hotmail.com Embraer S.A., São José Dos Campos, Brazil

ITA - Instituto Tecnológico de Aeronáutica, Sâo José Dos Campos, Brazil

Global Navigation Satellite Systems (GNSS) have been used over the years to provide precise information on time and positioning for several applications. For the aeronautical and aerospace community, the GNSS has been widely used to increase flight safety and also reduce operational costs. Avionic systems based on GPS technology have expanded aircraft routes, increased flight availability, airport efficiency and flight safety. These systems are highly dependent on signals transmitted by navigation satellite systems such as the American GPS and the Russian GLONASS. As these radio waves propagate through the ionosphere, they may suffer disruptions and signal losses due to ionospheric plasma and its structuring. Scintillation, characterized by rapid phase and amplitude fluctuations in the signal as it travels through the ionosphere is among the most common effect. Its consequences range from small precision and accuracy errors to a complete loss of signal lock and, ultimately, a complete failure of the system that may prove to be catastrophic. In equatorial and low-latitude regions that cover most of Brazilian territory the scintillations are more frequent and intense due to the presence of the Equatorial Ionization Anomaly characterized by a global maximum in plasma density. The objective of this work is to apply a methodology based on GPS ephemeris data and simple scintillation monitor parameters to characterize the plasma irregularities associated with the scintillation mainly thorough their drift velocity. Data from two monitoring stations in Brazil (Fortaleza and Porto Alegre) receiving information from GPS satellites at three frequencies (L1, L2 and L5) were used to investigate the applicability of the method for different latitudes inside Brazilian territory. The data analyzed is from Spring and Summer months of 2013-2016, a period of seasonal maximum in ionospheric scintillation occurrences.

C1.1-0111-18 A COMPARISON OF STATISTICAL FEATURES OF IONOSPHERIC SCINTILLATIONS AND CYCLE SLIPS IN THE MID-SOUTH REGION OF CHINA

Jisheng Xu, jsxu@whu.edu.cn Wuhan University, Wuhan, China Jie Cheng, cj9891@163.com China

Liang Xu, lix0413@whu.edu.cn Wuhan University, Wuhan, China

In this paper, the statistical features of scintillations and cycle slips of GPS (Global Positioning System) signals, as well as the effects of solar activity and geomagnetic activity on scintillations and cycle slips have been analyzed and compared by means of the observations from a scintillation observation network in the mid-south region of China during 2012-2015. Results show that the statistical features of scintillations and cycle slips. The results show that the variation features of cycle slip occurrence with local time, month, solar activity and geomagnetic activity are very similar to those of scintillation occurrence, and the occurring probability of cycle slip increases as the S4 index increases, suggesting that cycle slips are closely related to scintillations and scintillations are a key factor which can cause cycle slips. Scintillations and cycle slips occur mainly during the night, most frequently before midnight and seldom in the daytime. It is found that scintillations and cycle slips occur mainly in equinox months but seldom in solstice months at the ionization anomaly crest and its adjacent regions, and an equinoctial asymmetry that scintillations and cycle slips occur more frequently in Spring than in Autumn is also found. The occurrence of scintillations and cycle slips shows a strong dependence on the solar activity, it increases as the solar activity increases. However, the occurrence of scintillations and cycle slips shows a negative correlation with geomagnetic activity. The geomagnetic disturbances inhibit scintillations and cycle slips as a whole. On average, the closer to the magnetic equator, the more frequently and the earlier scintillations occur, indicating that the scintillations are caused by ionospheric irregularities which originate at the magnetic equator. In addition, there is a good consistency between the spatial distributions of scintillations and cycle slips. They mainly occur in the area with elevation angle between 35º and 55º and azimuth angle between 150º and 240º.

C1.1-0112-18 OBSERVATIONAL STUDY OF LOW LATITUDE IONOSPHERIC IRREGULARITIES OVER CHINA

Baiqi Ning, nbq@mail.iggcas.ac.cn

Institute of Geodesy and Geophysics,Chinese Academy of Sciences, Beijing, China Guozhu Li, gzlee@mail.iggcas.ac.cn

Institute of Geology and Geophysics, CAS, Beijing, China

In recent years, a multi instrument observational network which including VHF coherent scatter radar, ionosonde, GNSS scintillation/TEC receiver and all-sky airglow imager, has been built in low latitude of China. By using this network, the occurrence characteristics of low latitude ionospheric irregularities have been investigated. In this report, some of the recent progress made in understanding the ionospheric irregularities, F region plasma bubbles over the Chinese longitude sector will be introduced. This involves results obtained mainly from the multi-beam Sanya (18.3°N, 109.6°E) VHF radar (pre-sunset bottom-type scattering layer, bubble onset, bubble zonal structure), the Fuke (19.3°N, 109.1°E) VHF radar and all-sky airglow imager (bubble onset and evolution, F layer bottomside large-scale wave structure LSWS, and small-scale wave structure SSWS), and the ground-based GNSS TEC/scintillation receivers (morphological aspects of EPB). Moreover, attempts were made with simultaneous Kototabang (0.2°S, 100.3°E) and Sanya radar multi-beam steering measurements to investigate the longitudinal variation in equatorial plasma bubble generation. The results obtained from the two stations closely located in longitude will be discussed. Finally, a brief introduction on our future efforts in equatorial plasma bubble observation will also be given.

C1.1-0113-18 STRONG IONOSPHERIC DISTURBANCES OVER THE BRAZILIAN SECTOR ASSOCIATED WITH THE GEOMAGNETIC STORM DURING THE SEPTEMBER 27 - 30, 2017

Valdir Gil Pillat, valdirgp@univap.br

Universidade do Vale do Paraíba - UNIVAP, São José Dos Campos, Brazil Paulo Roberto Fagundes, fagundes@univap.br

Universidade do Vale do Paraiba, São José Dos Campos, Brazil Venkatesh Kavutarapu, venkatkau@gmail.com

Universidade do Vale do Paraiba, Sao Jose Dos Compos, Brazil Brunno Augusto Ribeiro, augustobrunno@hotmail.com

Universidade do Vale do Paraíba - UNIVAP, SÃO JOSÉ DOS CAMPOS, Brazil

Study of the strong ionospheric disturbances due to geomagnetic storm occurred on September 27-30, 2017 (low solar activity) has been carried out using a network of 130 GPS-TEC stations over the Brazilian sector. During this event the Dst reached a minimum value of -76 nT, the Kp reached maximum value of 7-, the solar wind velocity (Vp) was about 300 km/s before the storm and reached the maximum value of about 720 km/s during the main phase, and the proton density (Np) reached about 60 #/cm3 during the main phase. The IMF Bz during the main phase had multiple reversals, turning 3 times southward and twice northward. It is noted that the vertical total electron content (VTEC) showed a positive phase during the main and recovery phases. It is observed that the equatorial and low latitude regions are most disturbed while the region beyond the EIA crest is less disturbed. The disturbances took place almost the same time in both regions, indicating the prompt penetration of electric field (PPEF). In addition the EIA was severely disturbed due to this PPEF. This study shows that the ionosphere can be strongly disturbed by geomagnetic storm even during the low solar activity (F10.7= 80 sfu) conditions.

C1.1-0114-18 IONOSPHERIC SPACE WEATHER RESPONSE DUE TO THE GEOMAGNETIC STORM OF MAY 2017, IN THE BRAZILIAN SECTOR

Brunno Augusto Ribeiro, augustobrunno@hotmail.com

Universidade do Vale do Paraíba - UNIVAP, SÃO JOSÉ DOS CAMPOS, Brazil Paulo Roberto Fagundes, fagundes@univap.br

Universidade do Vale do Paraiba, São José Dos Campos, Brazil Kavutarapu Venkatesh, venkatkau@gmail.com

Universidade do Vale do Paraíba - UNIVAP, São José Dos Campos, Brazil Francisco Vieira, francisco.vieira478@gmail.com

Instituto Federal de Tocantins, Araquatins, Brazil

We investigated the response of the F-region in the Brazilian sector during the geomagnetic storm of May 27-30, 2017 using multisite and multi-instrument observations over the Brazilian sector. This study was carried out using a network of 129 GPS-TEC receivers, 3 ionosondes, and 4 all-sky imaging systems (OI 630 mm emission). During this event the geomagnetic indices (Dst and Kp) and interplanetary parameters of the solar wind (Bz, Vp and Np) were significantly disturbed; the Dst reached a maximum value of 43 nT (initial phase) and a minimum value of -125 nT (main phase) with the Kp index reaching a value of 6+. The solar wind during the quiet period was about 300 km/s and increased to 380 km/s during disturbed period.

The proton density reached the maximum values close to 60 #/cm−3. The IMF-Bz reversed south during the main and recovery phases of the storm. The vertical total electron content (VTEC), during the main phase, had a similar magnitude and variation as compared with quiet days. However, during the first day of the recovery phase, an oscillatory positive ionospheric disturbance was noted, probably due to simultaneous perturbations caused by the disturbed dynamo and TID propagation. The equatorial ionization anomaly (EIA) was investigated using a chain of GPS-TEC receivers and it is noted that during the first day of the recovery phase there was an intensification of the EIA followed by a decrease in its intensity on the second day of the recovery phase.

C1.1-0115-18 PLASMA BLOBS OBSERVED BY GROUND-BASED OPTICAL AND SATELLITE DMSP THE F-REGION

Flavia Coelho Tardelli, jcaf80@gmail.com

Universidade do Vale do Paraíba - UNIVAP, São José Dos Campos, Brazil

Discrete increase in plasma electron density by a factor of two or more was observed in the F region of the nocturnal ionosphere in the Brazilian sector, in the Manaus-AM region (MAN; 2,59°S; 60,22°O; dip. latitude 12,1°N; region near the magnetic equator). This increase was observed through the imaging photometer data and measured by the DMSP F15 satellite. Plasma density irregularities in the nighttime equatorial ionosphere were first observed by Booker and Wells in 1938, when they discovered spread-F in the ionogram of backscattered signals of ionosonde in Huancayo, Peru. The increase in plasma electron density was reported for the first time by Oya et al. in 1986, and they named this irregularity as plasma blobs. The plasma blobs that we observed on the MAN region were events that occurred independently, that is, without the presence of plasma bubbles. Cases of independent plasma blobs are rare events to observe, with more frequent occurrence with the simultaneous presence of plasma bubbles. In this work we present results of 4 nights of occurrence of independent plasma blobs in the period from October to November 2015, calculations of zonal and latitudinal drift of these blobs, besides measuring the north/ south and east / west dimensions that they reached, during all the time they were visible on the lens of the imaging photometer.

C1.1-0116-18 ON THE RESPONSE OF EQUATORIAL IONOSPHERIC ANOMALY DURING GEOMAGNETIC STORM EVENTS AND COMPARISONS WITH IRI MODEL PREDICTIONS

Elijah Oyeyemi, e_oyeyemi@yahoo.co.uk University of Lagos, Lagos, Nigeria

Segun Bolaji, oloriebimpjch2002@yahoo.co.uk University of Lagos, Lagos, Nigeria

Adekola Adewale, aadewale@unilag.edu.ng University of Lagos, Lagos, Nigeria Andrew Akala, aakala@unilag.edu.ng University of Lagos, Lagos, Nigeria

Paul Amaechi, paoloobiaks@yahoo.fr University of Lagos, Lagos, Nigeria Busola Olugbon, busola.olugbon University of Lagos, Lagos, Nigeria

This paper discuses variability of electron density of F2 ionospheric region (NmF2) using ionosonde observations from stations in the region of equatorial ionization anomaly (EIA), during geomagnetic storm periods. Data based on availability during periods of high solar activity and different seasons from each station considered were used to carry out our stud- ies. The results obtained were used to evaluate the performance of the International Reference Ionosphere (IRI-2012) model predictions in the EIA region of the ionosphere. These results showed that the model predictions have agreement with the observed values in terms of the pattern of variations but there are number of cases where either the model overestimates and underestimates the observed values. Results from this study will be of help to improving prediction ability of the IRI model, most especially in this region of the ionosphere where there is paucity of data. Details of the statistical analysis of the results and the accuracy of the IRI model predictions are presented.

C1.1-0117-18 IRREGULARITIES AND SCINTILLATION, END TO END FROM SWARM TO THE GROUND

Sharon Aol, sharonaol@ymail.com

Mbarara University of Science and Technology, Mbarara, Uganda Stephan Buchert, scb@irfu.se

Swedish Institute of Space Physics, Uppsala, Sweden Edward Jurua, ejurua@gmail.com

Mbarara University of Science and Technology, Mbarara, Uganda

This study focused on observations of irregularity structures using Swarm Langmuir Probe (LP) measurements in comparison with amplitude scintillation events recorded by the Global Positioning System-Scintillation Network and Decision Aid (GPS-SCINDA) receiver installed in Mbarara (Geog. lat = -0.60°, Geog. lon = 30.74°, Mag. lat = -10.2°). For some Swarm satellite passes, there was a good agreement between the increase in level of amplitude scintillation index (S4) and the depth of electron density perturbations. Cases where scintillation was seen without clear variation in density suggests that irregularities can be effective quite locally, horizontally or in height. Also, irregularities with no associated scintillation event were noted and this was attributed to a low background electron density. Initial results from this study indicate the capability of in situ density fluctuations observed by Swarm satellite passes over Mbarara of being used as indicators of ionospheric radio wave scintillation at that site. This is true even when the measurements are made at horizontal ranges of over 1000 km away from the ground site as long as the field line apex altitudes are less than 500 km. An attempt was made to model amplitude scintillation from Swarm LP electron density measurements using the power law phase screen model developed by Rino (1979). A spectral analysis procedure carried out to aid the modelling of amplitude scintillation for the Swarm satellite electron density revealed that the power spectrum follows a power law with spectral index ranging between -1.8 and

-2.2. The results also indicate that the Swarm satellite in situ measurements of electron density fluctuations may be used to model scintillation over the low latitude.

C1.1-0118-18 STUDY OF THE F3 AND STF4 LAYERS NEAR THE SOUTHERN CREST OF THE EIA ON THE WESTERN AND EASTERN SOUTH AMERICAN SECTOR

Alexandre Tardelli, tardelli@univap.br

Universidade do Vale do Paraíba - UNIVAP, São José Dos Campos, Brazil Paulo Roberto Fagundes, fagundes@univap.br

Universidade do Vale do Paraiba, São José Dos Campos, Brazil Michael Pezzopane, michael.pezzopane@ingv.it

Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy Venkatesh Kavutarapu, venkatkau@gmail.com

Universidade do Vale do Paraiba, Sao Jose Dos Compos, Brazil Valdir Gil Pillat, valdirgp@univap.br

Universidade do Vale do Paraíba - UNIVAP, São José Dos Campos, Brazil

This investigation presents the seasonal and solar cycle variations of the daytime F-layer multiple stratification (F3 and StF4 layers) near the southern crest of the EIA on the western and eastern South American sector. The ionograms recorded by a CADI digital ionosonde installed at Sao Jose dos Campos (SJC eastern sector; 23.21°S, 45.97°O; dip latitude 17.6°S) Brazil, from 2002 to 2006, and the ionograms recorded by an AIS-INGV ionosonde installed at Tucumán (TUC western sector; 26.9ºS, 65.4ºW; dip latitude 13.9°S) Argentina, from 2007 to 2015, are used for this study. Both stations are localized near the EIA southern crest in the South American sector. The F3 layer occurrence shows an annual variation with maximum during summertime and minimum during wintertime, in both stations (SJC and TUC). Concerning the StF4 occurrence at SJC and TUC, the results have shown a maximum during summertime, and no occurrence during wintertime. At SJC, a total of 1477 days were analyzed and the results shown that the F3 layer was found in 382 days (25.9%), while the StF4 layer was found in 5 days (0.3%), indicating that the StF4 is seen during 1.3% of F3 layer days. At TUC 1812 days were analyzed, and the F3 layer was found in 370 days (20.4%), while the StF4 layer was found in 41 days (2.3%) indicating that the StF4 layer is seen during 11% of F3 layer days. Moreover, at TUC, the F3 and StF4 layers occurrences show a solar activity dependence with maximum during high solar activity. On the other hand, at SJC, the F3 and StF4 layers do not show a clear solar activity dependence. Furthermore, a significant connection between StF4 and F3 has been noticed in both stations, since the StF4 layer is always preceded and followed by a F3 layer appearance.

C1.1-0119-18 TOWARD AN INTEGRATED VIEW OF IONOSPHERIC PLASMA INSTABILITIES

Roman Makarevich, rmakarevich@alaska.edu

University of Alaska Fairbanks, Fairbanks, Alaska, United States

The Earth's ionosphere is filled with irregularities in the electron density generated by electrostatic plasma instabilities including the Farley-Buneman instability (FBI) and the gradientdrift instability (GDI). In this study, a general analytic expression is derived for the FBI/GDI growth rate using a recently developed cubic dispersion relation that is valid in the broad range of ionospheric altitudes. It is demonstrated that the previously considered limiting cases of FBI/GDI in the E region and GDI in the F region are successfully reproduced using the more general expression. The obtained analytic expressions provide a unified theoretical framework for considering plasma irregularity generation in the lower ionosphere including the previously unexplored transitional region between the E and F layers. A number of specific applications are presented, with a particular focus on critical density gradient scales sufficient for irregularity generation in the GDI linear regime and their dependence on the irregularity wavelength.

C1.1-0120-18 FORMATION MECHANISMS OF THE SEMI-ANNUAL ANOMALY OF NMF2 AT MIDDLE LATITUDES DURING DAYTIME GEOMAGNETICALLY QUIET CONDITIONS AT LOW SOLAR ACTIVITY

Anatoli Pavlov, pavlov@izmiran.ru

Pushkov Institute of Terrestrial Magnetism, Ionosphere and Radio wave propagation of Russian Academy of Sciences, Moscow, Troitsk, Russia

The ionosonde and radar observations and theoretical calculations of the F2-layer peak altitude and peak number density, NmF2, over Millstone Hill during geomagnetically daytime quiet conditions on 22 January 2008, 8 April 1997, 12 July 1986, 26 October 1995, 29 January 2008, 2 April 1986, 11 July 2008, and 5 October 2010 at low solar activity are used to study the formation mechanisms of the observed daytime semi-annual anomaly of NmF2. The onedimensional time-dependent model of the mid-latitudinal ionosphere and plasmasphere is used to calculate number densities and temperatures of electrons and ions. The study shows that the semi-annual anomaly of NmF2 is mainly cased by seasonal variations of the following atmospheric parameters: (1) the plasma drift along geomagnetic field lines due to corresponding changes in neutral wind components, (2) temperature and number densities of the neutral atmosphere, and (3) an optical thickness of the atmosphere caused by the dependence of the solar zenith angle on the day of the year for the same altitude and solar local time. Seasonal variations of the production rate of unexcited O+ ions due to chemical reactions involving electronically excited O+ ions and the reactions of unexcited O+ ions with vibrationally excited N2 and O2 cannot produce a significant impact on the formation of the semi-annual anomaly of NmF2.

C1.1-0121-18 LATITUDE DEPENDENT DELAY IN THE RESPONSES OF THE EQUATORIAL ELECTROJET AND SQ CURRENTS TO X-CLASS SOLAR FLARES.

Federal Institute of Education, Science and Technology of São Paulo, Jacarei, Brazil

We have analyzed low latitude ionospheric current responses to two intense (X-class) solar flares that occurred on 13-May-2013 and 11-March-2015. Sudden intensifications, in response to solar flare radiation impulses, in the Sqand Equatorial electrojet (EEJ) currents, as detected by magnetometers over equatorial and low latitude sites in South America are studied. In particular we show for the first time 5 to 8 minutes time delay is present in the peak effect in the EEJ, with respect that of Sq current outside the magnetic equator, in response to the flare radiation enhancement. The Sq current intensification peaks close to the flare X-ray peak, while the EEJ peak occurs 5 to 8 minutes later. We have used the Sheffield University Plasmasphere-Ionosphere Model at National Institute for Space Research (SUPIM-INPE) to simulate the E-region conductivity enhancement as caused by the flare enhanced solar EUV and soft X-rays flux. We propose that the flare induced enhancement in neutral wind occurring with a time delay (with respect to the flare radiations) could be responsible for a delayed zonal electric field disturbance driving the EEJ, in which the Cowling conductivity offers enhanced sensitivity to the driving zonal electric field.

C1.1-0122-18 CAUSES OF THE SPRING-AUTUMN ASYMMETRY OF NMF2 AT MIDDLE LATITUDES DURING DAYTIME GEOMAGNETICALLY QUIET CONDITIONS AT LOW SOLAR ACTIVITY

Anatoli Pavlov, pavlov@izmiran.ru

Pushkov Institute of Terrestrial Magnetism, Ionosphere and Radio wave propagation of Russian Academy of Sciences, Moscow, Troitsk, Russia

The ionosonde and radar observations and theoretical calculations of the F2-layer peak altitude and peak number density, NmF2, over Millstone Hill during geomagnetically daytime quiet conditions on 3 March 2007, 29 March 2007, 12 September 2007, and 18 September 1984 at low solar activity are used to study the causes of the observed daytime spring-autumn asymmetry of NmF2. The one-dimensional time-dependent model of the mid-latitudinal ionosphere and plasmasphere is used to calculate number densities and temperatures of electrons and ions. The study shows that the spring-autumn asymmetry of NmF2 occurs mainly due to seasonal variations of the plasma drift along geomagnetic field lines caused by corresponding changes in neutral wind components and seasonal variations of temperature and number densities of the neutral atmosphere at the same altitude and solar local time. Seasonal variations of the production rate of unexcited O+ ions due to chemical reactions involving electronically excited O+ ions and the reactions of unexcited O+ ions with vibrationally excited N2 and O2 cannot produce a significant influence on the formation of the spring-autumn asymmetry of NmF2.

C1.1-0123-18 ESTIMATION OF GPS-TEC USING DIFFERENT TECHNIQUES AND COMPARISON WITH VALUES FROM IRI-2012, NEQUICK-2 AND IRI-PLAS 2015 MODELS DURING GEOMAGNETIC STORMS

Adekola Adewale, aadewale@unilag.edu.ng University of Lagos, Lagos, Nigeria

Elijah Oyeyemi, e_oyeyemi@yahoo.co.uk University of Lagos, Lagos, Nigeria

Total Electron Content (TEC) is an important element for effective satellite communication and it constitutes one of the key parameters for observing the variable structure of the ionosphere. This work, which is divided into two parts, compared Vertical Total Electron Content (VTEC) obtained from seven different sources, namely: estimation from method developed by the IONOLAB group (www.ionolab.org), estimation from GPS TEC application software developed by Dr Gopi Seemala (GOPI-VTEC), IRI2012 model (using three different options: IRI2001, IRI01cor and NeQuick), NeQuick-2 model and IRI-Plas model, during geomagnetic storm and non-storm days. The first part compared between GPS-VTEC computed using the estimation method developed by the IONOLAB group and that developed by Dr Gopi Seemala. The second part compared the performance of different model based VTECs with these estimations (IONOLAB-VTEC and GOPI-VTEC). It is observed that IONOLAB-VTEC is in good agreement with the estimates from the GOPI-VTEC for all ionospheric states and regions. All the models followed the diurnal pattern of the observed values of VTEC. Our result shows that IRI-Plas model did not predict observed VTEC better than existing models, as expected.

C1.1-0125-18 FORECASTING TOTAL ELECTRON CONTENT OVER ARGENTINA

Dinibel Perez Bello, dinibel@gmail.com

Facultad de Ciencias Astronómicas y Geofísicas, Universidad Nacional de La Plata, La Plata, Argentina

Maria Paula Natali, mariapaula.natali@gmail.com

Facultad de Ciencias Astronómicas y Geofísicas, Universidad Nacional de La Plata, La Plata, Argentina

Amalia Meza, amalia.meza@gmail.com

Facultad de Ciencias Astronómicas y Geofísicas, Universidad Nacional de La Plata, La Plata, Argentina

Global Navigation Satellite Systems (GNSS) positioning are affected by the ionosphere refraction causing serious propagation errors. The forecast of ionospheric parameters is useful to predict the possible degradation of the performance of these systems for warning purposes. Total Electron Content (TEC) is an important parameter for monitoring the behavior of the ionosphere and indeed a magnitude of interest to understand the properties and behavior of the Sun-Earth System. This work presents the simulation of a framework to forecast the Vertical Total Electron Content (vTEC) using GNSS data (Global Navigation Satellite System) and geospheric information. The GNSS observations were processed with the Bernese V5.2 software to obtain a regional vTEC model. The geospheric data such as Solar Flux F10.7, DST, Kp, among others, were obtained from different repository and processing centers. To perform the vTEC forecast, a Neuro Fuzzy Inference System (NFIS) was implemented, using a 5-layer Neural Network architecture with fuzzy input. The input data in the NFIS model are those that are directly related to the temporal variation of the vTEC and the geospheric information. In order to analyze the spatial and temporal performance of the model different scenarios were proposed. Three specific sectors were selected: near the equatorial anomaly, mid-latitude and sub-auroral regions. Finally, different geospheric conditions were analyzed for each sector

C1.1-0126-18 CORRELATION BETWEEN THE NUMBER OF LIGHTNING STRIKES AND TOTAL ELECTRON CONTENT (TEC) OVER THE STATE OF PARANA, BRAZIL

Mauro Alves, mauro.a.alves@gmail.com

Space Research Institute of the Russian Academy of Sciences (IKI), Moscow, Russia Mauricio Gende, mgende@fcaglp.unlp.edu.ar

Universidad Nacional De La Plata., La Plata, Argentina

The total electron content measured by a station using global positioning system (GPS) receiver and the number of lightning strikes (cloud to ground) recorded by the National Integrated Network for the Detection of Atmospheric Discharges (RINDAT) in the State of Parana, Brazil, were examined to determine the correlation between the occurrence of lightning storms and variations in TEC. The length of both of lightning strike and TEC times series was 120 days. Lightning strike counts were accumulated over one-hour intervals, and TEC values were averaged also over one-hour intervals. Data were collected from September 1 to December 31, 2014. Time series analysis techniques were used to analyze the TEC and lightning strike data sets. Results show a clear correlation between the occurrence and number of lightning strikes and variations in TEC. Increases of up to 80% in TEC were measured during lightning storms.

The international reference ionosphere (IRI) model is an empirical ionosphere model, which is based on worldwide available data of ground-based and satellite observations. In this paper, the precision of the latest IRI-2016 model is validated through the comparison of NmF2 and HmF2 data between IRI-2016 and ionosondes during geomagnetic quiet periods in 2014 and geomagnetic storm periods in 2015, respectively. The NmF2 and HmF2 data of five ionosonde stations(Juliusruh:68.54°, Okinawa:37.26°, Jicamarca:-0.26°, Port Stanley:-51.24°, Hermanus:

-64.24°), which are available in different geomagnetic dip zones are compared with those of IRI-2016, since the variations of NmF2 during day and night can reach more than an order of magnitude, so we utilized the standard deviation (std) of relative error to show its error characteristics, and using std of absolute error to show that of HmF2. The results indicate that

IRI predictions have good agreements with ionosonde data for both NmF2 and HmF2, and are higher than the measured data during most time of the two years. In 2014 which geomagnetic quiet period (Kp<4) accounts for 98% of the year, IRI-2016 showed the worst correlation with Port Stanley station (std=83.54%) and Okinawa station(std=45.72km) in NmF2 and HmF2, respectively. The highest correlations were held by Juliusruh station(std=34.69%,20.28km) for both NmF2 and HmF2. Analysis on local time and seasonal characteristics at Juliusruh indicate that the error in daytime was lower than that in nighttime, the model in sum- mer season has a better accuracy. In 2015 which geomagnetic disturbance period (Kp>=4) accounts for 15.3% of the year, IRI-2016 showed the worst correlations with Juliusruh station(std=100.18%,68.79km) in both NmF2 and HmF2, while the highest correlations were held by Jicamarca(std=40.38%,26.83km) in both NmF2 and HmF2. Analysis on local time at Jicamarca indicate that the error in daytime was lower than that at nighttime. The above analyses initially obtained the statistical error characteristics of the IRI-2016, thus providing the priori error information for the application of the IRI model and laying a foundation for the further improvement of it. Due to the limited quantity and quality of ionosonde data, this study is not statistically perfect, we can see the big error especially in the geomagnetic storm period. Our next step is to acquire more ionosonde data (such as the data of "meridian project" of China), evaluating the controlling the quality of ionosonde efficiently, so we can obtain more statistically significant error characteristics of the IRI model.

C1.1-0128-18 SEASONAL VARIATION OF OI 630.0 NM NIGHTGLOW EMISSION: MODELING AND OBSERVATIONS

Thirupathaiah Pothuraju, thirucospar12@gmail.com University of Petroleum & Energy Studies, Dehradun, India Syed A. Haider, haider@prl.res.in

Physical Research Laboratory, Ahmedabad, Ahmedabad, India

The OI 630.0 nm nightglow was observed at Cachoeira Paulista (22.7°S, 45°W) by multichannel photometer during the year 2015. The seasonal variation of OI 630.0 nm nightglow is studied using the data. It is found that the temporal variation of OI 630.0 nm nightglow intensity shows a peak at post-midnight hours (01:00hrs) during the summer. During autumn, this peak is shifted towards pre-midnight hours (22:00hrs). It is noticed that this peak again shifted towards post-midnight hours, 02:30hrs and 01:50hrs, during winter and spring, respectively. The intensity values increase a factor of 4 in summer than compare to other three seasons.

We have developed a model to compute excitation, loss, emission rates and intensity of OI

630.0 nm nightglow during four seasons. The dissociative recombination of O2+ with electron is considered as major production source of O(1D) atoms during night time. All possible loss processes of O(1D) are incorporated in the model. The measured electron density by the ionosonde at Cachoeira Paulista (22.7°S, 45°W) is used in the calculations. The neutral parameters are adopted from NRLMSISE-00 model. We have calculated O2+ density within the model by considering its production and loss processes. The excitation, loss and emission rates of O(1D) are calculated at different local times during four seasons. By integrating the emission rate profile, we obtained the intensity of OI630.0 nm at a particular local time. The model intensities are compared with the measured intensities. It has been found that the model intensities are reasonably in good agreement with the measurement for all four seasons and model reproduces the features of peak intensities very well. It can be noted that a detailed OI630.0 nm nightglow model is developed for the first time which can explain the temporal variation of OI630.0 nm nightglow during all four seasons.

C1.1-0129-18 PERFORMANCE OF NEQUICK-2 MODEL AND IRI-PLAS 2017 MODEL DURING SOLAR MAXIMUM YEAR IN 2013-2014 OVER GLOBAL EQUATORIAL AND LOW LATITUDE REGIONS

Kenneth Iluore, kiluore@yahoo.co.uk University of Nigeria, Nsukka, Nsukka, Nigeria Francisca Okeke, francisca.okeke@unn.edu.ng Nigeria

This paper inspect the prediction Capability of Nequick-2 model and the latest version of International Reference ionosphere IRI Extended to the Plasmasphere (IRI-Plas 2017) model in predicting the Total electron content (TEC) over eight different equatorial and low latitude regions across the globe during solar maximum year 2013-2014. In all, the diurnal and the seasonal variations agree fairly well with GPS-TEC in all the station although with some upward and downward offsets. The observed GPS-TEC shows the presence of winter anomaly which is high in December (DecSol) and Low in June solstices (June sol).The monthly and seasonal variations of the NeQuick-2 model TEC with IRI-Plas 2017 model has been compared with the GPS-TEC. From the prediction errors, it shows that the monthly and seasonal variation of the IRI-Plas 2017 Overestimate GPS-TEC in all the regions when compared with NeQuick -2 models except in Addis Ababa station where there is a good agreement with the GPS-TEC. The NeQuick -2 model, in general performed better when compared with IRI-Plas 2017 in months and in season. These models exhibit latitudinal variation and showed a seasonal trend. The main problem of the NeQuick-2 model TEC representation is not situated in the Plasmaspheric part, its absence in NeQuick-2 model or its presence in IRI Plas 2017 model, the main source of the resulted discrepancies is still in the IRI topside ionosphere representation.

C1.1-0130-18 VISCOSITY OF THE MULTICOMPONENT NEUTRAL ATMOSPHERE

Anatoli Pavlov, pavlov@izmiran.ru

Pushkov Institute of Terrestrial Magnetism, Ionosphere and Radio wave propagation of Russian Academy of Sciences, Moscow, Troitsk, Russia

Approximate expressions for the viscosity coefficient of the multicomponent neutral atmosphere are analyzed and evaluated by comparing them with that given by the rigorous hydrodynamic theory. These approximations are tested for the atmosphere consisting of N2, O2, O, He, and H during geomagnetically quiet and disturbed spring conditions at low, moderate, and high solar activity in the altitude range of 100-500 km for different values of the universal time, latitude, and longitude. Two new approximate expressions for the viscosity coefficient of the multicomponent atmosphere are proposed. Their differences from the viscosity coefficient given by the rigorous hydrodynamic theory do not exceed 3.4% and 4.8%. These differences are significantly smaller than the maximum differences (from 11.8% to 15.1%) of the viscosity coefficient approximations used in atmospheric studies from the viscosity coefficient given by the rigorous hydrodynamic theory. The new approximate expressions for the viscosity coefficient of the multicomponent atmosphere are recommended for use in atmospheric studies to reduce errors of calculations of atmospheric parameters.

C1.1-0131-18 VALIDATION RESULTS OF NMF2 DERIVED FROM GLOBAL NAVIGATION SATELLITE SYSTEM RADIO OCCULTATION OBSERVED BY GNOS ON FY3C SATELLITE

National Space Science Center, Chinese Academy of Sciences, Beijing, China Danyang Zhao, 394481372@qq.com

National Space Science Center, Chinese Academy of Sciences, Beijing, China

The first Global Navigation Satellite System (GNSS) Occultation Sounder (GNOS) which is compatible with both BeiDou Navigation Satellite System (BDS) and Global Positioning System (GPS) was successfully launched into orbit onboard the FengYun3C satellite (FY3C) on September 23, 2013, and it has already gathered a large amount of ionospheric radio occultation data so far, including the GPS radio occultation (GPSRO) data and BDS radio occultation (BDSRO) data. In this work, we discuss the configuration of the FY3C/GNOS firstly, then we define matching principles of NmF2 data between GNOS-GPSRO/GNOS-BDSRO and ionosondes to match them into data pairs, thus the quality analysis of the GPSRO and BDSRO products can be carried out. We get that between NmF2 data of GNOS-GPSRO and ionosondes during October 1, 2013 and September 30, 2014, their correlation coefficient, bias and standard deviation (std) are 0.96, 6.71% and 18.03%, respectively, and between NmF2 data of GNOS-BDSRO and ionosondes during October 1, 2013 and October 10, 2015, their correlation coefficient, bias and std are 0.96, 10.21%, 19.61%, respectively. Not hard to see the NmF2 data of GPSRO and BDSRO observed by the same GNOS payload have very similar precision, they are also consistent to precision of other international radio occultation products, like those of CHAMP and COSMIC. That way

the precision consistency between GNOS-GPSRO and GNOS-BDSRO, GPSRO/BDSRO and ionosondes, GPSRO/BDSRO and other international radio occultation products are verified. The NmF2 quality analysis between GNOS-GPSRO/GNOS-BDSRO and ionosondes in different latitudes, local times, seasons, orbits are also included. The precision consistency of the ionospheric radio occultation products of different GNSS is significant to the ionospheric research and space weather forecasting based on the GNSS occultation sounding data. By comprehensively analyzing and utilizing its ionospheric occultation data with those of other GNSS, it is possible to improve the coverage and temporal-spatial resolution of occultation events, which is conducive to the real-time monitoring of ionospheric weather and the research and development of ionospheric climate models. And the enhancement of BDS and the continuous launches of FY3 series satellites in the future will greatly increase the number of ionospheric occultation events, which will enable GNOS to provide more occultation data for the world.

C1.1-0132-18 THE THERMAL CONDUCTIVITY COEFFICIENT OF THE MULTICOMPONENT NEUTRAL ATMOSPHERE

Anatoli Pavlov, pavlov@izmiran.ru

Pushkov Institute of Terrestrial Magnetism, Ionosphere and Radio wave propagation of Russian Academy of Sciences, Moscow, Troitsk, Russia

Approximate expressions for the thermal conductivity coefficient of the multicomponent neutral atmosphere are analyzed and evaluated by comparing them with that given by the rigorous hydrodynamic theory. These approximations are tested for the atmosphere consisting of N2, O2, O, He, and H during geomagnetically quiet and disturbed winter, spring and summer conditions at low, moderate, and high solar activity in the altitude range of 100-400 km for different values of the universal time, latitude, and longitude. The new approximations of the thermal conductivity coefficients of simple gases N2, O2, O, He, and H are derived and used. The approximation for the thermal conductivity coefficient of a multicomponent mixture of neutral gases given by Mason and Saxena is modified, and it is found that this modified approximation is more accurate in reproducing the atmospheric values of the rigorous hydrodynamic thermal conductivity coefficient in comparison with those that are generally accepted in atmospheric studies. The found approximation for the thermal conductivity coefficient of the multicomponent neutral atmosphere is recommended for use in calculations of the neutral temperature of the atmosphere.

C1.3-0001-18 THE ROLE OF ATMOSPHERIC “COLLISIONAL MACHINE” IN THE FORMATION OF ELECTRON PRECIPITATED FLUXES IN THE AURORA

George Khazanov, george.v.khazanov@nasa.gov

NASA/GSFC Heliophysics Science Division, Greenbelt, Maryland, United States Eftyhia Zesta, eftyhia.zesta@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States David Sibeck, david.g.sibeck@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States

It is shown that wave particle interaction processes that drive precipitating fluxes in the region of diffuse aurora from the magnetospheric altitudes are only the first step in the formation of electron precipitation at ionospheric altitudes, and they cannot be separated from the atmospheric “collisional machine” that redistributes and transfers their energy inside the magnetosphereionosphere-atmosphere coupling system. We discuss the consequences of such interactions and coupling on the ionospheric conductivity and ultimate “absorbed” precipitating fluxes into the upper atmosphere. The ionospheric conductivity is a critical parameter for MagnetosphereIonosphere coupling as it regulates the amount of energy that can flow between magnetosphere and upper atmosphere. Having an accurate account of the ultimate precipitating electron flux allows us to accurately forecast the impact to upper atmosphere chemistry.

C1.3-0002-18 ASSESSING THE ROLE OF OUTFLOWING IONOSPHERIC HEAVY IONS IN THE DYNAMICS OF THE NEAR-EARTH ENVIRONMENT

Raluca Ilie, rilie@illinois.edu

University of Illinois at Urbana-Champaign, Urbana, Illinois, United States Mei-Yun Lin, mylin2@illinois.edu

University of Illinois at Urbana-Champaign, Urbana, Illinois, United States Yu Huang, yuhuang4@illinois.edu

University of Illinois at Urbana-Champaign, Urbana, Illinois, United States

Changes in the ion composition throughout the Earth's magnetosphere can have profound implications on plasma structures and dynamics, since it can modify the temperature and the magnetic field configuration, altering the convection patterns inside the magnetosphere. The ratio of hydrogen to oxygen ions has been shown to be highly dependent of geomagnetic activity, with the O+ content increasing with increasing activity. This suggest that ions of ionospheric origin can become the dominant species in the inner magnetosphere during disturbed times. Therefore, numerous studies focused on the transport and energization of O+ through the ionosphere-magnetosphere system; however, relatively few have considered the contribution of N+, in addition to that of O+ to the near-Earth plasma dynamics, even though past observations have established that N+ is a significant ion species in the ionosphere and its presence in the magnetosphere is significant. Ring current observations from the Active Magnetospheric Particle Tracer Explorer (AMPTE) spacecraft show that high energy N+ fluxes are comparable to those of O+ during disturbed times, confirming the substantial presence of N+ ions in the inner magnetosphere. In spite of only 12% mass difference, N+ and O+ have different ionization potentials, scale heights and charge exchange cross sections. The latter, together with the geocoronal density distribution, plays a key role in the formation of ENAs, which in turn controls the energy budget of the inner magnetosphere and the decay of the ring current. We present here numerical simulations using the Hot Electron and Ion Drift Integrator (HEIDI) model, which suggest that the contribution of N+ to the ring current dynamics is significant, as the presence of N+, in addition to that of O+, alters the development and the decay rate of the ring current. Electron transfer collisions are far more efficient at removing N+ the system, compared with O+ ions. These findings suggest that differentiating the N+ loss and transport from those of O+ in the near-Earth environment has a profound impact on global magnetosphere dynamics, as plasma composition affect both the local and the global properties of the plasma.

C1.3-0003-18 TEMPORAL AND SPATIAL DEVELOPMENT OF TEC ENHANCEMENTS DURING SUBSTORMS

James Weygand, jweygand@igpp.ucla.edu

University of California, Los Angeles, Los Angeles, California, United States Margaret Kivelson, mkivelson@igpp.ucla.edu

UCLA and Univ. Michigan, Los Angeles, California, United States

Total electron count (TEC) enhancements due to space weather are a threat to communications and global positioning systems (GPS). It is known that TEC enhancements occur during magnetic storms and can cover large areas for many hours, but it is also not uncommon for TEC enhancements as large as 10 TEC units to occur during substorms. Although much is known about storm-associated TECs, the temporal and spatial characteristics of substorm-associated TECs are not well established. By combining two dimensional maps of TECs over North America and Greenland and with maps of ionospheric currents derived with the spherical elementary current method [Weygand et al., 2011], we investigate the temporal and spatial changes of TEC enhancements events for both a single substorm and for multiple substorms combined using a two dimensional superposed epoch analysis. Both the single event analysis and the statistical analysis show an increase of TECs during the expansion phase. Substorm values of the TEC enhancements peak within 10 min after auroral onset and recover to nominal levels after about 40 min. TEC enhancements occur mainly within the night side Region 1 downward current system and cover millions of square kilometers. Furthermore, these enhancements appear to be associated with enhanced precipitating particle fluxes. These results address one of goals of the Space Weather Action Plan, which are to establish benchmarks for space weather events and improve modeling and prediction of their impacts on infrastructure.

C1.3-0004-18 PHYSICAL PROCESSES ASSOCIATED WITH HEATING, PLASMA CONVECTION AND FIELD ALIGNED CURRENTS IN THE HIGH LATITUDE IONOSPHERE

Anthony Mannucci, anthony.j.mannucci@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Field aligned currents (FACs) flowing between the magnetosphere and ionosphere, across a wide range of temporal and spatial scales, have been a major focus of magnetosphere-ionosphere coupling and its effects on the high latitude ionosphere. At the same time, theoretical treatment of MI coupling processes using magnetohydrodynamic frameworks reveal an important role played by neutral species. An example is Ohm's law, which clearly shows the dependence of high latitude currents on the neutral wind in an Earth-fixed frame. Another example is heating at high latitudes during geomagnetic storms, which has been associated with the term "Joule heating". However, such heating can occur in the absence of an electric field and is more properly interpreted as frictional heating between ions and neutral species near ionospheric E-region altitudes. Since the 1970s and the theoretical work of Vasyliunas, magnetospheric convection appears intimately related to FACs such that they appear to be manifestations of the same phenomenon: specifying FACs allows one to calculate magnetospheric convection, or specifying magnetospheric convection permits the calculation of FACs (certain boundary conditions must be assumed). We will discuss how including neutral species in MI coupling alters this picture. Finally, we describe how neutral wind divergence due to local auroral heating of the thermosphere may lead to measurable field aligned currents originating in the ionosphere.

C1.3-0005-18 DRIVING AF STRONG NIGHTSIDE GEOMAGNETIC ACTIVITY ACTIVITY BY MULTIPLE MEOS-SCALE POALR CAP FLOW ENHANCEMENTS

It is now known that meso-scale flows within the polar cap often cross the magnetic separatrix into the plasma sheet, leading to plasma sheet flow bursts, auroral poleward boundary intensifications (PBIs), streamers, and poleward motion of the polar cap boundary from reconnection. At times, these flows can enhance in magnitude and there can be several approaching the nightside polar cap boundary over a broad longitude range and for a prolonged period (several to tens of minute). We will show evidence that such enhancements in meso-scale flows can lead to strong auroral nightside activity and concurrent poleward expansion under several different circumstances. These include immediately following impacts of large increases in solar wind dynamic pressure as can occur at a storm sudden commence, enhancing substorm occurrence rate during storms, controlling the poleward expansion and duration of post-substorm-onset auroral activity, and leading to explosions of activity from the auroral poleward boundary. This strong effect with its several important manifestations has not yet been the subject of through investigations, but is accessible for future study using available observations from ground-based auroral imagers and radars and from low-altitude satellites.

C1.3-0006-18 THE EFFECT OF PRECIPITATING ELECTRONS ON THE INNER MAGNETOSPHERIC ELECTRIC FIELD AND THE THERMOSPHERE DURING THE MARCH 17, 2013 STORM

Diffuse auroral electrons are important for magnetosphere-ionosphere-thermosphere coupling because they are a major energy source to the auroral ionosphere. We investigate how the precipitating electrons modify the ionospheric conductivity, ionospheric electric potentials, and thermospheric density and wind profiles during the large 17 March 2013 magnetic storm. Our approach is to couple (1) the magnetically and electrically self-consistent Rice Convection Model - Equilibrium (RCM-E) of the inner magnetosphere, (2) the B3C transport model for electron-proton-hydrogen atom aurora in the ionosphere, and (3) the Thermosphere-IonosphereElectrodynamics General Circulation Model (TIEGCM) for the ionosphere and thermosphere. We use parameterized rates of whistler-generated electron pitch-angle scattering from Orlova and Shprits [JGR, 2014] that depend on equatorial radial distance, magnetic activity (Kp), and magnetic local time (MLT) outside the simulated plasmasphere. Inside the plasmasphere, parameterized scattering rates due to hiss [Orlova et al., GRL, 2014] are used. Spectral properties of the RCM-E precipitating electrons at 500 km are used as the upper boundary input to the B3C transport model for calculating height-integrated conductance and to the TIEGCM as the source of auroral heating. We compare simulated trapped, precipitating electron flux distributions, electric field properties, and thermospheric densities with measurements from the Van Allen Probes/MagEIS, Defense Meteorological Satellite Program (DMSP), and the Gravity field and steady-state Ocean Circulation Explorer (GOCE) satellites for the March 17, 2013 event.

C1.3-0007-18 GLOBAL MODELLING OF MAGNETOSPHERE-IONOSPHERE COUPLING: EPOP-SWARM OBSERVATIONS

Robert Rankin, rrankin@ualberta.ca University of Alberta, Edmonton, Canada Dmytro Sydorenko, sydorenk@ualberta.ca University of Alberta, Edmonton, Canada

We present first results from a comprehensive three-dimensional model of magnetosphereionosphere coupling. The model describes plasma flow produced by global scale (Volland-Stern) convection electric fields that are coupled with a physical model of the ionosphere. The initial magnetospheric plasma density is specified using the Global Core Plasma Model (GCPM), while initial density and temperature profiles of electrons and various species of ions and neutrals are taken from the IRI and MSIS models, respectively. The interaction of magnetospheric plasma with the ionosphere is self-consistent and includes effects of sunlight, ionization and recombination, heating and cooling processes, Hall and Pedersen conductivity altitude dependence, and chemistry. The model has already been used to study the development and erosion of plasmaspheric plumes that exert influence over energetic particle dynamics in the inner magnetosphere. It also describes plasma flow over the entire polar cap, which, when combined with data-assimilation of, for example, SuperDARN data, will eventually lead to improved accuracy of space weather forecasting. The main application of the new model is focused on interpreting measurements from the ePOP/CASSIOPE and SWARM satellite missions, which have combined their operations. First modelling results utilizing observations from this new ESA-Canada joint mission will be presented. The novel Yin-Yang overset grid and flexibility of the model to describe non-dipolar magnetic fields will be briefly described, as well as methodology needed to combine the model with more global models such as the LFM MHD model.

C1.3-0008-18 STATISTICAL ANALYSIS OF THE AKR-LIKE EMISSIONS OBSERVED BY RELEC MISSION DURING AUGUST-DECEMBER 2014

Moscow State University, Skobeltsyn Institute of Nuclear Physics, Moscow, Russia Sergei Svertilov, sis@coronas.ru

SINP MSU, Moscow, Russia

AKR-like emissions are phenomena similar to the typical Auroral Kilometric Radiation (AKR) events, but observed by satellites at lower altitudes, as well as by the ground-based instruments. The typical Auroral Kilometric Radiation (AKR) consists of intense electromagnetic emissions generated by energetic electron beams in the Electron Cyclotron Maser process at heights over 2000 km in the auroral region, whereas the exact nature of AKR-like emissions observed in the ionosphere as well as on the ground is still not well understood.

In this work, we selected observations of AKR-like emissions from the RELEC (Relativistic Electron) mission, in the time period from August to December 2014. The statistical analysis of AKR-like events observed for different invariant latitudes, magnetic local times and altitudes (in the range of 600-850 km, well below AKR sources lower height limit) will be presented. The selected events have also been divided due to the observed features that might shed light on the physical processes responsible for their origin.

C1.3-0009-18 EQUATORIAL ELECTRODYNAMICS PERTURBATION DURING THE GEOMAGNETIC STORMS DURING THE MAXIMUM PHASE OF THE CURRENT SOLAR CYCLE 24

Aliaa Abdelnasser, aliaa.afify@gmail.com Helwan University, Cairo, Egypt

Ayman Mahrous, amahrous@helwan.edu.eg Helwan University, Cairo, Egypt

Ibrahim Fathy, ibrahimfathy131@yahoo.com space weather monitoring center, physics deparment, faculty of science, helwan university, cairo, Egypt., Egypt, Egypt

This paper investigates the geomagnetic pulsation in Pc5 band associated with the enhancement of the Equatorial Electrojet EEJ current and its ionospheric response detected at the equatorial region during the maximum phase of the current solar cycle 24. We used several techniques of ground-based and satellite instrument to perform this study. The day side vertical E×B drift velocity is estimated at the equator using data from a pair of magnetometers based on the technique described by (Anderson et al., 2004). We found a good correlation between the EEJ disturbances revealed by Pc5 pulsation and the interplanetary electric field (IEF). This correlation was noticeable in the day time response of H, Pc5 and IEF. Our results show that Pc5 oscillation can penetrate to the equatorial region and modulate the equatorial electrodynamics through the E×B drift which can be estimated from ground-based magnetometer data. This was verified by the signature of Pc5 oscillation in H data. The time-response (Tr) between the Dst triggering and the Total Electron Content (TEC) disturbance was estimated during the day-time of the most energetic geomagnetic storms which have been detected. The relation between Tr and the Dst values showed a good correlation with a correlation factor of 0.85. This time-response parameter can be considered as an important feature that could improve our understanding of the equatorial ionospheric phenomena. Key Words: Equatorial Electrodynamics - Geomagnetic storm - Geomagnetic pulsations - Total Electron Content - Equatorial Electrojet - interplanetary electric field.

C1.3-0010-18 DYNAMICS OF THE UPPER THERMOSPHERIC WINDS DURING MAGNETOSPHERIC SUBSTORMS

Lei Cai, lei.cai@oulu.fi

University of Oulu, Oulu, Finland Anita Aikio, anita.aikio@oulu.fi University of Oulu, Oulu, Finland

Shin-ichiro Oyama, soyama@stelab.nagoya-u.ac.jp

Solar-Terrestrial Environment Laboratory, Nagoya University, Nagoya, Japan Heikki Vanhamäki, heikki.vanhamaki@oulu.fi

University of Oulu, Oulu, Finland Ilkka Virtanen, ilkka.i.virtanen@oulu.fi University of Oulu, Oulu, Finland

Thermospheric winds play a key role in momentum and energy transfer between the magnetosphere and the high-latitude ionosphere-thermosphere system. We use the Fabry-Perot Interferometer (FPI) at Tromsø, the collocated EISCAT incoherent scatter radar, and the IMAGE magnetometer chain over Scandinavia to investigate the upper thermospheric wind dynamics during non-stormtime substorms. Based on the simultaneous measurements, we can assess the effect of local ion-drag force and Joule heating on the wind dynamics.

The upper thermospheric winds have different responses during substorm growth, expansion, and recovery phases. During the growth phase, the wind generally accelerates slowly in the direction of background plasma convection, which increases due to increased dayside merging between the IMF and the terrestrial magnetosphere. Hence, the ion drag force is the dominant factor. In addition, mesoscale wind disturbances are found in the vicinity of growth phase arcs.

During the expansion phase, the horizontal winds are accelerated in the eastward and southward directions within the substorm current wedge. The eastward acceleration takes place when the ionospheric westward electrojet expands over Tromsø, and therefore we suggest that even though ion drag may provide a part of the eastward acceleration, Joule heating is the dominant force. Acceleration often continues in the early part of the recovery phase. During the late recovery phase, the winds decay to pre-substorm conditions.

During substorms, atmospheric gravity waves (AGWs) may be generated centered at the onset region. The propagation of the AGWs causes periodic perturbations (20-40 min) in the vertical and horizontal winds. The perturbations are predominant during the recovery phase.

C1.3-0011-18 GENERATION, DYNAMICS, AND DECAY OF A POLAR CAP PATCH AND ASSOCIATED GPS SIGNAL SCINTILLATION

Thayyil Jayachandran, jaya@unb.ca

The polar cap ionosphere, an important part of the solar wind-magnetosphere-ionosphere system, is formed by ionization of the neutral atmosphere by solar radiation and particle precipitation under internal transportation and chemical processes. The polar ionosphere is primarily driven by magnetospheric convection and neutral circulation, and undergoes structuring over a wide range of temporal and spatial scale sizes. This structuring is due to the interplay of mechanical forces, electrodynamics, and ionization chemistry. The most prominent and frequent structure of the polar cap ionosphere is the polar patch, which is defined as a region of enhanced F layer ionization distinguishable from the background electron density. Several theories, observations, and hypotheses on the generation and dynamics of these patches are available in the literature. However, a coherent understanding of patch formation is still lacking, mainly due to the lack of high spatial and temporal resolution observations. This is also compounded by our attention to more dramatic patch events. This presentation will focus on a less-dramatic patch event using observations from the Canadian High Arctic Ionospheric Network (CHAIN), in order to provide a coherent view of formation, dynamics, and decay of polar patches. We also present the role of this patch in the generation of GPS amplitude and phase scintillation.

C1.3-0013-18 SWARM SATELLITE AND EISCAT RADAR OBSERVATIONS OF A PLASMA FLOW CHANNEL IN THE AURORAL OVAL NEAR MAGNETIC MIDNIGHT

We present a multi-instrument case study of ionospheric electrodynamics in the midnight sector at high latitudes, showing an existence of a plasma flow channel with high eastward flow velocities. The flow channel is 1.5° wide in latitude and contains southward electric field of 150

mV/m, corresponding to eastward plasma velocities of 3300 m/s in the F-region ionosphere. The flow channel measured by both the Swarm satellite and the EISCAT incoherent scatter radar is located equatorward of the polar cap boundary within the dawn convection cell.

While the poleward part of the auroral oval in this event is electric field dominant with low conductivity and the flow channel, the equatorward part is conductivity dominant with at least five auroral arcs. The main part of the westward electrojet flows in the conductivity dominant part. According to Kamide and Kokubun [1996], the whole oval is expected to be conductivity dominant in the post-midnight sector, so the studied event challenges the traditional view.

The flow channel is observed after a substorm onset. We suggest that the observed flow channel, which is associated with a 13-kV horizontal potential difference, accommodates increased nightside ionospheric plasma flows during the substorm expansion phase as a result of reconnection in the near-Earth magnetotail.

C1.3-0014-18 IN-SITU OBSERVATIONS OF REDUCED TOPSIDE PLASMA DENSITY AND ASYMMETRIC INTER-HEMISPHERIC ION FLOW AND RESULTING TRAVELING IONOSPHERIC DISTURBANCES DURING THE 2017 ECLIPSE

Andrew W. Yau, yau@phys.ucalgary.ca University of Calgary, Calgary, AB, Canada Victoria Foss, vfoss@ucalgary.ca

University of Calgary, Calgary, Canada Andrew Howarth, howarth@phys.ucalgary.ca University of Calgary, Calgary, Canada Gareth Perry, perry@phys.ucalgary.ca University of Calgary, Calgary, Canada Chris Watson, watsonc@ucar.edu

UCAR, Boulder, Colorado, United States

During the August 21, 2017 solar eclipse over North America, the Enhanced Polar Outflow Probe (e-POP) traversed the path of totality at 640 km altitude over Idaho at 17:37 UT within 10 minutes of totality, which provided a unique vantage point for observing several significant effects of the eclipse on the topside ionosphere. We present observations from the imaging ion mass spectrometer (IRM) and GPS receiver-based attitude, positioning and profiling experiment (GAP) onboard showing that during the eclipse: (1) the topside plasma density decreased by a factor of two; (2) the light H+ ions exhibited a concurrent and significant (50%) drop in only the upward ion flux that was not accompanied by a corresponding drop in downward flux from the conjugate hemisphere; and (3) the resulting traveling ionospheric disturbances (TID) resulting from the eclipse had an apparent spatial scale of about 200 km and an amplitude of about 0.2 TECU (total electron content unit). In addition, observations from the radio receiver instrument (RRI) in conjunction with ground radio transmitters reveal a distinct reduction in radio absorption in the eclipsed ionosphere relative to non-eclipse ionosphere. These observations are attributed to the temporary cessation or reduction of photoionization in the F-region over the umbra and penumbra regions as the moon's shadow and the resulting maximum solar obscuration moves at supersonic speed across the continent.

C1.3-0015-18 IMPACT OF LOWER ATMOSPHERIC FORCING ON STORM TIME RESPONSE OF THE IONOSPHERE-PLASMASPHERE-MAGNETOSPHERE COUPLING

This study aims to evaluate the impact of whole atmospheric coupling on storm time response in the ionosphere and plasmasphere during geomagnetically disturbed periods. The influence of coupling to terrestrial weather during storm time has drawn little attention. There are some unresolved questions: Whether or not the geo-effectiveness of magnetic storms could be changed when the upper atmosphere has been pre-conditioned by the lower atmospheric forcing; How does the lower atmospheric forcing modulate the recovery to a quiet level from a disturbed level? Recently, we have coupled the Ionosphere-Plasmasphere-Electrodynamics (IPE) model with the Whole Atmosphere Model (WAM) to investigate the connection between terrestrial and space weather. This presentation focuses on how some typical storm time phenomena in the ionosphere and plasmasphere are affected by the inclusion of forcing from below during geomagnetically active periods in simulations performed using the coupled WAM-IPE model. The presentation focuses on such phenomena as (1) temporal and spatial evolution of the Storm Enhanced Density (SED) plumes/Tongue of Ionizations (TOIs); (2) hemispheric asymmetry in SED plumes/TOIs; (3) Ionosphere-Plasmasphere-Magnetosphere Coupling via plumes and refilling, for the two St. Patricks' day storms in 2013 and 2015. The impact of lower atmospheric forcing is evaluated by comparing results with and without including forcing from below. Furthermore, the presentation discusses how the lower atmospheric forcing can influence the differences in storm time response in the ionosphere and plasmasphere.

C1.3-0016-18 IONOSPHERIC POLAR CAP PATCHES OBSERVED IN ANTARCTIC SUMMER USING SWARM

Alex Chartier, alex.chartier@jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, United States

Dense, fast-moving regions of ionization called patches are known to occur in the highlatitude F-region ionosphere. Patches are widely believed to be caused by convection of dense, sunlit plasma into a dark and therefore low-density polar cap. Therefore patches are not expected to be found in summer. Counter to previous reports, a long-term analysis of Swarm ionospheric measurements shows that patches typically occur in the same calendar months across both hemispheres, with very few around June in either hemisphere. This finding is surprising because it means there are many patches in southern hemisphere summer, and very few in southern hemisphere winter. Therefore current patch formation theories are incomplete and the physical cause of this annual variability remains unknown.

C1.3-0017-18 STORM-TIME IONOSPHERIC CONVECTION IN THE CENTRAL POLAR CAP

Jianjun Liu, liujianjun@pric.org.cn

Polar Research Institute of China, Shanghai, China

Observations of the ionospheric convection during a storm main phase on 9th September 2011 were examined. Measurements were obtained by three SuperDARN radars (ZHO, SYE and MCM) located in the southern hemisphere, the conjunction of these 3 radars plays an important role in revealing the dynamic process in magnetosphere-ionosphere coupling system. During the storm period, MCM radar scanning polar cap ionosphere monitored sequential strong antisunward large-scale plasma irregularities, which clearly presents the highly structured polar cap patches moving across the pole to the nightside and eventually into the the nightside auroral oval in quasi-periodical variation. While the ZHO radar recorded intense ionospheric backscatter echo power and moderate Doppler negative velocity in the poleward boundary of the nightside auroral oval, and simultaneous observation by the optical auroral imager did not get aurora data. In the duskside sector, Doppler velocity monitored by the SYE showed irregular plasma structures towards or away from the radar site. Furthermore, ionospheric digisonde at Zhongshan station observed strong spread F during the storm main phase. Concerning this event, coordinated observations suggest that the ionospheric convection dominates the periodical plasma transportation during typical disturbed geomagnetic environment.

C1.3-0018-18 A STUDY OF COUPLED SOLAR WIND-MAGNETOSPHERE-IONOSPHERE DYNAMICS AND THEIR SPACE WEATHER IMPLICATIONS

Victor U.J. Nwankwo, victornwankwo@yahoo.com Anchor University, Lagos, Nigeria

Sandip Kumar Chakrabarti, chakraba@bose.res.in

The solar wind is the principal medium through which the activity of the sun is communicated to the region of the Earth. The variability and interaction of the solar wind with the Earth's magnetosphere drives dynamic and variable conditions in the geo-space environment. The coupling effects of such perturbations on the ionosphere results in adverse conditions that can affect the performance and reliability of spaceand ground-based systems, and services that rely on them. In this study we investigate the effects of solar (and geomagnetic) induced variations in high-latitude ionosphere via the critical frequencies and virtual heights of radio sounding. We analyse solar wind speed (Vsw) and associated particle density (PD), geomagnetic Ap, disturbance storm time (Dst) index, and X-ray flux output, in association with ionospheric parameters (e.g. foF2, h'F2, foF1, h'f1, foEs, h'Es, foE, h'E) during 1-31 July 2000 and 1-31 July 2006. The periods represent intervals of high and low solar activity. We also simulate the orbital decay rate (ODR) of low Earth orbiting satellites (LEOSs) during these regimes, to infer the resultant effects of solar-induced ionospheric variations on satellites trajectory. Bulk of the effects of solar-driven ionospheric variations on LEOSs' ODR are mainly due to solar EUV and geomagnetic field-induced Joule heating, and consequent density increase. In modeling the ODR for two hypothetical LEOSs (having different ballistic coefficients), we show a strong connection between solar and geomagnetic activity, associated ionospheric disturbances and changes in ODR of the satellites.

C1.3-0019-18 MULTISCALE FIELD-ALIGNED CURRENTS: CHARACTERISTICS, CONTROLLING PARAMETERS, RELATIONSHIPS, AND CONNECTION TO IRREGULAR SPACE WEATHER ACTIVITY

The magnetosphere, ionosphere and thermosphere (MIT) act as a coherently integrated system, driven in part by solar influences and space weather disturbances. It is now recognized that studying these regions under a 'system science' framework is a key path forward for advancing our understanding of space weather to the point of prediction. Fundamental to the success of system science in the MIT is the ability to describe coupling phenomena, especially in the highlatitude region where the effects are most direct. Field-aligned currents (FACs), or the system of currents flowing along Earth's magnetic field lines, are the dominant form of energy and momentum exchange between the magnetosphere and ionosphere. FACs are ubiquitous across the high-latitude regime and have unique characteristics depending on the magnetospheric or solar wind source mechanism, and, therefore, mapping location in the ionosphere (i.e. auroral zone, polar cap, cusp). Further complicating the picture, FACs also exhibit a large range of spatial and temporal scales. In order to create new understanding of FAC spatial and temporal scales, their cross-scale effects, and the impact on the polar region, new data analysis approaches are required.

We explore the characteristics, controlling parameters, and relationships of multiscale FACs using a rigorous, comprehensive, and cross-platform analysis. We present the repeatable behavior of FACs across scales (i.e., the characteristics), the dependence on the interplanetary magnetic field orientation, and the degree to which each scale "departs" from nominal large-scale specification. We find that the relationships between scales are complex and reveal new information about the connection between multiscale FACs and irregular space weather activity.

C1.3-0020-18 GLOBAL IONOSPHERIC RESPONSES TO SPACE WEATHER DISTURBANCES

Xiaoqing Pi, xiaoqing.pi@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, United States

Solar coronal mass ejections and high-speed solar wind streams can cause geomagnetic storms, which have significant impact on Earth's magnetosphere, ionosphere, and thermosphere (M-IT). Coupling effects within the M-I-T system can dramatically and globally disturb the ionospheric state. We will present our research investigating ionospheric responses to space weather disturbances on global scales. Using ionospheric total electron content (TEC) measurements derived from GPS data, and Global Ionospheric Maps constructed using GPS data, we inspect the responses from high to low latitudes and at various local times and longitude sectors, according to different phases of space weather perturbations. Several approaches to characterizing the resulting disturbance patterns will be presented. These patterns could become essential to distinguishing major dynamical and chemical effects in the ionosphere in different regions, and to supporting the effort of forecasting space weather effects. Analyses of the responses to several storms, including the 2013 and 2015 St. Patrick's Day storms, using these approaches will be presented.

We analyze ionosphere-thermosphere (IT) responses to driving by complex solar wind structures during strong storms at 15 minutes to about hourly time scales. We focus on lowand middlelatitude total electron content (TEC), global thermospheric infrared nitric oxide emission, composition ratio and locations of the auroral boundary obtained from multiple satellite platforms and ground-based measurements (GPS, TIMED/SABER, TIMED/GUVI, DMSP/SSUSI). We analyze IT storm dynamics in relation to the efficiency of solar wind-magnetosphere coupling and driving by particular solar wind structures. The impacts of direct external driving and of IT pre-conditioning in these storms are discussed. We identify IT effects that can be important for long-lasting strong storms.

C1.3-0022-18 FEBRUARY 2, 2017 OBSERVATION OF MAGNETIC IMPULSIVE EVENT (MIE) BY AUTUMNX AND VAN ALLEN PROBES

Jerry Manweiler, manweiler@ftecs.com

Fundamental Technologies, LLC, Lawrence, Kansas, United States Martin Connors, martinc@athabascau.ca

Athabasca University, Athabasca, Canada Mark Engebretson, engebret@augsburg.edu

Augsburg College, Minneapolis, Minnesota, United States

Transient magnetic impulse events (MIE), lasting for 5-15 min have been frequently recorded by high-latitude ground-based magnetometers [Lanzerotti et al., 1991, Sibeck and Korotova, 1996]. Multiple theories of the cause and drivers of these events have been proposed for the dayside such as bursty reconnection (Glassmeier et al., 1984; Lanzerotti et al., 1986) and magnetic motion by pressure pulses due to abrupt changes in the Interplanetary Magnetic Field (IMF) (FriisChristensen et al., 1988; Sibeck et al., 1989); and for the nightside Field Aligned Currents (FAC) associated with plasmapause transients [Lanzerotti et al., 1991, Sibeck and Korotova, 1996]. In this work, we report on the simultaneous observation of a Magnetic Impulsive Event (MIE) on the nightside by ground based (Connors et al., 2017) and orbital detectors. On February 2, 2017, Canadian AUTUMNX ground stations on the east bank of the Hudson Bay in Quebec Canada and the MACCS CDRT ground station in Cape Dorset on Baffin Island, Nunavet, Canada recorded a large MIE with a negative surface z component of the induced magnetic field of -1,200 nT at the INUK station and a positive 500 nT at the CDRT station which is 647 km north. At the same time, the Van Allen Probes A spacecraft using the Radiation Belt Storm Probes Ion Composition Experiment (RBSPICE) and the Electric and Magnetic Field Instrument suite and Integrated Science (EMFISIS) DC magnetometer observed a magnetic pulse and associated changes in the energetic proton and electron particle distributions. We provide details of these observations as reported by the ground stations and the as well as the simultaneous changes to the magnetosphere as observed by the Van Allen Probes A and B instruments. C1.3-0023-18 STATISTICAL STUDY OF IONOSPHERIC CONDUCTIVITY DEPENDENCE OF THE SUBAURORAL POLARIZATION STREAMS USING THE SUPERDARN HOKKAIDO EAST HF RADAR

Yuting Zhang, zhang.yuting@isee.nagoya-u.ac.jp Nagoya University, 8601, Japan

Nozomu Nishitani, nisitani@stelab.nagoya-u.ac.jp

Solar-Terrestrial Environment Laboratory, Nagoya University, Nagoya, Japan Tomoaki Hori, horit@stelab.nagoya-u.ac.jp

STEL, Nagoya Univ., Nagoya, Japan

In this study, we investigate characteristics of the subauroral polarization streams (SAPS), focusing on ionospheric conductivity dependence, especially the solar zenith angle(SZA) dependence, using the Super Dual Auroral Radar Network (SuperDARN) Hokkaido East radar, National Oceanic and Atmospheric Administration (NOAA) Polar Operational Environmental Satellites (POES) system and Meteorological Operational Satellite Program of Europe (MetOp) system data. The time span for the present study is from 2008/1/10 to 2016/12/31, which contains over 3180 days, and we limited the time range of the analysis to 3-8 UT (12-17 LT). We found 60 SAPS events over seasons except for summer, and for each event we examined the SZA and the peak Line-of-sight velocity observed in the SAPS, in order to identify the threshold of the possible SZA and illuminated ionospheric altitude for SAPS to be generated. We have determined location of the echo region based on the straight ray path geometry with empirical offset value for multiple-hop paths, whereas in order to investigate the effect of HF propagation geometry and achieve a more precise mapping of scattering locations, we are trying to apply a new empirical virtual height model to the SuperDARN Hokkaido East radar, which uses different coefficients in the model when mapping backscatter targets propagate via different propagation paths. We also took into account the effect of EUV absorption in the atmosphere. As a result of the statistical study, we find that SAPS tend to appear when the SZA is larger than 98.5 degrees, and that the minimal threshold of illuminated ionospheric altitude for SAPS occurrence is estimated to be about 138 km, which is just above the altitude of the peak of Pedersen conductivity. This result suggests that the low background Pedersen conductivity plays an important role in the generation of SAPS through a positive feedback in which the enhanced electric filed drives frictional heating of the neutral atmosphere and thereby lowers the conductivity further. To the best of our knowledge, this is the first detailed study of

SAPS-associated SZA, and shows quantitatively the importance of Pedersen conductivity for SAPS generation.

C1.3-0024-18 PERFORMANCE OF IRI-PLAS MODEL WITH GIM-TEC INPUT DURING 2017 EQUINOX MONTHS

Feza Arikan, arikan@hacettepe.edu.tr HACETTEPE UNIVERSITY, ANKARA, Turkey

Umut Sezen, u.sezen@ee.hacettepe.edu.tr HACETTEPE UNIVERSITY, Ankara, Turkey Tamara Gulyaeva, gulyaeva@izmiran.ru

Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation of the Russian Academy of Sciences (IZMIRAN), Moscow, Russia

International Reference Ionosphere (IRI) extended to Plasmasphere (IRI-Plas) is one of the most acclaimed climatic models of ionosphere that is used to obtain various parameters of ionosphere and plasmasphere such as electron density distribution, critical layer plasma frequency, maximum ionization height and ion and electron temperatures. IRI-Plas uses CCIR or URSI background hourly-monthly median model coefficients in determination of F2 layer critical frequency, foF2. All the other parameters are computed using this model foF2, foF2model. The two major drawback of all standard deterministic climatic models is that the hourly-monthly median values typically do not represent the current state of the ionosphere and the coupling of solar and geomagnetic activities into the ionosphere are represented by basic 12 month running averages of solar and ionospheric indices such as Sun Spot Number (SSN) and F10.7. As opposed to these standard models, IRI-Plas has two very important advantages. The first one is the input of GPS-TEC and the second one is user defined choice of 9 solar/ionospheric indices such as SSN1, SSN2, F10.7, Lyman-α, Mg II, IG, TEC, GEC, GECRZ. IRI-Plas can be downloaded from http://ftp.izmiran.ru/pub/izmiran /SPIM/ as a FORTRAN code. IONOLAB group provides user friendly online computation of IRI-Plas at www.ionolab.org with a choice of automatic input of all ionosonde station locations and, IGS and EUREF GPS receiver locations along with GIM-TEC values for all IGS Analysis Centers for the user defined location, date and time. In this study, IRI-Plas model F2 layer critical frequency, foF2model, is compared with ionosonde foF2, foF2iono, in Root Mean Square (RMS) and Normalized RMS (NRMS) sense for the equinox months of 2017, March and September. All available ionosondes are grouped into global, high-latitude, midlatitude and equatorial regions and northern and southern hemispheres are also considered as separate groups. It has been observed that URSI and CCIR models provide the same background globally both in March and September 2017.

The input of TEC is very successful in lowering the error fit to ionosonde foF2 if JPL GIMTEC input with IG index and Mg II are used in March and September 2017, respectively. For the overall midlatitude, high-latitude and equatorial best fitting choices are JPL GIM-TEC input with IG index (March) and Mg II or TEC

(September), IG or Lyman-α (March) and GECRZ (September), IG (March) and no input GEC and Lyman-α(September), respectively. This study is supported by TUBITAK 115E915.

C1.3-0025-18 IMPACT OF GEOMAGNETIC VARIATION OVER SUB-AURORAL IONOSPHERIC REGION DURING HIGH SOLAR ACTIVITY YEAR 2014

Arun Kumar Singh, arsurya123@gmail.com

National Physical Laboratory India, NEW DELHI, India

The present work is an attempt to evaluate the sub-auroral ionospheric behavior under changing space weather conditions especially during high solar activity year 2014. In view of this, the GPS TEC along with Ionosonde data over Indian permanent scientific base "Maitri", Antarctica (70°4600 S, 11°4356 E) has been utilized. The results suggested that the nature of ionospheric responses to the geomagnetic disturbances mainly depended upon the status of high latitudinal electro-dynamic processes along with season of occurrence. Fortunately, in this study, both negative and positive ionospheric impact to the geomagnetic disturbances has been observed in a single year but in different seasons. The study revels that the combination of equatorward plasma transportation along with ionospheric compositional changes causes a negative ionospheric impact during summer and equinox seasons. However, the combination of poleward contraction of oval region along with particle precipitation may leads to exhibits positive ionospheric response during winter season. Other than this, some Ionosonde based new experimental evidences also provided clear evidence of particle precipitation deep up to the low altitudinal ionospheric heights i.e. up to E-layer by sudden and strong appearance of E-layer at 100 km altitudes. The sudden appearance of E-layer along with decrease in F-layer electron density suggested the dominance of NO+ over O+ at considered region under geomagnetic disturbed condition. The strengthening of E-layer is responsible for modification of auroral electrojet and field aligned current system. The present study provided a good scientific insight on sub-auroral ionospheric to the changing space weather condition.

C1.3-0026-18 CLASSIFICATION AND QUANTIFICATION OF SOLAR WIND DRIVER GASES LEADING TO INTENSE GEOMAGNETIC STORMS

Bolarinwa Adekoya, adekoyabolarinwa@yahoo.com Olabisi Onabanjo University, Ago-Iwoye, Nigeria Victor Chukwuma, uzodinmachukwuma@gmail.com

Olabisi Onabanjo University, Ago Iwoye, Nigeria, Ago Iwoye, Nigeria

Classification and quantification of the interplanetary structures causing intense geomagnetic storms (Dst -100 nT) that occurred during 1997-2016 are studied. The subject of this consists of solar wind parameters of seventy-three intense storms that are associated with the southward interplanetary magnetic field. About 30.14% of the storms were driven by a combination of the sheath and ejecta (S+E), magnetic clouds (MC) and sheath field (S) are 26% each, 10.96% by combined sheath and MCs (S+C), while 5.48% of the storms were driven by ejecta (E) alone. Therefore, we want to aver that for storms driven by: (1) S+E. The Bz is high (10 nT), high density () (> 10 N/cm3), high plasma beta () (> 0.8), and unspecified (i.e. high or low) structure of the plasma temperature (T) and the flow speed (V); (2) MC. The Bz is 10 nT, low temperature (T 400000°K), low (10 N/cm3), high V (450 km), and low (0.8); (3) The structures of S+C are similar to that of MC except that the V is low (V 450 km); (4) S. The Bz is high, low T, high, unspecified V, and low ; and (5) E. Is when the structures are directly opposite of the one driven by MCs except for high V. Although, westward ring current indicates intense storms, but the large intensity of geomagnetic storms is determined by the intense nature of the electric field strength and the Bz. Therefore, great storms (i.e. Dst -200 nT) are manifestation of high electric field strength (13 mV/m).

C1.3-0027-18 OBSERVATION OF INTERMITTENCY-INDUCED CRITICAL DYNAMICS IN GEOMAGNETIC FIELD TIME SERIES PRIOR TO THE INTENSE MAGNETIC STORMS OF MARCH, JUNE AND DECEMBER 2015

Criticality has been proposed as a suitable framework to study the nonlinear system of the Earth's magnetosphere. The magnetic field variations observed by the mid-latitude HellENIc GeoMagnetic Array (ENIGMA) with respect to the most intense magnetic storms (Dst < 150 nT) of the current solar cycle (i.e. 17 March, 23 June and 20 December 2015) are analyzed using the method of critical fluctuations (MCF). We show that the application of MCF to the ENIGMA time series reveals the existence of intermittency induced criticality in the range of 6 to 45 hours prior to the onset of these events. The results suggest that the underlying dynamical processes in the magnetosphere prior to intense magnetic storms present dynamics analogous to those of thermal systems undergoing second order phase transition.

C1.3-0028-18 THE TURBULENT PLASMASPHERE BOUNDARY LAYER

Evgeny Mishin, evgeny.mishin@us.af.mil

Air Force Research Laboratory, Albuquerque, New Mexico, United States

We present multisatellite observations of enhanced plasma turbulence caused by substorminjected plasma jets penetrating into the plasmasphere and creating the turbulent plasmasphere boundary layer between the plasma sheet boundary at the pre-substorm plasmapause and the drop in the injected ion flux. A number of plasma instabilities develops during this highly dynamic process via interaction of the overlapping hot and cold plasma populations. The outcomes of the excited turbulence for the subauroral geospace, such as precipitation of the radiation belt electrons and collisionless heating and acceleration of plasma particles to suprathermal energies, which enhances the downward heat flux and concomitant heating of the ionospheric electrons, are described.

C1.3-0029-18 MID-LATITUDE IMPACT OF THE MEMORIAL DAY STORM 2017

MIT Haystack Observatory, Westford, Massachusetts, United States

A slow-moving CME hit the earth on May 27-28, 2017 causing Kp to reach 7 and sparking largescale impact. This impact was widely observed at mid-latitudes, specifically in the F-region. We present here the observed impact of this storm at F-region altitudes using the Mid-latitude All-sky-imaging Network for Geospace Observations (MANGO), which is a network of 630nm imagers covering the continental United States, and detrended GPS total electron content data from the same region. The observations suggest that impact at sub and mid-latitudes was not limited to auroral enhancements at these latitudes, but also modulated wave propagation and airglow enhancements.

C1.3-0030-18 INTERMEDIATE SCALE IRREGULARITIES OBSERVED USING GPS SCINTILLATION DURING THE HALLOWEEN STORM OF 2003

Superstorms are unusually strong storms where the Dst index reaches below -300 nT and understanding the effects of such space weather events is a key component of the National Space Weather Action Plan. Magnetospheric-Ionospheric coupling during extreme events can be very complex as compared to the more typical geomagnetic activity, thus the associated ionospheric irregularities (which are basically density structures in the ionosphere) can be different for superstorms. Ionospheric irregularities can cause rapid variations in amplitude and phase of radio waves (such as a satellite signal from global navigation satellite systems (GNSS)), referred to as amplitude and phase scintillation. Scintillation are due to diffraction and delays within ionospheric irregularities with scale sizes on the order of 0.1-100 km (intermediate-medium scales). We study the superstorm on Oct. 2003 (with Dst index below -300 nT), known as the Halloween event using GNSS scintillation observations, ground-based optical and incoherent scatter radar data. To complement the proposed data analysis efforts, we will use our physics based model of ionospheric plasma instabilities (GEMINI) and the EM wave propagation model (SIGMA) to propagate the GNSS signals through turbulent media to simulate scintillation on ground before and during the extreme event. Our models will be initialized with conditions consistent with available ISR and optical data during the time of interest. Based on our investigation, we predict the type of instability (Gradient Drift or Kelvin-Helmholtz) responsible for scintillation.

C1.3-0031-18 SIMULATIONS OF IONOSPHERIC DYNAMICS DURING A SUBSTORM

We present numerical simulations of the coupled ionosphere-inner magnetosphere during a substorm interval on March 1, 2017. Simulation results of the chosen event intervals are obtained with the SAMI3-RCM ionosphere-magnetosphere coupled model. The latest version of the model includes a self-consistent 3-dimensional ionosphere responding to dynamic electric fields of magnetospheric origin as well as enhanced structured auroral electron precipitation. We compare these simulation results with co-incidental high precision GNSS receiver data providing local overhead total electron content (TEC) measurements at Poker Flat and Venetie (Alaska). Additional comparison will be presented with the Poker Flat Incoherent Scatter radar measurements of the rapid ionization enhancement in the 100-200 km region across multiple beams looking in the auroral region. The available SuperDARN data from this time period will also be used to determine the regional pattern of ionospheric flows. We will discuss these initial results to provide physical interpretation observed ionospheric dynamics during a substorm.

C1.3-0032-18 RECONSTRUCT SMALL-SCALE ELECTRIC FIELD IN THE HIGH LATITUDES USING DIFFERENT METHODS

Yue Deng, yuedeng@uta.edu

University of Texas at Arlington, Arlington, Texas, United States Qingyu Zhu, qingyu.zhu@mavs.uta.edu

Texas, United States

Mingwu Jin, mingwu@uta.edu Texas, United States

In the high latitudes, in addition to the large-scale background electric field there is a significant component of small-scale electric field or electric field variability. Its contribution to the Joule heating can be comparable to or even larger than the background electric field. While the significance of electric field variability to the Joule heating has been recognized, we still face a big challenge to describe it precisely and implement it in the GCMs appropriately. To improve our capability to specify the high-latitude electrodynamics, both traditional and machine-learning methods have been applied to the DE-2 and SWARM satellite measured electric field data. The reconstruction of small-scale electric field will be compared with empirical model and DMSP satellite observations. The influence on the upper atmosphere will be simulated through coupling with Global Ionosphere-Thermosphere Model (GITM).

C1.3-0033-18 HEMISPHERIC ASYMMETRIES IN IONOSPHERIC HORIZONTAL AND FIELDALIGNED CURRENTS FROM THE SWARM SATELLITE MEASUREMENTS

Abiyot Workayehu, abiyot.workayehu@oulu.fi University of Oulu, Oulu, Finland

Heikki Vanhamäki, heikki.vanhamaki@oulu.fi University of Oulu, Oulu, Finland

Anita Aikio, anita.aikio@oulu.fi University of Oulu, Oulu, Finland

The Swarm mission by ESA is the first ionospheric multi-satellite mission. Each of the three Swarm satellites carries magnetometers and other instruments that make e.g. measurements of plasma density and electric field. Analysis of the magnetic measurements by these satellites allow the determination of ionospheric horizontal and field-aligned currents (FAC) more accurately than ever before. In combination with the plasma and electric field measurements on the same satellite, these data can provide detailed information about electrodynamics of the ionosphere and the ionosphere-magnetosphere coupling processes. In this study, we use the spherical elementary current system (SECS) method for the analysis of the vector magnetic field measurements by the two parallel-flying Swarm satellites [Amm et al., 2015]. This method allows us to estimate the field-aligned currents, and the curl-free (cf) and divergencefree (df) components of the horizontal current. We will present statistical investigation of the high-latitude current systems based on 3 years of Swarm data on the Northern and Southern hemisphere at geomagnetic latitudes greater than 50o. The results show that generally the currents are more intense in the Northern hemisphere, but the difference has seasonal dependence. We have carried out model calculations to find possible reasons behind the observations.

C1.3-0034-18 FIRST RESULTS ON CLIMATOLOGICAL RESPONSE OF INDIAN LOW LATITUDE IONOSPHERE TO GEOMAGNETIC STORMS DURING SOLAR CYCLE 23 AND 24

Sunanda Suresh, sunandasuresh88@gmail.com

National Atmospheric Research Laboratory, Tirupati, India Nirvikar Dashora, nirvikardashora@gmail.com

National Atmospheric Research Laboratory, Gadanki, India

For the first time, a climatological response of low latitude ionosphere to geomagnetic storms is presented using long term global ionospheric maps (GIM) data from June 1998 to June 2015 covering two solar cycles 23 and 24. The results are not only the first from Indian region but also the first around the globe to bring latitudinal character of daytime ionospheric storms with use of newly defined criteria. The results are presented for daytime forenoon and afternoon sectors under minor, moderate and major ionospheric storm categories based on minimum Dst index criterion. For the first time the effectiveness of storms is identified using monthly standard deviation as an indicator of the day-to-day variability in equatorial and low latitude ionosphere. Thus results on climatology are definitive and form a data base that would be comparable to statistical results from any other longitude and time. Seasonal statistics for total storms, effective positive and negative storms, and amplitude of mean seasonal perturbation in total electron content are obtained. Total and effective storms are found to be higher in solar cycle 23 than in 24 and only couple of effective storms occurred during low solar activity 2007- 2009 that also in minor category. Afternoon sector is found to be favourable for occurrence of maximum number of effective positive storms. A latitudinal preference is found for a given storm to be effective in either time sectors. Equinoctial asymmetry in ionospheric response both in terms of occurrence and perturbation amplitude is found. September equinoxes are found to bear maximum total, effective positive and negative storms. Winters are found more prone to negative storms whereas summers have recorded minimum number of either of storms and minimum perturbation amplitudes.

C1.3-0035-18 POLAR CAP STRUCTURES AND DYNAMICS REVEALED BY TEC KEOGRAMS EXTRACTED FROM TEC MAPS

Total Electron Content (TEC) keograms constructed from TEC maps used to study various polar cap structures and their dynamics. The TEC keongrams along various meridians from dayside lower latitudes to nightside lower latitudes in two cases studies revealed several interesting structures and their dynamics associated with corresponding Interplanetary Magnetic Field (IMF). Some of the structures such as polar patches were simultaneously identified by using SuperDARN radars as well. During the talk, we will discuss these results and their implications in Solar-Terrestrial coupling research as well as the use of TEC keograms in surveying polar cap structures.

Earth's plasmasphere is a region of cold (T 1 eV), dense (n 101 to 104 cm-3) plasma located in the inner magnetosphere and coincident with a portion of the ionosphere that co-rotates with the planet in the geomagnetic field. Plasmaspheric plasma originates in the ionosphere and fills the magnetic flux tubes on which the corotation electric field dominates over the convection electric field. The corotation electric field results from Earth's spinning magnetic field while the convection electric field results from the solar wind driving of global plasma convection within the magnetosphere. The outer boundary of the plasmasphere is the plasmapause, and it corresponds to the transition region between corotation-driven vs. convection-driven plasmas. When the convection electric field is enhanced during active solar wind periods, such as magnetic storms, the plasmasphere can rapidly erode to L 2.5 or less. During subsequent quiet periods of low solar wind speed and weak interplanetary magnetic field (IMF), ionospheric outflow from lower altitudes refills the plasmasphere over the course of several days or more, with the plasmapause expanding to higher L-shells. The combination of convection, corotation, and ionospheric plasma outflow during and after a storm leads to characteristic features such as plasmaspheric shoulders, notches, and plumes.

In this presentation, we focus on the dynamics of the plasmapause during two storms in 2013: March 17 and June 28. The minimum Dst for the two storms were -139 and -98 nT, respectively. We examine plasmapause dynamics utilizing data from an extensive global network of groundbased scientific GPS receivers (4000) and line-of-sight observations from the GPS receivers on the COSMIC and C/NOFS satellites, along with data from THEMIS and van Allen Probes, and Millstone Hill Incoherent Scatter Radar. Using the various datasets, we will compare the prestorm and storm-time plasmasphere. We will also examine the location, evolution, and erosion time scales of the plasmapause during the active portion of the storm using a combination of the observational data, the assimilative PDA model, and the RCM-E model.

C1.3-0038-18 FAILURES IN ELECTRICAL GRIDS IN SOUTHERN POLAND IN 2010 AND 2014 IN RELATION TO SPACE WEATHER EFFECTS

The impact of space weather events on energy infrastructure via geomagnetically induced currents is very well known and widely studied since at least Quebec blackout on 13rd of March 1989. Those effects are not very extensively studied in relation to Polish energy infrastructure. Pulkkinen and coauthors (2005), describing the Halloween Storm's (October/November 2003) aftermath mentioned two episodes on SwePol Link cable (SwePol Link connects, under the Baltic Sea, Polish and Swedish energy infrastructure, by the 450 kV high voltage direct current).

Taking into account the conductances map of Europe (Viljanen et al., 2014) we consider the data of failures in electrical grids in the south part of Poland. Here we analyze two years during the ongoing solar activity cycle 24: 2010 (an early ascending phase of the cycle, near to solar minimum) and 2014 (solar maximum). We consider 228 failures in 2010 and 186 in the first half of 2014, which might be connected with space weather effects. We analyze data of unexplained breakdowns which occurred during the periods of an increased geomagnetic activity. Based on the data from The Institute of Meteorology and Water Management -National Research Institute (IMGW-PIB) we exclude from the consideration those failures which had meteorological causes.

C1.3-0039-18 EFFECTS OF THERMOSPHERIC DENSITY AND COMPOSITION CHANGES DURING GEOMAGNETIC STORMS ON ION OUTFLOW

Roger Varney, roger.varney@sri.com

SRI International, Menlo Park, California, United States Binzheng Zhang, binzheng@ucar.edu

University of Hong Kong, Hong Kong, Hong Kong, China

The mass loading of the magnetosphere by ionospheric ion outflow has substantial effects on the evolution of geomagnetic storms, and methods for including this ion outflow in global geospace models are still under development. Most of the ion outflow models currently in existence use empirical specifications of the neutral thermosphere. Nonetheless, it is well established that the high-latitude energy dissipation during geomagnetic storms causes significant changes to thermospheric density and composition. We explore the effects of these changes on ion outflow using coupled geospace models. We model the thermospheric changes during storms using the Coupled Magnetosphere Ionosphere Thermosphere (CMIT) model, which combines the Thermosphere Ionosphere Electrodynamics General Circulation Model (TIEGCM) with the Lyon-Fedder-Mobarry (LFM) global magnetospheric magnetohydrodynamics model. We use TIEGCM thermospheric state variables from CMIT runs as inputs to the Ionosphere/Polar Wind Model (IPWM) to quantify the changes in ion outflow associated with changes in the thermosphere.

C1.3-0040-18 LOFAR SCINTILLATION MEASUREMENT AS A TOOL FOR PLASMA DIAGNOSTIC

As a part of the The Low Frequency Array (LOFAR) network, the Polish station PL610 in Borówiec provides observational data useful for studying distant radio sources in a frequency range between 10-270 MHz. It can also be used to investigate weak scintillation regimes commonly found in mid-latitude ionosphere. Strong radio sources (such as Cassiopea A and Cygnus

A) and bright quasars have been observed in the local mode of the station to study ionospheric and interplanetary scintillations. As an EM wave propagates through a medium where electron density fluctuations are present, variations in the refractive index of this medium occur. Such density irregularities of interplanetary medium cause signal diffraction, producing diffraction patterns that can be used to obtain estimates on the local speed of solar wind. Moreover, since observations carried out in low frequency range are more sensitive to ionospheric disturbances than in higher frequencies, they can provide information on irregular structure of this layer that influences f.e. low frequency radioastronomy and radio communication. By using raw amplitude measurements over full bandwidth of LOFAR, daily statistics of ionospheric scintillation index S4 have been determined, which is a common parameter describing ionosperic disturbances. Very good frequency and time resolution of LOFAR observations enable studying dynamical changes of the S4 index, through which changing conditions of ionospheric layer can be monitored. We present examples of analysis of LOFAR observational data, including theoretical background of such analyses and scattering properties of solar wind and ionospheric disturbances.

C1.3-0041-18 GNSS AS A GLOBAL OBSERVING SYSTEM FOR DISTURBED IONOSPHERE STUDY

Iurii Cherniak, tcherniak@ukr.net

University Corporation for Atmospheric Research, Boulder, Colorado, United States Irina Zakharenkova, zakharenkovai@gmail.com

University of Warmia and Mazury in Olsztyn, Poland, Olsztyn, Poland

Techniques based on the transionospheric radio waves propagation, in particular Global Navigation Satellite Systems (GNSS), has been effectively used during several decades for ionospheric climatology research as well as for monitoring and study of main parameters of ionospheric plasma disturbances. The number of the ground-based receivers within the global and regional GNSS networks grew significantly from several hundred worldwide in the 1990s to more than 6000 stations today. Many of operated Low-Earth-Orbit satellites are also equipped with dualfrequency GNSS receivers and give possibilities to estimate ionosphere plasma density above and below LEO orbit and to detect ionospheric irregularities signatures at high altitudes. The proven and most informative in a global scale Radio Occultation (RO) technique also based on GNSS signal parameters analysis. Ground-based GNSS networks, COSMIC RO constellations and LEO GPS provide continuous measurements of navigation signals parameters, that allows to consider these facilities as a global observatory for permanent monitoring of ionospheric plasma density spatial distribution and its dynamics. We present results demonstrating advantages of using dense ground-based GNSS networks, COSMIC RO data and products as well as LEO GPS observations for investigation of ionospheric responses on Space Weather drivers and focus on representative case studies during the 2015 severe geomagnetic storms. In this study, we investigate signatures of the large-scale traveling ionospheric disturbances (LSTIDs) recognized in the ground-based total electron content (TEC) and storm-induced ionospheric plasma density irregularities caused by auroral particles precipitations, plasma gradients associated with SED/TOI (storm-enhanced density / tongue of ionization) formation and storm time plasma bubbles development. Also, we present recent results of GNSS TEC analysis of the ionosphere's response to the 21 August 2017 solar eclipse.

C1.3-0042-18 EFFECT OF GEOMAGNETIC STORM CONDITIONS ON THE EQUATORIAL IONIZATION ANOMALY AND EQUATORIAL TEMPERATURE ANOMALY

Gaurav Bharti, bharti09081990@gmail.com

Indian Institute of Technology Roorkee, Roorkee, India

M.V. Sunil Krishna, suneel.krishna@gmail.com

Indian Institute of Technology Roorkee, Roorkee, India

The effect of the geomagnetic storm on the equatorial ionization anomaly (EIA) and equatorial temperature anomaly (ETA) has been studied using the atomic oxygen dayglow emissions at 577.7 nm (OI 557.7 nm) and 732.0 nm (OII 732.0 nm). For the purpose of this study, four intense geomagnetic storms during the ascending phase of solar cycle 24 have been considered. This study is primarily based on the results obtained using photochemical models with necessary inputs from theoretical studies and experimental observations. The latest reaction rate coefficients, quantum yields, and the corresponding cross-sections have also been incorporated in these models. The volume emission rate of airglow emissions has been calculated using the neutral densities from NRLMSISE-00 and charged densities from the IRI-2012 model. The modeled volume emission rate (VER) for OI 557.7 nm shows a positive correlation with the Dst index at 150 km and negative correlation with Dst at 250 and 280 km altitudes. Latitudinal profile of the green line emission rate at different altitudes shows a distinct behavior similar to what has been observed in EIA with crests on either side of the equator. The EIA crests are found to show poleward movement in the higher altitude regions. The volume emission rate of 732.0 nm emission shows a strong enhancement during the main phase of the storm. The changes observed in the airglow emission rates are explained with the help of variations induced in neutral densities and parameters related to EIA and ETA. The latitudinal variation of 732.0 nm emission rate is correlated to the variability in EIA during the storm period.

C1.3-0043-18 EQUATORIAL SATELLITE DRAG EFFECTS DURING SUPER MAGNETIC STORMS

Gurbax Singh Lakhina, gslakhina@gmail.com

Indian Institute of Geomagnetism, Navi Mumbai, India Bruce Tsurutani, bruce.tsurutani@jpl.nasa.gov

JPL, Pasadena, California, United States

Prompt penetration electric fields (PPEFs) associated with intense magnetic storms have been found to uplift the dayside ionosphere through E×B forces near the magnetic equator. This effect is known as the “dayside superfountain effect”. The upward moving O+ (oxygen ions) will elevate the oxygen atoms to higher altitudes via the ion-neutral drag forces between the two particle species. The uplifted oxygen ions and neutrals could produce extra drag on low orbiting satellites. This paper presents a linear calculation on the satellite drag effect during a 1859- type (Carrington) superstorm. The analysis shows that uplifted oxygen neutral densities at low-Earth-orbiting (LEO) satellite altitudes may be sufficiently high to present severe satellite drag. It is estimated that with a prompt penetrating electric field of 20 mV m-1 turned on for 20 min, the O atoms and O+ ions are uplifted to 850 km where they produce about 40 times greater satellite drag per unit mass than normal. Stronger electric fields will presumably lead to greater uplifted mass.

C1.3-0046-18 SWARM DUAL SATELLITE OBSERVATION OF LONGITUDINAL VARIATION OF FIELD-ALIGNED CURRENTS

Hui Wang, h.wang@whu.edu.cn Wuhan University, Wuhan, China

Hermann Luehr, hluehr@gfz-potsdam.de

Deutsches GeoForschungsZentrum, GFZ, Potsdam, Germany

In this study we investigated the longitudinal variations in the mean densities of field-aligned currents (FACs) at high latitudes in different seasons, by using magnetic field data from SWARM A and C satellites. There appears a wave-1 longitudinal structure in FACs in both hemispheres. Longitudinal variations are about a factor of 1.2-3.2 larger in the Southern Hemisphere than in the Northern. Variations in solar illumination can explain certain longitudinal variations in FACs, with more solar illumination and stronger FACs at near pole longitudes than at far-from-pole longitudes. On the nightside in the local winter a higher value of FACs is generally associated with more intense auroral precipitation in the same area. The theoretical study from the global ionosphere and thermosphere model revealed that the role of neutral wind is comparable to that of electric field in the longitudinal modulation of FACs. A tidal analysis was applied to both FACs and cos0.5(SZA) (SZA= solar zenith angle). FACs contain a large DW2 component, in particular during summer and equinox, which is absent for cos0.5(SZA). Factors like the geomagnetic field strength, conductivity gradient, and dipole tilt angle might contribute to the observed DW2 features in FACs.

C1.3-0047-18 ON GEOMAGNETIC STORMS AND IONOSPHERIC RADIO WAVE ABSORPTION IN THE EQUATORIAL REGION: A PHILOSOPHICAL REINFORCEMENT

Victor Chukwuma, uzodinmachukwuma@gmail.com

Olabisi Onabanjo University, Ago Iwoye, Nigeria, Ago Iwoye, Nigeria

Investigations using radio waves reflected from the ionosphere, at high-and mid-latitudes indicate that ionospheric absorption can strongly increase following geomagnetic storms; which appears to suggest some definite relationship between ionospheric radio wave absorption and geomagnetic storms at these latitudes. However, corresponding earlier studies in the equatorial region did not appear to show any explicit relationship between ionospheric radio wave absorption and geomagnetic storm activity. This position appeared acceptable to the existing scientific paradigm, until in an act of paradigm shift, by a change of storm selection criteria, some more recent space weather investigations in the low latitudes showed that ionospheric radio wave absorption in the equatorial region clearly increases after intense storms. Given that these results in the equatorial region stood against the earlier results, this paper presently attempts to highlight their philosophical underpinning and posit that they constitute a scientific statement.

Keywords: Geomagnetic storm, A3 method, Ionosphere, Radio wave absorption, Equatorial Region, Popper’s Demarcation Rule.

C1.3-0048-18 ON IONOSPHERIC PHENOMENA DURING PRE-STORM AND MAIN PHASE OF A VERY INTENSE GEOMAGNETIC STORM

Victor Chukwuma, uzodinmachukwuma@gmail.com

Olabisi Onabanjo University, Ago Iwoye, Nigeria, Ago Iwoye, Nigeria

An investigation to elucidate the mechanisms responsible for the pre-storm and main phase ionospheric phenomena during November 20-21, 2003, is presented using heliophysical, interplanetary, geomagnetic, and global ionospheric data. The results show that the ionospheric responses in the main phase do not indicate prompt penetration electric fields as the main ionospheric driver. The results also show that the prestorm phenomena do not originate from a local time effect. The simultaneous occurrence of foF2 enhancements at two widely separated longitudinal zones appeared to suggest a role played by the magnetospheric electric field. However, the analysis of hmF2 at the stations could not confirm the notion that these fields are the main drivers of pre-storm phenomena. An investigation of flare effects on the pre-storm phenomena also revealed that solar flares are not the main drivers. The present results appear to suggest that the pre-storm ionospheric phenomena could be a result of some underlying mechanisms that are working together with varying degree of importance.

Keywords: geomagnetic storm, solar X-rays, solar wind, shock gas, ionosphere, pre-storm phenomena.

C1.3-0049-18 UNEXPECTED SOUTHERN HEMISPHERE IONOSPHERIC RESPONSE TO GEOMAGNETIC STORM OF 15 AUGUST 2015

Jan Lastovicka, jla@ufa.cas.cz

Institute of Atmospheric Physics, AS CR, Prague, Czech Republic Ilya Edemskiy, ilya@iszf.irk.ru

Irkutsk State Technical University, Irkutsk, Russia

When studying the ionospheric response to a geomagnetic storm of 15 August 2015, an unexpected phenomenon was observed at higher middle latitudes of the Southern Hemisphere. This phenomenon was a localized TEC enhancement (LTE) in the form of two separated plumes, which peaked southward of South Africa. The plumes were first observed at 5 UT near the southwestern coast of Australia. The southern plume was associated with local time slightly after noontime (1-2 hours after local noon). The plumes moved with the Sun. They peaked near 13 UT southward of South Africa. The southern plume kept constant geomagnetic latitude (63-64oS); it persisted for about 10 hours, whereas the northern plume persisted by about two hours more. Both plumes disappeared over the South Atlantic Ocean. No similar LTE event was observed during the prolonged solar activity minimum period of 2006-2009. In 2012-2016 we detected altogether 26 LTEs and all of them were associated with the southward excursion of Bz. The negative Bz excursion seems to be necessary but not sufficient condition for the LTE occurrence.

C1.3-0050-18 SELF-CONSISTENT MODELING OF ELECTRON PRECIPITATION AND RESPONSES IN THE IONOSPHERE: APPLICATION TO LOW-ALTITUDE ENERGIZATION DURING SUBSTORMS

Yiqun Yu, yiqunyu17@gmail.com Beihang University, Beijing, China Vania Jordanova, vania@lanl.gov

Los Alamos National Laboratory, Los Alamos, New Mexico, United States Ryan McGranaghan, ryan.mcgranaghan@colorado.edu

Stanley Solomon, stans@ucar.edu

NCAR, Boulder, Colorado, United States

We report a new modeling effort that self-consistently couples the physics-based magnetospheric electron precipitation to its impact on the ionosphere, representing significant improvement over previous modeling capabilities, in which the ionosphere is either treated as a 2D spherical boundary of the magnetosphere, or is driven by empirical precipitation models that are incapable of capturing small-scale, transient variations. In specific, we two-way couple a kinetic ring current model RAM-SCBE with a two-stream electron transport code GLOW. The newly coupled model allows us to examine the impact of substorm-associated, short-lived energetic electron precipitation on the 3D ionosphere. It is found that during substorms, precipitating energetic electrons (10<E<100 keV) resonantly scattered by whistler-mode waves exhibit as a high-energy tail in the spectra at the top of the ionosphere. Subsequently, an ionospheric sub-layer characterized by enhanced Pedersen conductivity arises at unusually low altitude (85 km) at auroral latitudes in the midnight-to-noon sector. The intermittent occurrence of the sub-layer is strongly correlated with recurrent substorm injections. This layer structure, which often appears transient in observations, propagates eastward in accordance with the drift path of source electrons in the magnetosphere, resulting in a global impact within the ionosphere. Such a global structure may provide insights on the large-scale current closure in the coupled magnetosphere-ionosphere system during substorms, and further indicates the necessity of using a self-consistent modeling capability for studies of a fully coupled system.

C1.3-0051-18 THE STUDY OF CORONAL HOLES FROM 2015 TO 2017 YEARS

Alexei Borisenko, sunw77@mail.ru

Crimean Astrophysical Observatory, RAS, Nauchny, Russia

The systematic study of coronal holes began in the late 1970s with the coordinated scientific program of observations of the SkyLab orbital observatory and ground-based observations in the HeI 1083nm line (Kitt Peak Observatory, USA). In the Soviet Union began to study coronal holes employees of the Laboratory of Sun Physics of the Crimea Astrophysical Observatory since the late 80's under the leadership of N.N. Stepanian on the spectral heliograms data of the universal spectrophotometer of the BST-2 telescope in the HeI 1083nm line. The analysis of the observations obtained from the data of the spacecraft ACE / SWEPAM showed that coronal holes are the only sources of fast solar wind (> 450 km / s) on the quiet Sun. Thus, the previously obtained results were confirmed [1]. The SDO / AIA 19.3 nm, CRAO / TST2 HeI 1083 nm data and calculate PFSS models (for more accurate coronal hole detection) were analyzed on the quiet Sun from 2015 to 2017 years. A direct relationship between the change in the area of coronal holes single polarity and the speed of the solar wind for whole visible disk was obtained. With the growth of the coronal hole area, the speed of the solar wind increases and vice versa. A correlation coefficient of 0.7 is obtained. The connection between a giant coronal hole and space weather phenomena was analyzed.

C1.3-0052-18 VARIATION OF RADIATIVE COOLING AND NITRIC OXIDE ABUNDANCE DURING INTENSE GEOMAGNETIC STORMS AS OBSERVED BY TIMEDSABER AND GUVI

M.V. Sunil Krishna, suneel.krishna@gmail.com

Indian Institute of Technology Roorkee, Roorkee, India Gaurav Bharti, bharti09081990@gmail.com

Indian Institute of Technology Roorkee, Roorkee, India

The variation of O/N2 (reference to N2 column density 1017 cm−2) and nitric oxide radiative emission flux exiting the thermosphere have been studied over the northern hemisphere during the super-storm event of November 7-12, 2004. The data have been obtained from GUVI and SABER onboard the NASA's TIMED satellite. The NO radiative flux is observed to show an anti-correlation with O/N2 on a global scale. Both NO radiative flux and O/N2 ratio show equatorward motion with maximum penetration in western longitude sectors. A local variation of O, O2 and N2 densities have been calculated using NRLMSISE-00 model over a mid latitude location (55°N,180°E). On a local scale, model calculated O/O2 and O/N2 ratios are found to follow the observations made by GUVI. The collisional excitation of NO with atomic oxygen is the most dominant process for the total cooling rate. The SABER retrieved NO cooling rate (CR) at a local site suggests an enhancement during the storm period with the peak emission rate closely correlated to the progression of the storm. The peak emission altitude of NO CR moves upward during the main phase of the storm. The NO abundance has been calculated by using cooling rate and Nitric Oxide Empirical Model (NOEM) model. Both these suggest a vary large (3-15 times) increase in NO density during the storm which is required to account the changes in NO radiative flux. A similar kind of enhancement in NO abundance is also noticed in Student Nitric Oxide Explorer observations during intense geomagnetic storms.

C1.3-0053-18 A STUDY OF FOF2 ANOMALY DURING INTENSE GEOMAGNETIC STORMS OF THE 24TH CYCLE

Rashmi Patowary, rashmi_patowary@yahoo.co.in Digboi College, Digboi, India

The foF2 is an important ionospheric parameter and any change in foF2 during geomagnetic storms reveals important aspects of M-I coupling .15 intense (Dst<-nT) geomagnetic storms of the 24th cycle were identified by observing the dst indices. In order to study the effect of these geomagnetic storms on the ionosphere foF2, ionosonde data for stations in the latitudinal range 30°N to 30°S and three different longitudinal ranges (-149 to-159.8) ,(72.6 to -88) and (142.3 to 152.4) were recorded.The effect of geomagnetic storms on the F2 region was studied by calculating the deviation foF2 of foF2 during storm time .Though Negative phase of foF2 was predominant Positive phase were also observed for a few events at a few stations.

C1.3-0054-18 MAGNETOSPHERIC-IONOSPHERIC COUPLING DURING THUNDERSTORM LIGHTNING AS OBSERVED FROM ENERGETIC PARTICLE BURST (C3.2)

Sudipta Sasmal, meet2ss25@gmail.com

S.N. Bose National Centre for Basic Sciences, Kolkata, India

Lightning discharge originates electromagnetic waves propagating in all directions through the earth-ionosphere waveguide. A small component of such wave enters into the earth magnetosphere and propagates along the magnetic field lines as a whistler mode wave. During this propagation, they interact with radiation belt electrons and due to this some of the electrons get trapped or precipitated in the ionosphere as a sporadic patch of excess ionization. The trapping electrons increase the count rate in the inner radiation belt and this particle count rate can be measured through satellite observation. Low Earth Orbital (LEO) satellite observes count rate of energetic particle burst in Van Allen Radiation Belt. We mainly use data from Medium Energy Proton and Electron Detector (MEPED) instrument associated with NOAA 15 satellite for this study. We use WWLLN network and global lightning data to get the lightning information. A significant increase of count rate is observed in MEPED data. We also corroborate our findings by the excess ionization due to lightning as observed from amplitude modulation of Very Low Frequency radio signal.

C1.4-0001-18 REGIONAL DIFFERENCES IN CLIMATE CHANGE OF THE IONOSPHERE

Jan Lastovicka, jla@ufa.cas.cz

Institute of Atmospheric Physics, AS CR, Prague, Czech Republic

The increasing concentration of greenhouse gases, particularly carbon dioxide CO2, in the atmosphere affects not only the troposphere and surface climate, it affects the whole atmosphereionosphere system and it induces long-term trends and/or climate change in the ionosphere. The geographic distribution of CO2 in the upper atmosphere/ionosphere is relatively homogeneous and the long-term increase of CO2 concentration in the atmosphere is known to be stable. However, there are some other secondary drivers of long-term trends in the upper atmosphere/ionosphere, whose long-term behavior and/or effects either are not spatially homogeneous or are not stable in time (or both). Geomagnetic activity, solar activity, secular change of the Earth's magnetic field, long-term evolution of stratospheric ozone concentration and atmospheric wave activity are such trend drivers. They are responsible for regional differences in trends and also for their temporal non-stability. Regions of strong trends as a consequence of regional differences of trends represent a specific kind of risk from the point of view of space/ionospheric climate. These features of ionospheric trends will briefly be treated in this presentation.

C1.4-0002-18 THE IMPACT OF SPACE WEATHER ON THE IONOSPHERE

Andreas Goss, andreas.goss@tum.de

Deutsches Geodätisches Forschungsinstitut, Technische Universität München (DGFI-TUM), München, Germany

Klaus Börger, klausboerger@bundeswehr.org

Space Situational Awareness Center Germany (Weltraumlagezentrum), Uedem, Germany IAG-ICCT Joint Study Group 0.20

Mahmut Onur Karsioglu Ehsan Forootan Barbara Görres Johannes Hinrichs Jürgen Matzka Michael Schmidt George Zhizhao Liu Eren Erdogan

Space Weather is not only an up-to-date but also an interesting research topic and has a significant importance for modern society. As a matter of course, technical progress also means an increasing vulnerability of technical systems. Space weather events, i.e. solar superstorms like the prominent Carrington event from 1859, will have an enormous impact on our technical systems and infrastructure and can even lead to their collapse. In recent years some solar storms have happened, like the Halloween storm in 2003 or the St. Patrick's storm in 2015, but there was no event in a dimension like the Carrington event. Therefore it remains unclear which effects in numbers a solar superstorm would have for ionosphere, Earth and society. The IAGICCT Joint Study Group 0.20 (JSG0.20) is exactly working on this subject, i.e. the JSG 0.20 investigates the impact of a solar superstorm on different technical systems. For this purpose, it is necessary to simulate such an extreme event and to produce data representing the storm. Based on this, the effect of a solar superstorm on different technical issues can be examined. This presentation describes the basic considerations and thoughts, serving as a guide to simulate datasets for, e.g., the planetary K-index, the F10.7 index and the ionosphere in the case of an occurring solar superstorm. In this contribution we regard to the mutual relations of the above mentioned parameters. Furthermore, the ionosphere requires a detailed investigation w.r.t. its temporal and spatial behaviour during a superstorm as well as the strength of ionisation. The methods and computations to study ionospheric storm-time characteristics will be represented.

C1.4-0003-18 WIDE SENSE STATIONARITY PERIOD OF SLANT AND VERTICAL TOTAL ELECTRON CONTENT IN DETERMINATION OF TEMPORAL CORRELATION OF MIDLATITUDE IONOSPHERE

Feza Arikan, arikan@hacettepe.edu.tr HACETTEPE UNIVERSITY, ANKARA, Turkey

Ozan Koroglu, okoroglu@roketsan.com.tr Roketsan Inc., Ankara, Turkey

Sinem Deniz Yenen, sdyenen@aselsan.com.tr ASELSAN INC., ANKARA, Turkey

The temporal correlation of ionosphere as observed by Total Electron Content (TEC) estimated from ground based dual-frequency GPS receivers plays an integral role in monitoring the structural variability. Wide Sense Stationarity (WSS) indicates the period where the first and second moment of a random process (ie mean and autocorrelation functions) stay constant. In modeling spatio-temporal variability of TEC as a random field, the WSS can represent the optimum duration where the statistical structure can be tracked to reduce the near-real time computational load. In this study, WSS periods of Slant TEC (STEC) and Vertical TEC (VTEC) are investigated over regional networks of Czech Republic and Turkey for the years of 2010 to 2012. The TEC values are estimated as IONOLAB-STEC and IONOLAB-TEC. The novel algorithm which is developed to determine the WSS period of TEC data is named as IONOLAB-WSS. All the GPS stations that were active in the Permanent GPS Networks of EUREF, TNPGN and TNPGN-Active are incorporated. The GPS stations are classified into subregional sections of 20x30 in latitude and longitude, respectively. The satellites are grouped into east, west, north and over directions according to their IPP tracks of each subregion. The day is divided into five periods according to solar diurnal movement. The year is divided into seasons reflecting ionospheric trend structure. It has been observed that the WSS of midlatitude ionosphere has a median value of 7.5 to 11 min, independent of region, subregion, satellite track, time of the day, and seasonal variation. The WSS reduces to 3 to 5 min during severe geomagnetic storms or ionospheric disturbances. For quiet and non-disturbed periods, the WSS can be as long as 13 to 15 min. The results indicate the importance of optimum temporal update periods of near-real time monitoring systems that are under heavy computational burden. This study is supported by TUBITAK 115E915 and joint TUBITAK 114E092 and AS CR 14/001.

C1.4-0004-18 MID-LATITUDE TROUGH RESPONSE TO THE GEOMAGNETIC ACTIVITY

Dorota Przepiórka, dprzepiorka@cbk.waw.pl Polish Academy of Sciences, Warsaw, Poland Barbara Matyjasiak, bmatyjasiak@cbk.waw.pl

Space Research Centre, Polish Academy of Sciences, Warsaw, Poland Hanna Rothkaehl, hrot@cbk.waw.pl

Space Research Centre of the Polish Academy of Sciences, Warsaw, Poland

Mid-latitude trough is characteristic structure of the ionosphere, that is observed in great majority during the nighttime. The phenomenon manifests itself as a significant depletion in the electron density, which can be found in the sub-auroral region of the top side ionosphere. In favorable conditions when insolation is limited at higher latitudes (e.g. during local winter), the main ionospheric trough can occur extended for almost whole range of the geomagnetic longitudes. It is well known that trough is highly sensitive to dynamic geomagnetic conditions. Especially distinct feature is that the trough properties change accordingly to the geomagnetic storm phase. In particular it moves equatorward with the storm onset, and as the storm develops it narrows and deepens. This paper provides the qualitative and quantitative answer for the question how the geomagnetic activity impacts the mid-latitude trough characteristics. The studies are based on the data set provided by DEMETER mission in 2005-2010.

C1.4-0005-18 LATITUDINAL ASYMMETRY DURING THE LARGEST IONOSPHERIC STORMS OF THE SOLAR CYCLE 23.

Kingsley Okpala, kingsley.okpala@unn.edu.ng University of Nigeria, Nsukka, Nigeria, Nsukka, Nigeria Eucharia, Chidinma Okoro, chidikoro@yahoo.com University of Nigeria, Nsukka, Enugu, Nigeria

Latitudinal asymmetry has been observed in NmF2 variation during the largest ionospheric storms. Five (5) storms have been analyzed individually to unravel succinct information about the flow of plasma across the F layer of the atmosphere during positive ionospheric storms. Ionosonde records from four (4) stations in the northern hemisphere were employed. The ionospheric NmF2 profile was obtained after removing quiet-time variations such that only the strongest positive ionospheric storms that could clearly be identified from their profiles were considered. Analysis of the Time series of these ionospheric storms showed clear latitudinal dependence. These positive ionospheric storm variations are discussed in view of composition changes and the role played by asymmetric geomagnetic field.

C1.4-0006-18 VARIABILITY OF THE SUN AND ITS TERRESTRIAL IMPACT (VARSITI): RESEARCH ACTIVITIES ON SPACE WEATHER AND SOLAR EFFECTS ON CLIMATE

Kazuo Shiokawa, shiokawa@nagoya-u.jp

Institute for Space-Earth Environmental Research, Nagoya University, Nagoya, Aichi, Japan Katya Georgieva, katyageorgieva@msn.com

Space Research and Technology Institute - Bulgarian Academy of Sciences, Sofia, Bulgaria

The Scientific Committee On Solar-TErrestrial Physics (SCOSTEP) operates the scientific program "Variability of the Sun and Its Terrestrial Impact" (VarSITI, http://www.varsiti.org/) in 2014-2018 to focus on the recent and expected future solar activity and its consequences for the Earth, for various time scales from the order of thousands years to milliseconds, and for various locations and their connections from the solar interior to the Earth's atmosphere. During the last solar minimum in 2008-2009, solar activity was extremely low for an extended period, and the maximum of sunspot cycle 24 is the lowest in the last 100 years. It is not clear how this long-term solar activity variations influences the geospace and global climate change. It is also not clear how the short-term solar activity variations, such as solar flare and CME influences the geospace and the Earth's atmosphere. In order to elucidate these various Sun-Earth connections, we encourage close communication between solar scientists (solar interior, atmosphere, and heliosphere) and geospace scientists (magnetosphere, ionosphere, and atmosphere). Four scientific projects are carried out under the VarSITI program: (1) Solar Evolution and Extrema (SEE), (2) International Study of Earth-Affecting Solar Transients (ISEST/MiniMax24), (3) Specification and Prediction of the Coupled Inner-Magnetospheric Environment (SPeCIMEN), and (4) Role Of the Sun and the Middle atmosphere/thermosphere/ionosphere In Climate (ROSMIC). In this presentation, we review recent scientific results related to the VarSITI activities on the space weather researches and solar influence on climate change.

C1.4-0007-18 VARIATIONS OF REGIONAL VTEC MODEL DUE TO IONOSPHERIC SCINTILLATION OCCURRENCE

M.Mahdi Alizadeh, alizadeh@kntu.ac.ir

K.N.Toosi University of Technology, Tehran, Iran Sahar Sobhkhiz, sobhkhizsahar@yahoo.com

K.N. Toosi University of Technology, Tehran, Iran Harald Schuh, schuh@gfz-potsdam.de

GFZ German Research Centre for Geosciences, Potsdam, Germany

Global Navigation Satellite Systems (GNSS) which are extensively used for various purposes such as navigation, surveying, remote sensing and telecommunication, are strongly affected by the Earth's upper atmosphere, the ionosphere. Ionosphere is a very complex medium that is ionized by the radiation of high energy particles from Sun and cosmic rays. When a GNSS electromagnetic signal passes through this region, it may experience rapid amplitude fluctuations or an unexpected phase change, which is referred to as ionospheric scintillation. Ionospheric scintillation is caused by small scale irregularities in the electron density and is one of the dominant propagation disturbances for microwave signals. These irregularities severely affect the accuracy and reliability of GNSS measurements; therefore it is necessary to investigate ionospheric scintillation and its effects on GNSS observations. The focus of this paper is to detect ionospheric scintillation effects on GPS observations and also on regional Vertical Total Electron Content (VTEC) models over Iran's region, during different periods of solar activity. The results show that effectiveness of this phenomenon depends on geographic location, local time, and global geomagnetic storm index (kp index). The required data for this study are the ground-based measurements of permanent GPS stations over Iran (IPGN), established by the National Cartographic Center of Iran (NCC).

C1.4-0008-18 CLASSIFICATION OF IONOSPHERIC IRREGULARITIES OVER TURKEY IN 2012 USING DROT ON STEC

Meltem Koroglu, mkutlu@roketsan.com.tr HACETTEPE UNIVERSITY, ANKARA, Turkey

Feza Arikan, arikan@hacettepe.edu.tr HACETTEPE UNIVERSITY, ANKARA, Turkey

Ionosphere causes variable time delays on GPS signals. Variable time delays affect both timing and positioning of GPS receivers. GPS position errors are mainly originate from satellite clocks, orbit errors, receiver noise, multipath, troposphere, and ionosphere. Consequently, the ionosphere is the largest source of error in GPS receivers. General values of position errors due to ionosphere are approximately 5 m and 30 m for ionospheric quiet and disturbed days, respectively. Therefore, detection and estimation of ionospheric irregularities are very important for precise positioning. Most of ionospheric disturbances are modeled as wave-like oscillations which have constant velocity, direction, wave front slope, and frequency. One of the most important ionospheric parameter is Slant Total Electron Content (STEC) for investigating the ionospheric disturbances. STEC is defined as total number of electrons along a ray path from satellite to receiver. Wave-like ionospheric disturbances cause oscillations on STEC values. Differential Rate Of TEC (DROT) is a new algorithm for automatic detection of wave-like oscillations on STEC and TEC. It is defined as intensity of difference between ROT and its trend. In order to detect wave-like disturbances over Turkey, STEC estimates obtained from Turkish Permanent GPS Network Active (TNPGN-Active) by using IONOLAB-STEC method. DROT values are computed by using STEC estimates for each receiver-satellite pair and each day. Subsequently, DROT values are classified into three categories as higher than %70 (Category 3), between %50 and %70 (Category 2), less than %50 (Category 1). Category 3 DROT values indicate that there might be Large Scale Ionospheric Disturbances (LSTIDs) or some strong TIDs. For the purpose of detection of time and direction of disturbance, Category 3 DROT values are classified into four groups according to satellite tracks as north, east, west and over. Occurrence percentage of category 3 DROT values observed daily for each direction during 2012. It is observed that Category 3 occurrence percentage decreases in summer whereas percentages get high values in winter for all directions. For east direction and in spring, category 3 DROT occurrence percentages are less than other directions. It is observed that, the most affected direction from the wave-like disturbances is west for all seasons. This study is supported by TUBITAK 115E915 and joint TUBITAK 114E092 and AS CR 14/001.

C1.4-0009-18 EFFECT OF IONOSPHERE AND PLASMASPHERE ON GEOSTATIONARY COMMUNICATION SATELLITE SIGNALS

Esra Erdem, esraerdem@aselsan.com.tr ASELSAN INC., Ankara, Turkey

Feza Arikan, arikan@hacettepe.edu.tr HACETTEPE UNIVERSITY, ANKARA, Turkey

Geostationary orbit (GEO) communications satellites allow radio, television, and telephone transmissions to be sent live anywhere on Earth. They are extremely important in daily life and also for military applications. Since, satellite communication is an expensive technology addressing crowd of people, it is critical to improve its performance. Radio frequency ranges C, X, Ku, Ka and V-band are used in satellite communications. Satellite signals are disturbed by atmospheric effects on the path between the satellite and the receiver antenna. These effects are mostly cloud, rain and gaseous attenuation. It is expected that ionosphere and plasmasphere have a minor effect on the satellite signals when the ionosphere is quiet. But there are anomalies and perturbations on the structure of ionosphere with respect to geomagnetic field and solar activity and these conditions may cause further affects on the satellite signals. In this study IONOLAB-RAY algorithm is adopted to examine the effect of ionosphere and plasmasphere on satellite signals. IONOLAB-RAY is developed to calculate propagation path and wave parameters of high frequency signals. The algorithm does not have any frequency limitation and models ionosphere and plasmasphere up to 20,200 km altitude, so that propagation between a GEO satellite and antenna on Earth can be simulated. The algorithm models inhomogeneous, anisotropic and time dependent structure of the ionosphere with a 3-D spherical grid geometry and calculates physical parameters of the ionosphere using IRI-Plas software. One of the outstanding features of IONOLAB-RAY is the opportunity of Total Electron Content (TEC) assimilation. This feature enables more realistic representation of ionosphere, especially for the times when ionosphere deviates from the generalized models, such as during geomagnetic storms. This feature is critical to examine the effect of ionosphere and plasmasphere on satellite signals under ionospheric storm conditions. In this study the effect of ionosphere and plasmasphere on the signal propagating from Earth to GEO satellite by comparing the attenuation and time delay calculated by IONOLAB-RAY for the scenarios of calm date and time with respect to storm date and time. This study is supported by TUBITAK 115E915 and joint TUBITAK 114E092 and AS CR 14/001. Keywords: Ionosphere, IRI-Plas, GEO Satellite, Satellite Communication, IONOLAB.

C1.4-0011-18 GEOSPACE STORM INDUCED SUBAURORAL AND MIDLATITUDE IONOSPHERIC DENSITY DISTURBANCES BASED ON GNSS AND INCOHERENT SCATTER RADAR OBSERVATIONS

Shunrong Zhang, shunrong@mit.edu

MIT Haystack Observatory, Westford, Massachusetts, United States
Philip Erickson, pje@haystack.mit.edu

MIT Haystack Observatory, Westford, United States Anthea Coster, ajc@haystack.mit.edu

MIT Haystack Observatory, Westford, Massachusetts, United States

Large plasma density gradients have severe impact on modern radio communication and technology applications in general. Particularly for midlatitudes where the dense population resides, the geospace storm induced significant gradients, Storm Enhanced Density (SED) plumes, for instance, have been a main concern for its space weather consequences, and also a research topic of strong scientific interest. With the use of dense networks of GNSS receivers for total electron content (TEC) observations, SED structures are getting readily visualized with unprecedented details. It is generally believed that SED plumes are generated through a very dynamical process where the zonal (westward) ion drift — in the form of either Sub-Auroral Polarization Stream (SAPS) and expansion of polar convection — and northward (upward) ion drift associated the meridional component of ion convection (perpendicular to the magnetic field line) or penetration electron field induced upward ion drift, work jointly to transport plasma to high altitudes as well as poleward and westward into the dayside cusp region. In this study, using GNSS TEC and incoherent scatter radar observations at Millstone Hill and elsewhere, we discuss some stormtime subauroral and high latitude plasma dynamical processes that link SED, tongue of ionization (TOI) in the polar region and polar cap patches. We discuss also evolution of these plasma density gradients during the geospace storm. We focus on the 2015 St Patrick's Day event.

C1.4-0012-18 REGIONS OF INTEREST FOR CHARGED DRAG ON SMALL SATELLITES USING GITM DATA

Lewis Freeland, lewis.freeland@student.adfa.edu.au

University of New South Wales Canberra, Canberra, Australia Melrose Brown, melrose.brown@adfa.edu.au

University of New South Wales Canberra, Canberra, Australia Christopher Capon, c.capon@unsw.edu.au

University of New South Wales Canberra, Canberra, Australia James Gilmore, james.gilmore@unsw.edu.au

University of New South Wales Canberra, Campbell, Australia

Recent research has indicated that the contribution of charged drag to total atmospheric drag on satellites in low-earth orbit (LEO) may be more significant than is usually assumed. The research presented here suggests these forces may be as strong as 25% of the drag force due to the neutral atmosphere at some times and locations. This work utilises data from the Global Ionosphere-Thermosphere Model (GITM), along with recent analytical work used to quantify LEO plasma-body interactions, to identify regions of Earth's upper atmosphere where spacecraft experience higher forces due to charged drag. The space weather conditions that lead to the formation of these regions are also described. In order to quantify the effect of the charged environment on satellites, the forces over a variety of simple orbits are integrated to show the work done by charged drag on these satellites. The implications of these regions of enhanced drag to the problems of satellite drag calculations, maneuvers by charged spacecraft, and the broader field of space situational awareness will be discussed.

C1.4-0013-18 COMPARISON OF IRI-PLAS MODEL WITH EQUATORIAL IONOSONDES DURING SUMMER AND WINTER SEASONS OF 2011 AND 2015

Feza Arikan, arikan@hacettepe.edu.tr HACETTEPE UNIVERSITY, ANKARA, Turkey

Umut Sezen, u.sezen@ee.hacettepe.edu.tr HACETTEPE UNIVERSITY, Ankara, Turkey Tamara Gulyaeva, gulyaeva@izmiran.ru

Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation of the Russian Academy of Sciences (IZMIRAN), Moscow, Russia

Equatorial ionosphere is a very special region that offers various challenges in modeling and monitoring of the anomalies and disturbances that are geomagnetic, solar or seismic in origin. In addition to the spatial sparsity of ionosondes that are located in this region (about 7 or 8 ionosondes compared to 50 in midlatitude), the average monthly temporal data samples hardly exceed 500 as opposed to 3500 in midlatitude regions. Therefore, a reliable ionospheric model is a very important asset in representation of both trend and spatio-temporal variability. International Reference Ionosphere (IRI) extended to Plasmasphere (IRI-Plas) is one of the most acclaimed climatic models of ionosphere that is used to obtain various parameters of ionosphere and plasmasphere such as electron density distribution, critical layer plasma frequency, maximum ionization height and ion and electron temperatures. IRI-Plas uses CCIR or URSI background hourly-monthly median model coefficients in determination of F2 layer critical frequency, foF2. As opposed to the standard models, IRI-Plas has two very important advantages. The first one is the input of GPS-TEC and the second one is user defined choice of 9 solar/ionospheric indices such as SSN1, SSN2, F10.7, Lyman-α, Mg II, IG, TEC, GEC, GECRZ. IRI-Plas can be downloaded from http://ftp.izmiran.ru/pub/izmiran/SPIM/ as a FORTRAN code. IONOLAB group provides user friendly online computation of IRI-Plas at www.ionolab.org with a choice of automatic input of all ionosonde station locations and, IGS and EUREF GPS receiver locations along with GIM-TEC values for all IGS Analysis Centers for the user defined location, date and time. In this study, IRI-Plas model F2 layer critical frequency is compared with ionosonde foF2, in Root Mean Square (RMS) and Normalized RMS (NRMS) sense for the winter (January) and summer (June) months of 2011 and 2015. All available ionosondes in equatorial region are included in the analysis. It has been observed that URSI and CCIR models provide the same background. The input of TEC is very successful in lowering the error fit to ionosonde foF2 if JPL, CODE or IGS GIM-TEC inputs with TEC index in 2011 and SSN2 index in 2015 are used. The overall RMS (NRMS%) differences are 1.4 MHz (20.8%) in January 2011, 1.32 MHz (19.1%) in June 2011, 1.38 MHz (15.1%) in January 2015 and 1.07 MHz (13.6%) in June 2015. Overall fit error is slightly lower for June as compared to January in both 2011 and 2015. This may be an indicator of increased seasonal variability during winter months in equatorial region. This study is supported by TUBITAK 115E915.

C1.4-0014-18 ENHANCEMENT OF HF COMMUNICATION LINK BY USING NEAR REALTIME UPDATED BACKGROUND IONOSPHERIC MODEL

Ozan Koroglu, okoroglu@roketsan.com.tr Roketsan Inc., Ankara, Turkey

Feza Arikan, arikan@hacettepe.edu.tr HACETTEPE UNIVERSITY, ANKARA, Turkey

Tamara Gulyaeva, gulyaeva@izmiran.ru

Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation of the Russian Academy of Sciences (IZMIRAN), Moscow, Russia

Ionosphere plays very important role in HF (3-30 MHz) communications as the primary propagation environment. Ionospheric plasma layer structures depend on a wide variety of forcing from above and below such as solar, geomagnetic and seismic activities. The spatio-temporal variability of ionosphere causes many effects on radio signals such as dispersion, attenuation, and delay. These effects are observed not only on HF signals but also on radionavigation and satellite signals. Total Electron Content (TEC), which is obtained from Global Positioning System (GPS) measurements, critical layer parameters such as F2 layer maximum plasma frequency foF2 and maximum ionization height hmF2 which are obtained from ionosondes are the main observable parameters for investigating the ionosphere. International Reference Ionosphere extended to plasmasphere (IRI-Plas) is one of the most acclaimed climatic models of ionosphere and plasmasphere. IRI-Plas provides hourly, monthly median values of critical layer parameters which may not reflect the current state of the ionosphere for a desired location, date and time. IRI-Plas can use GPS-TEC as input and extends the Electron Density Profiles (EDP) up to GPS satellite orbit altitude. In IRI-Plas, the ionospheric slab thickness is defined as the ratio of TEC to the maximum electron density of the F-region, NmF2. Since IRI-Plas model is a background model, hourly median values of slab thickness and instant slab thickness values are assumed to equal in the algorithm. The update of ionospheric state using instant GPS-TEC cannot be possible and it may not match to instant ionosonde foF2. Therefore, in this study, a new statistical update parameter K is proposed for modification of the instant model foF2 value using instant GPS-TEC and median slab thickness. Using proposed K parameter, the background model can be updated by using GPS-TEC as inputs which can be obtained from both dense networks of GPS receivers and high resolution in time. For initial investigations, Pruhonice Digisonde (Czech Republic) and gope station GPS-TEC values are used for year 2012. It is observed that update of background ionospheric model using parameter K reduced the fit error between the model foF2 and the ionosonde foF2 more than %40. By using updated background model in ionospheric ray tracing algorithm IONOLAB-RAY, HF communication parameters, operating frequency, azimuth and elevation angles of radio signal

direction, delay, and attenuation, can be obtained. This study is supported by TUBITAK 115E915 and joint TUBITAK 114E092 and AS CR 14/001.

C1.4-0015-18 IONOSPHERIC TEC DISTURBANCES DURING MAJOR GEOMAGNETIC STORMS IN 24TH SOLAR CYCLE AND PERFORMANCE ANALYSIS OF IRI2016 AND SPIM MODELS OVER THE INDIAN LOW LATITUDES

Sampad Kumar Panda, sampadpanda@kluniversity.in K L Deemed to be University, Guntur, India

Kanaka Durga Reddy Battula, rbkdurga1994@gmail.com K L Deemed to be University, Guntur, India

The present study investigates the response of ionospheric Total Electron Content (TEC) over the Indian low latitude station, Bangalore during 10 major geomagnetic storms in 24th Solar Cycle. Further, we compared the Global Positioning System derived TEC during the geomagnetically quiet and storm days with the newest versions of International Reference Ionosphere (IRI) and Standard Plasmasphere Ionosphere Model (SPIM) to evaluate their reliability over the low latitude zone across Indian region. As the SPIM model is an extended edition of IRI model capable of predicting up to the plasmasphere height at the GPS orbit, it enabled us to discriminate the characteristic response signatures in the topside, bottomside as well as plasmasphere electron content (PEC) during the disturbed periods. Selecting various solar proxy parameters, such as Sun Spot Number (SSN1), SSN2, F10.7, Global Electron Content (GEC), TEC, IG, Mg II, Lyman-α and GEC_RZ in the SPIM model, the effectiveness of solar proxies over the region realized.

C1.4-0016-18 MACHINE LEARNING BASED DETECTION OF EARTHQUAKE PRECURSORS USING IONOSPHERIC DATA

Orhan Arikan, oarikan@ee.bilkent.edu.tr Bilkent University, Ankara, Turkey

Ali Alp Akyol, akyol@ee.bilkent.edu.tr Bilkent University, Ankara, Turkey Feza Arikan, arikan@hacettepe.edu.tr

HACETTEPE UNIVERSITY, ANKARA, Turkey

Prediction of strong earthquakes is one of the challenging research areas that has the potential of saving significant loss of lives. In the last decade, it has been shown that strong earthquakes affect the electron distribution in the regional ionosphere that can be detected in GPS signals. Especially the Total Electron Content (TEC) estimated from GPS data can be used in the prediction of strong earthquakes. Unlike commonly used ground based seismic activity sensor networks, GPS based predictions can be a week or more earlier than the occurance of the earthquake. This is mainly because of the different mechanisms that generates the spatio-temporal anomalies that these sensors are sensitive to. The anomalies that leads to earlier prediction on TEC data is of pre-seismic in nature, whereas, seismic networks are most sensitive to co-seismic activities. In this study, a novel machine-learning based technique is proposed for detection of earthquake precursors in near-real time GPS-TEC data. The proposed algorithm utilizes an SVM classifier to decide whether an observed spatio-temporal anomaly is an earthquake precursor or not. The data fed to the classifier are composed of spatio-temporal variability map of a region. Also, the classifier has access to the daily solar and geomagnetic indices. Performance of the proposed approach is demonstrated in a case study over a region covering Italy between Jan. 1, 2014 and Sept. 30, 2016. The data in this time interval is partitioned into three non-overlapping time periods, that are used for training, validation and test of detecting precursors of earthquakes with magnitudes above 4 in Richter scale. It is observed that the proposed technique is able to predict 17 out of 21 earthquakes while generating 6 false alarms during the validation period of 266 days, and 23 out of 24 earthquakes while generating 13 false alarms during the test period of 282 days. As a future work, cost-sensitive supervised machine learning techniques will be implemented to provide about the same probability of false alarms on both the validation and test periods. This study is supported by TUBITAK 115E915 and Joint TUBITAK 114E092 and AS CR 14/001 projects.

C1.4-0017-18 COMPARATIVE STUDY OF THE POSSIBLE ANOMALIES IN D-REGION ELECTRON DENSITY PROFILE AS COMPUTED FROM UNUSUAL TERMINATOR SHIFTS IN SUB-IONOSPHERIC VERY LOW FREQUENCY (VLF) SIGNAL DURING HONSHU, 2011 AND NEPAL, 2015 EARTHQUAKES

We present the perturbations and anomalies in the propagation characteristics of Very Low Frequency (VLF) signals received at Ionospheric Earthquake Research Centre (IERC) (Lat.

22.50 N, Long. 87.48 E) during and prior to the two devastating earthquakes in Honshu on 11th March 2011 at 11:16:24 a.m. local time (05:46:24 UTC) with magnitude of M=9 and depth 29 km at the Pacific coast of Honsu, Japan and another in Nepal on 12 May 2015 at 12:35:19 pm local time (07:05:19 UTC) with magnitude of M=7.3 and depth 18 km at south-east of Kodari. The VLF signal emitted from JJI/22.2KHz in Japan (Lat. 32.05 N, Long. 131.51 E) shows strong shift in VLF-sunrise terminator times towards nighttime starting from a few days prior to the earthquake. We chose these two earthquakes to check the effectiveness of terminator time shift method on this particular propagation path as these two earthquakes have taken place near the VLF transmitter-end (JJI) and near the VLF receiver-end (IERC) respectively. In this work, we have utilized the situation and simulated the VLF sunrise terminator shifts using the RANGE model and EXPONENTIAL sub-program of Long Wavelength Propagation Capability (LWPC) code. To represent the D-region ionospheric variabilities clearly, we assumed a mean dynamic perturbation over the path and presented them with a set of effective Wait's parameters (eff, heff). We have also reproduced the temporal trend of the normalized VLF signal amplitude at VLF sunrise terminators for a few days around both the earthquakes. Then, we used Wait's two-component exponential ionospheric model for estimating the altitude profile of D-region electron density (Ne(h)) at VLF sunrise terminator

times on all those days around both the earthquakes. Hence, we have studied quantitative changes of those Ne(h) profiles during and prior to the seismic events.

C1.4-0018-18 STUDY OF A STRONG EARTHQUAKE OF MAGNITUDE M=8.5 OCCURRED IN SUMATRAN REGION USING GROUND AND IONOSPHERIC OBSERVATIONS AT A LOW LATITUDE STATION AGRA, INDIA

Om Prakash Singh, opsasd@gmail.com

Institute of Engineering & Technology, Lucknow, INDIA, Lucknow, India Devbrat Pundhir, devbratpundhir@gmail.com

RBS Engineering Technical Campus, Agra, India

In the present study, we have analyzed GPS based total electron content (GPS-TEC) data using a statistical technique over Agra in relation to an strong earthquake of magnitude M

= 8.5 which occurred in Sumatran region on 11 April, 2012. To strengthen our results, we have also analyzed the ground based ULF magnetic field data over Agra. We have found the enhancements and depletions in TEC data few days before and after the occurrence of the earthquake. In ULF data, we have found a burst on the day of earthquake which varies from

-1 to 1 (nT) and -2 to 2 (nT) in X and Y component respectively. We have also checked the other possible causes (magnetic storm, solar activity, and lightning etc.) of these disturbances in both sets and found that earthquake is only the possible cause of these disturbances. These perturbations are explained in terms of different mechanisms available in the literature. While the mechanisms of the ULF and TEC anomalies are not well known, it is expected that the ULF bursts occurred due to micro fracturing of the earth's crust during stress accumulation and that the TEC anomalies occurred as a result of the electric field induced in the ionosphere during such processes.

C1.4-0019-18 INFLUENCE OF SOURCE GEOMETRY IN DETERMINING THE CHARACTERISTICS OF TSUNAMI-INDUCED TIDS

M Sithartha Muthu Vijayan, vijayan@csir4pi.in

CSIR FOURTH PARADIGM INSTITUTE, Bangalore, India

Shimna Kannoth, shimna.kan@gmail.com

Academy of Scientific and Innovative Research, CSIR-4PI, BANGALORE, India

Acoustic-Gravity Waves (AGW) generated by tsunamis propagating in the open ocean perturb the ionosphere and generate Traveling Ionospheric Disturbances (TID). Recent investigations show that continuous monitoring of tsunamigenic TIDs can be used as a tsunami early warning system, provided such TIDs are properly characterized in order to differentiate it from the TIDs of other origins. The characteristics of tsunamigenic TIDs are primarily derived with a point source approximation and thus assuming the wavefronts of the tsunamis are circular. However, in reality, the wavefronts of the tsunamis generated by the submarine earthquakes mimic the shape of the rupturing faults. Hence, such simple approximations while studying the tsunamis generated by rupture of the fault with a length of 1200-1300 km in the case of 26th December 2004 Sumatra-Andaman tsunami and 500 km in the case of 11th March 2011 Tohoku tsunami will severely undermine the characteristics of the resultant TIDs. In this work, we present characteristics of TIDs induced by the 26th December 2004 Sumatra-Andaman tsunami, for the first time, by considering the elliptical wavefront mimicking the entire fault geometry. Our results show that the magnitude of horizontal velocities of TIDs increase from 3.5% to 65% with respect to the direction of propagation of the tsunami when the actual geometry is considered in place of simple point source assumption. This establishes the significance of considering the actual fault geometry while deriving the TID characteristics. Further, the results of crosswavelet analysis carried out between numerically simulated realistic tsunami wavefront and associated TIDs derived using GPS observations which reveal the dynamic coupling of tsunami and ionosphere are also discussed.

C1.4-0020-18 DEVELOPMENT OF SINGULAR VALUE DECOMPOSITION BASED INDICES FOR REGIONAL MONITORING OF SPACE WEATHER THREATS

Feza Arikan, arikan@hacettepe.edu.tr HACETTEPE UNIVERSITY, ANKARA, Turkey

Cenk Toker, cenk.toker@ee.hacettepe.edu.tr HACETTEPE UNIVERSITY, Ankara, Turkey Orhan Arikan, oarikan@ee.bilkent.edu.tr Bilkent University, Ankara, Turkey

The Sudden and Traveling Ionospheric Disturbances (SID and TID) are the major causes of loss of lock in positioning signals that are widely used in unmanned and/or autonomous vehicles. Such risks have to be detected and tracked regionally in near-real time. Singular Value Decomposition (SVD), which is commonly used in signal processing and data analysis, is applied to Total Electron Content (TEC) maps to detect structural changes in the regional ionosphere. TEC maps that are discretized in space and organized as a vector using lexicographical indexing, are arranged into a matrix format in a sliding time window frame of 15 minutes. When SVD is applied to this matrix of TEC maps, the singular values and corresponding singular vectors representing the energy content of the TEC maps are obtained. The first singular value contains most of the energy present in the TEC maps within 15 min interval, and it provides information about large scale - low frequency (trend-like) variations. The second and third singular values are generally two orders of magnitude smaller compared to the first one, and these singular values represent the secondary spatio-temporal variabilities that are related to the factors other than solar activity such as gravitational, geomagnetic or seismic in nature. In order to utilize the singular values as indicators of ionospheric disturbances and sudden and severe variations in the regional ionosphere, D-index of first singular value and V index of second singular value can be computed and tracked. In this study, singular values of regional TEC maps from Europe are investigated for quiet, positively disturbed and negatively disturbed ionospheric conditions during 2012. It has been observed that the first singular value represent the strong trend structure of ionosphere related directly to the solar activity. The first singular mode is enough to reconstruct the TEC map with an error less than 1%. The second singular value is more related to geomagnetic and seismic disturbances and the values of the lower order modes are related to the intensity of the disturbances in the ionosphere. It has been observed that the track of D-index and V index of singular values in time is very successful in identifying the severity of disturbance as compared to the variability of the ionosphere from three to seven days prior. This study is supported by TUBITAK 115E915 and joint TUBITAK 114E092 and AS CR 14/001.

C1.4-0021-18 A SIMPLE ALGORITHM TO REMOVE ARTEFACTS AND ALIASING FROM THE IONOSPHERIC IRREGULARITIES DETECTED USING GPS

Shimna Kannoth, shimna.kan@gmail.com

Academy of Scientific and Innovative Research, CSIR-4PI, BANGALORE, India M Sithartha Muthu Vijayan, vijayan@csir4pi.in

CSIR FOURTH PARADIGM INSTITUTE, Bangalore, India

The Total Electron Content (TEC) measurements using an increasing number of GPS ground stations fill the void of conventional ionospheric TEC measurements in both space and time with an unprecedented detail. GPS-TEC measurements are being increasingly used to map the ionospheric irregularities caused by various factors ranging from Space weather (solar, geomagnetic, etc.) to natural hazards (earthquakes, tsunami, thunderstorms, etc.). Monitoring the ionospheric irregularities is essential to assess its impact on the performance of the GPS system in one hand and on the other hand, it provides a plethora of opportunities to study the corresponding causative phenomena in detail. There are three different methods are being popularly used to estimate the ionospheric irregularities by the ionospheric researchers. 1. Rate of TEC Index (ROTI) derived from Rate of TEC (ROT) which is popularly used to monitor global distribution of ionospheric irregularities in studies related to space weather. 2. Horizontal TEC gradient derived either by numerically differentiating the Line-of-Sight (LOS) TEC between the cadence of observation (dTEC) or 3. Detrended LOS-TEC considering the higher order polynomial fit as a regular characteristic TEC variation are used to detect the Travelling Ionospheric Disturbances (TID) induced by the tsunami, seismic, tropospheric convections, etc. Fixing the order of higher order polynomial is arbitrary in third method and hence the order varies from case to case. However, the ionospheric irregularities derived using all these three methods are contaminated by signal aliasing and artefacts introduced by the non-linear motion of the Ionospheric Pierce Points (IPP) which eventually picks up sharp static spatial variations as signals. This signal aliasing corrupts both frequency and amplitude of the ionospheric irregularities which eventually limits the certainty of irregularities detected using GPS-TEC. In this work, we present a simple algorithm to eliminate the signal aliasing and artefacts introduced by the non-linear motion of the IPP while deriving the ionospheric irregularities from the GPS observations. We also demonstrate that the algorithm not only removes the signal aliasing and artefacts from the ionospheric irregularities but also improves the signal-to-noise ratio >50% by adopting it in three test cases of detecting ionospheric irregularities related to (i) a tsunami; an earthquake; and (iii) a space weather event.

C1.5-0001-18 WHY DO TEMPERATURES INCREASE AT LOW AND MIDDLE LATITUDES DURING GEOMAGNETIC STORMS?

Richard Eastes, richard.eastes@lasp.colorado.edu University of Colorado, Boulder, Colorado, United States

During geomagnetic storms temperatures in the middle and lower latitudes of the upper thermosphere get much larger (observations suggest that temperature increases can be as much as 600 K at middle latitudes, away from the Joule heating region). Despite the importance of these temperature changes, both scientifically and operationally (e.g., Skylab), we know very little about their global nature and evolution. This is largely the result of very little globalscale data being available about them. In this presentation, we discuss what we know about the global-scale temperature changes, their causes and how they evolve. Particular attention will be paid to the nature of these changes during both Coronal Mass Ejection and Co-rotating Interaction Region events. Finally, we will describe plans to study temperature changes during geomagnetic storms using Global-scale Observations of Limb and Disk data.

C1.5-0002-18 ANTICIPATED OBSERVATION OF GRAVITY WAVES AND TIDES BY THE GOLD MISSION USING A GCM AND GLOW MODEL

Katelynn Greer, katelynn.greer@lasp.colorado.edu

University of Colorado at Boulder, Boulder, Colorado, United States

One of the major scientific objectives of the GOLD mission is to address the significance of atmospheric waves and tides propagating from below on the thermospheric temperature structure. The GOLD instrument is an imaging spectrograph that will measure the Earth's emissions from 132 to 162 nm. These measurements will be used to image thermospheric temperature and composition near 160 km on the dayside disk at half-hour time scales. TIE-GCM is used to produce a realistic model atmosphere, where different wave and tidal components can be easily extracted, and GLobal AirglOW (GLOW) model produces the emissions in the spectral bands observed by GOLD. Here we use TIE-GCM as a background atmosphere and impose a gravity wave-like perturbation on the vertical profiles and model how the GOLD instrument will observe the perturbation as changes in the LBH band emission brightnesses.

C1.5-0003-18 GLOBAL-SCALE OBSERVATIONS OF THE LIMB AND DISK (GOLD) MISSION - ULTRAVIOLET IMAGING OF EARTH'S SPACE ENVIRONMENT FROM GEOSTATIONARY ORBIT

Richard Eastes, richard.eastes@lasp.colorado.edu University of Colorado, Boulder, Colorado, United States William McClintock, mcclintock@lasp.colorado.edu

LASP / University of Colorado, Boulder, Colorado, United States Alan Burns, aburns@ucar.edu

National Center for Atmospheric Research, High Altitude Observatory, Boulder,, Colorado, United States

NASA's GOLD Mission of Opportunity successfully launched a far ultraviolet (FUV), imaging spectrograph in on January 25, 2018. The imager is a hosted payload on SES-14, a commercial communications satellite, which is being placed into a geostationary orbit. This orbit allows the imager to stay above one location, over eastern South America at 47.5 degrees west longitude, near the mouth of the Amazon River, when it reaches its planned location. Science operations are expected to begin in October 2018. GOLD is the first NASA science mission to fly as a hosted payload on a commercial, communications satellite. The GOLD imager has two identical channels. Each can independently scan the full disk at a 30-minute cadence, making spectral images of Earth's FUV emission from 132 to 162 nm, as well as observations on the Earth's limb. Data from the GOLD instrument will be used to derive fundamental parameters for the neutral and ionized space environment, including the composition ratio (O/N2) and temperature of the neutral atmosphere on the dayside disk. On the nightside, peak electron densities will be obtained in the low latitude ionosphere. The remote sensing techniques to be used have been proven on previous Low Earth Orbit (LEO) missions, and many of the algorithms developed for the GOLD mission are extensions of ones used on previous Earth and planetary missions, with modifications for observations from geostationary orbit. From geostationary orbit, GOLD's imager can repeatedly observe the same geographic locations over most of the hemisphere at a cadence comparable to that of changes in the thermosphere-ionosphere (T-I) system. The imager's 30-minute cadence and hemispheric coverage will allow the mission to track the changes due to geomagnetic storms, variations in solar extreme ultraviolet radiation, and forcing from the lower atmosphere. In addition to providing a new perspective by being able to repeatedly observe the same hemisphere at a high cadence, GOLD's simultaneous measurements of temperatures as well as composition across the disk will provide a valuable, new parameter for understanding of how the T-I system responds to forcing from both the Sun and the lower atmosphere.

C1.5-0004-18 THERMOSPHERE MASS DENSITY VARIATIONS FROM SOLAR FLARE TO SOLAR CYCLE TIME SCALES

National Center for Atmospheric Research, High Altitude Observatory, Boulder, Colorado, United States

In this presentation, we will discuss variations in thermosphere mass density include abrupt changes with a time scale of minutes to hours due to solar flare, diurnal variation, solarrotational variation, annual/semiannual variation, and solar-cycle variation, using data and modeling. The neutral density data sets include neutral density observed by the accelerometers onboard the Challenging Mini-satellite Payload (CHAMP) and Gravity Recovery and Climate Experiment (GRACE), neutral density at satellite perigees, and global-mean neutral density derived from thousands of orbiting objects. Modeling results are from the National Center for Atmospheric Research (NCAR) thermosphere-ionosphere-electrodynamics general circulation model (TIE-GCM), and from the NRLMSISE-00 empirical model.

The Global-scale Observations of the Limb and Disk (GOLD) is a NASA mission of opportunity that will image the Earth's thermosphere and ionosphere from geostationary orbit. GOLD will investigate how the thermosphere-ionosphere (T-I) system responds to geomagnetic storms, solar radiation, and upward propagating tides. The mission is framed by four scientific questions: How do geomagnetic storms alter the temperature and composition structure of the thermosphere? What is the global-scale response of the thermosphere to solar extreme-ultraviolet variability? How significant are the effects of atmospheric waves and tides propagating from below on the thermospheric temperature structure? How does the structure of the equatorial ionosphere influence the formation and evolution of equatorial plasma density irregularities? GOLD will address these questions using data from a pair of identical imaging spectrographs designed to observe emissions from atomic oxygen and molecular nitrogen in the the far-ultraviolet from 132 to 162 nm. During the day, composition and temperature will be determined using molecular nitrogen Lyman-Birge-Hopfield (LBH) band and atomic oxygen 135.6 nm emissions. On the limb, exospheric temperature will be obtained from altitude profiles of LBH emission, and molecular oxygen density will be measured using stellar occultations. Electron density will be derived from 135.6 nm emission at night. This presentation describes the GOLD mission science implementation including the science measurement requirements and the anticipated instrument measurement performance. It also describes the forward modeling approaches used by the GOLD team to validate that the instrument and observing plan will return adequate data to answer the science questions.

C1.5-0006-18 PHYSICAL PROCESSES DRIVING THE THERMOSPHERIC VARIATIONS DURING THE MARCH 2015 ST. PATRICK'S DAY MAJOR GEOMAGNETIC STORM

Wenbin Wang, wbwang@ucar.edu

National Center for Atmospheric Research, High Altitude Observatory, Boulder, Colorado, United States

Alan Burns, aburns@ucar.edu

National Center for Atmospheric Research, High Altitude Observatory, Boulder,, Colorado, United States

Liying Qian, lqian@ucar.edu

National Center for Atmospheric Research, High Altitude Observatory, Boulder, Colorado, United States

Jing Liu, jingliu@ucar.edu

National Center for Atmospheric Research, High Altitude Observatory, Boulder, Colorado, United States

The thermosphere changes significantly during geomagnetic storms, when large amount of energy and momentum are deposited from the magnetosphere to the upper atmosphere. The changes in neutral, temperature, winds and composition have significant impacts on the stormtime behavior of the ionosphere through chemical and transport processes. Thus it is of fundamental importance to describe and understand the global temporal and spatial variations of thermospheric winds and composition during geomagnetic storms. In this presentation, we use Thermosphere Ionosphere Electrodynamics General Circulation Model (TIEGCM) to investigate the storm-time changes of thermospheric temperature, winds and composition during the March 2015 St. Patrick's Day major geomagnetic storm. The model results of thermospheric composition (O/N2) will be compared with TIMED/GUVI O/N2 observations to describe the global changes of O/N2 variations over the course of the storm. We also illustrate the association of the O/N2 changes with global wind circulation and neutral temperature changes. Through the diagnostic analysis of the model results, we demonstrate the physical processes that are responsible for the storm-time changes of the neutral temperature, winds and composition. We also determine the recovery time and global patterns of temperature, winds and composition, and the primary physical processes that control the recovery.

C1.5-0007-18 A TOMOGRAPHIC INVESTIGATION OF MID-LATITUDE NIGHTTIME IONOSPHERIC E-F COUPLING

Nicholas Ssessanga, nikizxx@gmail.com Chungnam National University, Daejeon, Korea

In this paper, a time dependent computerized ionospheric tomography (CIT) technique (in four dimension, 4-D) is utilized in examining the theoretically proposed E-F coupling during nighttime mid-latitude instabilities. To facilitate CIT, we utilize data from a dense Global Positioning System Earth Observation Network (GEONET) of more than 1000 receivers with average distance between two neighboring points being 25-30 km. Results show an existence of field aligned structures in both E and F regions, with wave fronts aligned NW-SE and propagating southwestward (in the Northern hemisphere). This result is in agreement with theory and simulation studies. Furthermore, in most cases, instabilities were first noticed in the E-region and later in the F-region.

C1.5-0008-18 ASSIMILATIVE ANALYSIS OF LOWAND MID-LATITUDE IONOSPHERIC ELECTRODYNAMICS

Tomoko Matsuo, tomoko.matsuo@colorado.edu University of Colorado, Boulder, Colorado, United States Chih-Ting Hsu, rine3774@gmail.com

National Central University, Taiwan, Boulder, Colorado, United States Astrid Maute, maute@ucar.edu

High Altitude Observatory, NCAR, Boulder, Colorado, United States

The Earth's lowand mid-latitude ionosphere hosts a number of complex phenomena resulting from the mutually coupled dynamics of thermospheric winds, conductivity, electric fields and currents under the influence of the magnetic field. This region is exposed to constantly varying conditions of both terrestrial weather and space weather, giving rise to large day-to-day variability. In spite of significant progress in the development of the climatological understanding of these phenomena though extensive experimental and modeling studies in recent decades, little progress has been made in terms of explaining their day-to-day variability. The paper presents an attempt to combine a multiple types of electrodynamics and plasma density observations with a first-principles model through a comprehensive data assimilation approach to address causes of the observed day-to-day variability of daytime large scale lowand mid-latitude phenomena, including equatorial plasma drifts, EIA, and EEJ.

C1.5-0009-18 IONOSPHERIC SCIENCE MISSION AND DATA PRODUCT OF FORMOSAT7/COSMIC-2

Charles Lin, charles@mail.ncku.edu.tw

National Central University, Jhongli City, Taiwan, China Tie Yue Liu, tie@nspo.narl.org.tw

National Space Organization, Hsinchu, Taiwan, China

For preparation of the space weather mission of the upcoming FORMOSAT-7/COSMIC-2 (F7- C2), we have developed ionospheric observation reanalysis and applications. To capture the day-to-day variability of the ionosphere driven by its interactions with solar outputs, planetary waves, and atmospheric and lunar tides, we develop a global ionosphere specification model using Gauss-Markov Kalman filter with hourly outputs of three-dimensional ionospheric electron density. To advance the ionospheric space weather forecast with advantage of the radio occultation observations, we also develop a physical based forecast model using ensemble Kalman filter. The short range (3-6 hours) forecast is possible at the midand low-latitude regions during magnetic storms. An empirical model of ionospheric scintillation is also constructed for providing global specifications of ionospheric irregularities. The empirical model is expected to be verified by observations of the secondary payloads of F7-C2, namely ion density and velocity measurements and beacon transmitters. The main contribution and advance of F7-C2 will be mapping the hourly global ionosphere specifications in electron density, electric field and irregularities in the midand low-latitude ionosphere.

C1.5-0010-18 WEATHER REVEALED BY COSMIC MISSIONS WITH THE GSI IONOSPHERE DATA ASSIMILATION SYSTEM

The Formosa Satellite-3/Constellation Observing System for Meteorology, Ionosphere and Climate (FORMOSAT-3/COSMIC) and its follow-on mission, FORMOSAT-7/COSMIC-2, can provide Radio Occultation (RO) slant total electron content (sTEC) with an unprecedented global distribution. Recently, a new ionospheric data assimilation system, the Community Gridpoint Statistical Interpolation (GSI) Ionosphere, is constructed with the NOAA GSI Ensemble Square Root Filter and the Global Ionosphere Plasmasphere and the Thermosphere Ionosphere Electrodynamics General Circulation Model. This paper showcases the ionospheric weather features, such as changes in the equatorial ionization anomaly and its longitudinal variations, unraveled by FORMOSAT-3/COSMIC and FORMOSAT-7/COSMIC-2 missions with the help of the GSI ionosphere. The GSI Ionosphere can provide instantaneous global pictures of the ionosphere variability, and help deepen our understanding of causes of the observed day-to-day variability.

Physics-based Data Assimilation (DA) has been shown to be a powerful technique for specifying and predicting ionosphere disturbances. However, it is also known that different data assimilation models simulating the same geophysical event can display different ionosphere features even if the same data are assimilated. In this study, we used our Multimodel Ensemble Prediction System (MEPS) of DA models to elucidate the similarities and differences in the individual DA model reconstructions of the mid-low latitude ionosphere when the same data are assimilated. Ensemble model averages were also obtained. For this ensemble modeling study, we selected the quiet/storm period of 16-17 March 2013 (equinox, solar medium). Five data assimilation models and one physics-based model were used to produce an ensemble mean output for TEC, NmF2 and hmF2 for latitudes less than 60 and all longitudes. The data assimilated included GPS TEC and COSMIC occultation data. Both a simple average and a weighted average of the models were used in the ensemble averaging in order to determine if there was an improvement of the ensemble averages over the individual models when compared to independent measurements.

C1.5-0012-18 ESTIMATION OF GLOBAL PLASMA BUBBLE OCCURRENCE USING DATA ASSIMILATION

University of Colorado, Boulder, Colorado, United States

In this study we report the improvement in the estimation of global plasma bubble occurrence based on flux tube integrated Rayleigh-Taylor instability (RTI) growth rates calculated using the results of ionosphere data assimilation. Thermosphere ionosphere electrodynamics global circulation model forecast results after assimilating total electron content (TEC) measurements using ground network of global positioning system (GPS) receivers are used in this work. The assimilation of TEC into the model by using the ensemble Kalman filter improved the forecast of eastward pre-reversal enhancement (PRE) electric field. The improved electric field promotes a stronger plasma fountain and deepens the equatorial trough. The adjustment of PRE electric field is enabled through self-consistent thermosphere-ionosphere coupling processes captured in the model. The improved estimate of zonal electric field in the data assimilation forecast essentially leads to the significant improvement in the RTI growth rates. The growth rates calculated during pre-storm and storm conditions in March 2015, reveal good agreement with rate of change of TEC index, as well as ground based all sky airglow observations. The assimilation model is being updated by incorporating FORMOSAT-3/COSMIC measurements, in addition to GPS TEC. With the availability of additional data from various upcoming space missions, a realistic estimate or prediction of plasma bubble occurrence could be feasible by taking advantage of the data assimilation approach adopted in this work.

C1.5-0013-18 SOME INITIAL OBSERVATIONS OF MIDLATITUDE IONOSPHERIC TROUGH VARIATION FROM ADVANCED IONOSPHERIC PROBE ONBOARD FORMOSAT5 SATELLITE

Shin-Yi Su, sysu@jupiter.ss.ncu.edu.tw

National Central University, Tauyuang City, Taiwan, China Chi-Kuang Chao, ckchao@jupiter.ss.ncu.edu.tw

National Central University, Chung-Li, Taiwan, Taiwan, China Ya-Chih Mao, ycmao@jupiter.ss.ncu.edu.tw

Taiwan, China

FORMOSAT-5 satellite was launched into a sun-synchronous orbit at 720 km altitude on 25 August 2017. The onboard scientific payload Advanced Ionospheric Probe (AIP) is capable of measuring the topside ionospheric density, drift velocities, ion composition and temperature with an un-precedent high sampling rate up to 8192 Hz (spatial scale of 7.4 m) in the 2030 LT sector. Here we will present some initial observations of global latitudinal variation of density and ion composition as well as temperature. In particular, we will focus on the equatorward edge of poleward density gradients and ion composition changes in that area. The longitudinal differences in the trough variation relating to the magnetic declination and zonal drift velocities will also be presented.

C1.5-0014-18 THERMOSPHERIC DENSITY ESTIMATION USING SATELLITE LASER RANGING OBSERVATIONS OF LOW EARTH ORBITING SATELLITES

The thermosphere causes the largest non-gravitational acceleration acting on the Earth orbiting satellites at altitudes up to 500 km. Thermospheric density is a key parameter for precise orbit determination (POD), mission planning, ephemeris computation, and re-entry prediction of these satellites. Since the thermospheric density depends on the level of solar and geomagnetic activity and varies in time and space, a precise determination of this parameter still represents a difficult task. Thermospheric density is provided nowadays by a number of empirical and physical models, and these models provide, unfortunately, rather different thermospheric density values. In this study, we use precise Satellite Laser Ranging (SLR) observations to five spherical satellites to scale the thermospheric density provided by four empirical and one physical model, namely, the Thermosphere Ionosphere Electrodynamics General Circulation Model (TIEGCM). The four empirical models used in this presentation are the COSPAR International Reference Atmosphere model CIRA86, the Naval Research Laboratory Mass Spectrometer Incoherent Scatter Radar Extended (NRLMSISE00), the Jacchia-Bowman 2008 (JB2008) and the Drag Temperature Model 2013 (DTM2013). In our investigation, we use SLR observations of ANDE-RR Active and ANDE-RR Passive satellites launched in 2006 at the initial altitude of about 400 km, ANDE Castor and ANDE Pollux satellites launched in 2009 at the altitude of about 350 km, and SpinSat launched in 2014 at the altitude of about 425 km. From the analysis of SLR observations to these satellites, we estimate 6-12 hour time series of scaling factors of thermospheric density and, thus, the scaled thermospheric density provided by each of five models. The analysis and interpretation of the obtained results will be given in this presentation.

C1.5-0015-18 THE NASA IONOSPHERIC CONNECTION EXPLORER MISSION: GOALS, DESIGN, AND STATUS

Thomas Immel, immel@ssl.berkeley.edu

UC Berkeley, Berkeley, California, United States The ICON Mission Team

Immel, T. J., S. L. England, S. B. Mende, R. A. Heelis, C. R. Englert, J. Edelstein, H. U. Frey,

A. I. Maute, R. R. Meier, C. Raftery, P. Rochus, O. H. W. Siegmund, A. W. Stephan, G. R. Swenson, S. Frey, D. L. Hysell1, A. Saito1, K. A. Rider, M. M. Sirk

The Ionospheric Connection Explorer is a NASA mission that will make new measurements of the unpredictable space environment near Earth. ICON's new mission design gives it the capability to simultaneously compare forcing of the lower atmosphere to conditions in the ionosphere above. To achieve this, ICON carries a set of visible and ultraviolet imagers and in-situ sensors that make coordinated observations, from the boundary of space up to the peak in ionospheric density. The specific orbit and payload design together provide a continuous set of related observations, with dozens of exact conjunctions between the in-situ and remote observations every day. The opportunities for research and collaboration with the mission science team will be discussed along with mission status, and an update on launch plans for mid-2018. The expected performance of the observatory will also be reported.

C1.5-0016-18 SIMULATING THE IONOSPHERE-THERMOSPHERE SYSTEM WITH THE ICON SAMI3-TIEGCM-AMIE MODEL

Astrid Maute, maute@ucar.edu

High Altitude Observatory, NCAR, Boulder, Colorado, United States
Geoff Crowley, gcrowley@astraspace.net

ASTRA LLC., Boulder, Colorado, United States

The Ionospheric Connection Explorer (ICON) is designed to study variability of the thermosphere and ionosphere at low latitudes. The ionosphere consists of a weakly ionized plasma embedded in the thermosphere, and is forced by electric field and ion-neutral coupling. The ionosphere-thermosphere (IT) is coupled to the lower atmosphere through upward propagating waves and tides which may induce dynamical and electrodynamical changes influencing the plasma distribution. In addition, the varying magnetosphere-ionosphere coupling and solar radiation add to the variability in the IT system. ICON will measure key IT parameters at low latitudes to describe the coupled IT system (e.g. ion drift, electron density, neutral wind, composition). The mission will be accompanied by numerical modelling to support the data interpretation and to get a comprehensive picture of the IT system response to forcing from the lower atmosphere and from geospace.

In this study we will employ the thermosphere-ionosphere-electrodynamics GCM (TIEGCM) and the Assimilative Modeling of Ionospheric Electrodynamics (AMIE), which will be used during the ICON mission, to simulate geomagnetic quiescent and disturbed periods of 2017. Addtionally, we will present results from the NRL SAMI3 ionosphere/plasmasphere model that will use both TIECGM and AMIE data as inputs. AMIE ingests observed ion drifts and magnetometer data to derived high latitude ion convection and particle precipitation patterns for TIEGCM. The lower atmospheric forcing of TIEGCM will include waves and tides based on TIMEGCM simulations. We will examine the IT response to the September 2017 geomagnetic storm with the ICON TIEGCM/AMIE model and simulate what ICON would have observed as suggested by the model. We will also investigate the ionosphere/plasmasphere response using the ICON SAMI3/TIEGCM/AMIE model. The simulation results will be compared to available ionospheric data, e.g., from COSMIC, ion drift. We will quantify the influence of the temporal variation of the high latitude forcing on the low latitude IT system by conducting numerical experiments to evaluate its sensitivity to the forcing.

C1.5-0017-18 GLOBAL DAND E-REGION ELECTRON DENSITY FROM GPS-RO: A NEW DATASET FOR STUDYING IONOSPHERE-MAGNETOSPHERE-THERMOSPHEREMESOSPHERE COUPLINGS

Dong Wu, dong.l.wu@nasa.gov

Goddard Space Flight Center, Greenbelt, Maryland, United States

A novel retrieval technique is developed for electron density (Ne) in the Dand E-region (80-120 km) using the high-quality 50-Hz GPS radio occultation (GPS-RO) phase measurements [Wu, 2017 in JASTP]. The new algorithm assumes a slow, linear variation in the F-region background when the GPS-RO passes through the Dand E-region, and extracts the Ne profiles at 80-130 km from the phase advance signal caused by Ne. Unlike the conventional Abel function, the new "bottom-up" approach produces sharp Ne weighting functions in the lower ionosphere, allowing the E-region retrieval less affected by the F-region residuals.

The retrieved background Ne profiles are in overall good agreement with the IRI (International Reference Ionosphere) model in terms of monthly morphology (e.g., zonal means and diurnal variations). The monthly Ne maps at high latitudes also reveal clear enhancement from auroral electron precipitation down to the 80-120 km altitudes as well as responses to magnetospheric disturbances (Kp). Strong tidal modulations of the Eand D-region electron density from the lower atmosphere are evident in the GPS-RO observations. The new Ne data allow a joint analysis of the sporadic E (Es) occurrence under different E-region backgrounds and solar activities. While the background E-region Ne is in phase with the solar cycle, the monthly Es amplitudes are out of phase with the 11-year cycle. The GPS-RO E-region electron density measurements provide a new observation source to study energetic electron precipitation (EEP) and its impacts on the upper atmosphere. It can also be used to evaluate influence of atmospheric forcings/processes, such as wave forcing and deep convective lightning, on the lower ionosphere.

The new algorithm for the Dand E-region Ne can be readily applied to other GNSS-RO observations and integrated into ionosphere data assimilation systems. It requires the top of RO tangent height to reach about 120 km, which is NOT implemented by all GNSS-RO operations. To maximize science returns of current and future operational GNSS-RO missions, it is recommended to homogenize the data acquisition from the GNSS-RO instruments such that global 3-hourly space weather monitoring will become feasible for the E-region Ne.

See paper for more details: http://www.sciencedirect.com/science/article/pii/S1364682617301050

C1.5-0018-18 THE SIMULATED PRODUCT OF THE IONOSPHERE CONNECTION EXPLORER (ICON) AND THE UNUNIFORMITY OF OI 630.0 NM NIGHTGLOW

High Altitude Observatory, NCAR, Boulder, Colorado, United States Scott England, englands@vt.edu

Virginia Tech, Blacksburg, Virginia, United States Geoff Crowley, gcrowley@astraspace.net

ASTRA LLC., Boulder, Colorado, United States

The NASA Ionosphere Connection Explorer (ICON) mission is scheduled to be launched in 2018. Before the actual ICON measurements are distributed, the NCAR TIEGCM along with the estimated ICON orbit and pointing prediction are used to simulate the ICON dataset. To show the response to the geomagnetic activity, the simulated zonal/meridional wind, neutral temperature and O/N2 product for Memorial Day 2017 storm are compared with the data in solar quiet days. The ununiformity of OI 630.0 nm night glow has been identified such as medium-scale traveling ionospheric disturbances (MSTID) and the midnight brightness wave due to the midnight temperature maximum(MTM). Utilizing the method of constructing the 3 dimensional structure of OI 630.0 nm nightglow from the Imager of Sprite and Upper Atmosphere Lightning(ISUAL) onboard FORMOSAT 2, the red-line brightness measurement from Michelson Interferometer for Global High resolution imaging of the Thermosphere and Ionosphere (MIGHTI) is discussed.

C1.5-0019-18 AN INITIAL ULF WAVE INDEX DERIVED FROM TWO YEARS OF SWARM OBSERVATIONS

Constantinos Papadimitriou, constantinos@noa.gr National Observatory of Athens, Athens, Greece Georgios Balasis, gbalasis@noa.gr

National Observatory of Athens, Athens, Greece Ioannis A. Daglis, iadaglis@phys.uoa.gr

National & Kapodistrian University of Athens, Athens, Greece Omiros Giannakis, og@noa.gr

National Observatory of Athens, Athens, Greece

The ongoing Swarm satellite mission provides an opportunity to a better knowledge of the near-Earth electromagnetic environment. Herein, we use a new methodological approach for the detection and classification of ultra low frequency (ULF) wave events observed by Swarm based on an existing time-frequency analysis (TFA) tool and utilising a state-of-the-art high resolution magnetic field model and Swarm Level 2 products (i.e. the Field Aligned Currents

FAC and Ionospheric Bubble Index - IBI). We present maps of the dependence of ULF wave power with magnetic latitude and magnetic local time (MLT) as well as geographic latitude and longitude from the three satellites at their different locations in low-Earth orbit (LEO) for a period spanning two years after constellation's final configuration. We show that the inclusion of the Swarm single-spacecraft FAC product in our analysis eliminates all the wave activity at high altitudes, which is physically unrealistic. Moreover, we derive a Swarm orbitby-orbit Pc3 wave (20-100 mHz) index for the topside ionosphere and compare its values with the corresponding variations of solar wind variables and geomagnetic activity indices. This is the first attempt, in our knowledge, to derive a ULF wave index from LEO satellite data. The technique can be potentially used to define a new Level 2 product from the mission, the Swarm ULF wave index, which would be suitable for space weather applications.

C1.5-0020-18 CHAMP, GRACE, GOCE AND SWARM DENSITY AND WIND CHARACTERIZATION WITH IMPROVED GAS-SURFACE INTERACTIONS MODELLING

Günther March, g.march@tudelft.nl

Delft University of Technology, Delft, Netherlands Eelco Doornbos, e.n.doornbos@tudelft.nl

Delft University of Technology, Delft, Netherlands Pieter N.A.M. Visser, p.n.a.m.visser@tudelft.nl Delft University of Technology, Delft, Netherlands

Accelerometers on board of the CHAMP, GRACE, GOCE and Swarm satellites have provided high-resolution thermosphere density data since 2000. This data has improved our knowledge on atmospheric dynamics and coupling processes in the thermosphere-ionosphere region. So far, the differences between different data sets, as well as between data sets and models, have been largely ignored or adjusted using ad hoc scale factors. The origin of these differences arises to a large extent from errors in the aerodynamic modelling of the accelerometer satellites, specifically in the modelling of the satellite outer surface geometry and of the gas-surface interactions (GSI). The first step to remove these differences is to develop and use high fidelity geometry models for the computation of aerodynamic forces. Direct Simulation Monte Carlo (DSMC) computations were used with these geometry models to investigate flow shadowing and complex concave geometries. Now that accurate geometry models of all satellites are available, an improved characterization of the gas-surface interactions can be investigated. The physics of particlesurface collisions is studied with the aim of improving the consistency of thermospheric density and wind products. Diffusive, specular and intermediate reflection modes were investigated. The accelerometer data has been reprocessed using newly estimated GSI parameters, leading to higher fidelity density and wind estimates. The results of the new data sets are intercompared and existing thermosphere density and wind data and models are used to assess increased consistency. The updated products are expected to be useful to the thermosphere-ionosphere science community, for improved validation of and assimilation in atmospheric models, and to further increase the understanding of atmospheric dynamics and long-term change.

C1.5-0021-18 CONTRIBUTION OF THE ESA SWARM MISSION TO THERMOSPHEREIONOSPHERE RESEARCH

Delft University of Technology, Delft, Netherlands

The three-satellite Swarm constellation continuously delivers high-quality data on the thermosphereionosphere region using in-situ measurements of the magnetic field vector, the ionospheric plasma environment and thermosphere neutral density. This presentation will highlight examples of current research utilising Swarm data, and provides an outlook for the future. Following in the footsteps of the CHAMP mission, Swarm extends the available magnetic field, ionosphere and thermosphere data into the next solar cycle, and for the first time provides multi-point measurements of this environment. This enables investigations of the response of the thermosphere to energy inputs and cooling processes over a wide range of external conditions. The high accuracy magnetic and electric field data of the Swarm satellites contribute to improved climatologies of the high-latitude current system and energy exchange. In addition, the high temporal resolution of these measurements enables the investigation of these currents at much smaller scales than has been possible before, uncovering details on the relationship between small and large scale currents. Based on a highly successful nominal mission Swarm has recently received an extension. The satellites are in excellent overall health and carry sufficient propellant for a prolonged on-orbit lifetime. The Swarm team is continuing to invest to improve its data products and science output, bringing together observations on the drivers and response of the thermosphere-ionosphere system, which can feed into improvement of models. In the near future, we can look forward to an excellent synergy with observations of the

thermosphere-ionosphere from NASA's GOLD and ICON missions, promising to bring both a global overview for context of the in-situ measurements, as well as increased detail of the dynamics of the system at midand low latitudes. The Swarm experience should also be of importance for the definition of the next US flagship mission Geospace Dynamics Constellation.

C1.5-0022-18 AN ARTIFICIAL NEURAL NETWORK-BASED IONOSPHERIC MODEL (ANNIM) TO PREDICT NMF2 AND HMF2 USING LONG-TERM DATA SET OF FORMOSAT-3/COSMIC RADIO OCCULTATION OBSERVATIONS: PRELIMINARY RESULTS

Sai Gowtam Valluri, gowtham.physics12@gmail.com Indian Institute of Geomagnetism, NAVI MUMBAI, India Tulasi Ram S., tulasi@iigs.iigm.res.in

Indian Institute of Geomagnetism, NAVI MUMBAI, India

Artificial Neural Networks (ANNs) are known to be capable of solving linear as well as highly nonlinear problems. Using the long-term and high-quality data set of Formosa Satellite3/ Constellation Observing System for Meteorology, Ionosphere, and Climate (FORMOSAT3/COSMIC, in short F3/C) from 2006 to 2015, an ANN-based two-dimensional (2-D) Ionospheric Model (ANNIM) is developed to predict the ionospheric peak parameters, such as NmF2 and hmF2. In this pilot study, the ANNIM results are compared with the original F3/C data, GRACE (Gravity Recovery and Climate Experiment) observations as well as International Reference Ionosphere (IRI)-2016 model to assess the learning efficiency of the neural networks used in the model. The ANNIM could well predict the NmF2 (hmF2) values with RMS errors of 1.87 × 105 el/cm3 (27.9 km) with respect to actual F3/C, and 2.98 × 105 el/cm3 (40.18 km) with respect to independent GRACE data. Further, the ANNIM predictions found to be as good as the IRI-2016 model with a slightly smaller RMS error when compared to independent GRACE data. The ANNIM has successfully reproduced the local time, latitude, longitude, and seasonal variations with errors ranging 15-25% for NmF2 and 10-15% for hmF2 compared to actual F3/C data, except the post-sunset enhancement in hmF2. Further, the ANNIM has also captured the global-scale ionospheric phenomena such as ionospheric annual anomaly, Weddell Sea Anomaly, and the midlatitude summer nighttime anomaly. Compared to IRI-2016 model, the ANNIM is found to have better represented the fine longitudinal structures and the midlatitude summer nighttime enhancements in both the hemispheres.

C1.5-0023-18 THERMOSPHERIC DENSITY VARIATIONS FROM ANALYSIS OF GRACE ACCELEROMETER DATA

Minkang Cheng, cheng@csr.utexas.edu

Center for Space Research, U. of Texas at Austin, Austin, Texas, United States Byron Tapley, tapley@csr.utexas.edu

Center for Space Research, U. of Texas at Austin, Austin, Texas, United States

The pair of the GRACE (Gravity Recovery And Climate Experiment) satellites has been orbited in a near circular and polar orbit during the 15.5-year mission that began from March 17, 2002. The GRACE-Follow-On mission, with a scheduled launch in April 2018, will use the same orbit configuration to continue monitoring the mass redistributions of the Earth and variations the upper thermosphere. The high-accuracy accelerometer (ACC) data carried by the GRACE satellites is used to measure the effects of the non-gravitational forces acting on the spacecraft, including atmospheric drag, solar and earth radiation pressure and translational accelerations associated with attitude control and orbit maintenance maneuvers. Past results have demonstrated that the GRACE accelerometer data are particularly well suited for measuring the atmospheric neutral density and its variations in response to changes in the solar and geomagnetic activity and the altitude, which occurred during the GRACE Mission lifetime. Neutral density measurements are obtained at altitudes between the initial launch at 495 km and the end of mission at 300 km. This presentation describes the solar and magnetic activity in solar cycle 23 and 24 induced atmospheric neutral variations along with the altitude dependent effects that were observed during the 15.5-year GRACE Mission. The neutral density measurements are compared with model-based predictions from the suite of current neutral density models, including the NRLMSIS-00 and the JB2008 models.

C1.5-0024-18 ESA FIELD ALIGNED CURRENTS - METHODOLOGY INTER-COMPARISON EXERCISE

Lorenzo Trenchi, lorenzo.trenchi@esa.int ESA/ESRIN, Frascati (Roma), Italy

Rune Floberghagen, rune.floberghagen@esa.int ESA, Frascati, Italy

Currently, ESA provides two different estimates of the Field Aligned Currents (FACs) from Swarm magnetic field data, based on single or dual-spacecraft approach: - single spacecraft FAC products, based on 1 Hz magnetic field data, which provide three individual products for each of the three satellites - dual spacecraft FAC product, based on 1 Hz magnetic field data collected by the lower pair (Swarm A and Swarm C), low pass filtered at 20 seconds time scale in order to meet the time stationarity assumption. Various ESA projects are developing new methods to compute the FACs and the ionospheric currents from Swarm data. Also several proposals in response to the first ESA Swarm Call for Ideas for new data products and services (May 2016) focussed on FACs, suggesting possible new approaches to estimate FAC densities and quality indicators. In order to identify a possible evolution of the present FAC products, and / or potential new FAC products and FAC quality indicators, ESA organized a FAC Methodology Inter-comparison Exercise (FAC-MICE), which consisted in a comparison of the different FAC methods, based on a test dataset of 28 Swarm auroral crossings. This comparison allowed to highlight the strengths of the various approaches, suggesting that several FAC products are useful, but for different purposes. In order to implement these new FAC approaches, in addition to the current Swarm L2 FAC products whose production will continue unchanged, we are implementing an open source platform for user definable FAC calculation. This presentation illustrates the main findings of FAC-MICE comparison, and the main features of the ESA open source platform for FAC calculation.

C1.5-0025-18 LATITUDINAL PROFILE OF THE FIELD ALIGNED CURRENT (FAC) ESTIMATED FROM SWARM CONSTELLATION.

Adel Fathy, afa05@fayoum.edu.eg Fayoum University, Fayoum, Egypt Essam Ghamry, essamgh@yahoo.com Egypt

We make use of the estimated the Field Aligned Currents (FAC) data provided by SwarmA/B/C constellation, to study the characteristics of the FAC in the northern geographic hemisphere. using 679 days of good FAC data provided by SwarmA/C. We got a profile of the FAC intensity at low and whole northern latitudes[15°,50°] at different Magnetic Local Time (MLT), seasons and latitudes. A statistical analysis of two months for each solstice in southern and northern showed that summer southern hemispheric FAC intensity is always larger than winter FAC intensity while northern summer and winter FAC are comparable. The mean FAC value each 5° latitude in the northern geographic hemisphere 15°-50° showed that; the night side FAC intensity FAC is always larger than the dayside FAC. Close to the equator the FAC is slightly larger than the low and mid latitude FAC regions until 40° latitudes, then it begins to increase slightly again with latitudes >40°. The latitudinal profile of the FAC intensity at different seasons showed that winter FAC is smaller than summer FAC within latitudinal region [15°- 50°], while summer FAC becomes larger than winter FAC within latitudinal region [50°- 65°].

The dawn time and day time FAC always have the same sign in summer and winter, while the nightside summer and winter have the reverse direction. The low latitudinal FAC always has positive value regardless the local time or the season. At low latitudes the FAC has no geomagnetic activity dependence except within dawn time region, while with increasing the latitude >45°, above this latitude the dusk-side FAC dramatically increases with increasing the magnetic activity.

C1.5-0026-18 HIGH LATITUDE INPUTS TO THE IONOSPHERE-THERMOSPHERE SYSTEM WITH THE ICON TIEGCM-AMIE MODEL

Geoff Crowley, gcrowley@astraspace.net

ASTRA LLC., Boulder, Colorado, United States Andy Gisler, agisler@astraspace.net

ASTRA LLC., BOULDER, United States Adam Reynolds, areynolds@astraspace.net

ASTRA LLC., BOULDER, Colorado, United States Astrid Maute, maute@ucar.edu

High Altitude Observatory, NCAR, Boulder, Colorado, United States Brian J. Anderson, brian.anderson@jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, United States

The Ionospheric Connection Explorer (ICON) is designed to study variability of the thermosphere and ionosphere at low latitudes. The ionosphere consists of a weakly ionized plasma embedded in the thermosphere, and is forced by electric field and ion-neutral coupling. The ionosphere-thermosphere (IT) is coupled to the lower atmosphere through upward propagating waves and tides which may induce dynamical and electrodynamical changes influencing the plasma distribution. In addition, high latitude magnetosphere-ionosphere coupling adds to the variability in the IT system. ICON will measure key IT parameters at low latitudes to describe the coupled IT system, e.g., ion drift, electron density, neutral wind, composition. The mission will be accompanied by numerical modelling to support the data interpretation and to obtain a comprehensive picture of the IT system response to forcing from the lower atmosphere and from geospace.

In this study we will employ two models which will be used for the ICON mission, the thermosphere-ionosphere-electrodynamics GCM (TIEGCM) and the Assimilative Modeling of Ionospheric Electrodynamics (AMIE) to simulate geomagnetic quiescent and disturbed periods during 2017. For the baseline ICON mission, AMIE ingests observed ion drifts and magnetometer data to derived high latitude ion convection and particle precipitation patterns for TIEGCM. Given the ion convection and auroral particle precipitation the TIEGCM calculates the ionospheric conductivities and solves globally for the electric potential considering the prescribed high latitude AMIE ion convection and the middle and low latitude wind dynamo. The high-latitude field-aligned current in the TIEGCM is mainly defined by the AMIE patterns however it also depends on the TIEGCM conductivities and, in regions equatorward of the ion convection reversal boundary there are important contributions from the wind dynamo. To evaluate the TIEGCM/AMIE simulations, the simulated high latitude field-aligned current will be compared to the AMPERE-derived field-aligned current.

C1.5-0027-18 IDENTIFYING INTERVALS OF PC1 WAVE ACTIVITY IN THE TOPSIDE IONOSPHERE BASED ON SWARM OBSERVATIONS

Georgios Balasis, gbalasis@noa.gr

National Observatory of Athens, Athens, Greece Constantinos Papadimitriou, constantinos@noa.gr National Observatory of Athens, Athens, Greece Ian Mann, imann@ualberta.ca

National & Kapodistrian University of Athens, Athens, Greece Omiros Giannakis, og@noa.gr

National Observatory of Athens, Athens, Greece

The recent magnetic field mission of Swarm has enabled us to study in situ the occurrence of ultra low frequency (ULF) waves in the topside ionosphere with great detail. In this study, we identify ULF wave events in the Pc1 frequency range (0.2-5 Hz) observed, for the first time, by the Swarm satellites. Additionally, we derive maps of the dependence of Pc1 wave power on magnetic latitude and magnetic local time (MLT) as well as geographic latitude and longitude from the three satellites at their different locations in the topside ionosphere for a period spanning two years after the constellation's final configuration. The observed wave events are disturbances in the Pc1 band in the Swarm frame - which could be Pc1 proper at low L-shell value but likely are related to magnetosphere-ionosphere coupling at higher latitudes. Our initial results emphasize the fact that the Pc1 power distribution at low-Earth orbit (LEO) as provided by the Swarm spacecraft is better organized in geographic than geomagnetic coordinates. We discuss some possible implications of this geographic ordering of the LEO disturbances in terms of the impact of dipole tilt on these signatures, and a possible relationship to magnetosphere-ionosphere coupling.

C1.5-0028-18 IONOSPHERIC RESPONSES TO THE 21 AUGUST 2017 SOLAR ECLIPSE BY USING DATA ASSIMILATION APPROACH

Chia-Hung Chen, koichi@mail.ncku.edu.tw

National Cheng Kung University, Taiwan, Tainan, Taiwan, China Charles Lin, charles@mail.ncku.edu.tw

National Cheng-Kung University (NCKU), Tainan, Taiwan, China Tomoko Matsuo, tomoko.matsuo@colorado.edu

University of Colorado, Boulder, Colorado, United States

Using the physical based thermosphere-ionosphere model with ensemble Kalman filter, this study reports the first data assimilation results of the ionosphere responses to the solar eclipse on 21 August 2017. The system with 2-minute assimilation cycle of ground-based GNSS observations show the dynamic variations of the equatorial ionization anomaly (EIA) due to modifications of the electrodynamics by the solar eclipse. Two major ionosphere responses are captured. First, there was an early appearance of EIA at the westward boundary of moon shadow, followed by the feature of the enhanced EIA at lower latitudes and the suppressed EIA at the higher latitudes. These eclipse-induced conjugate EIA variations are produced by the eastward electric field perturbation around magnetic equator and the westward electric field perturbation at the higher latitudes.

C1.5-0029-18 COMPARISON OF IONOSPHERIC VERTICAL TOTAL ELECTRON CONTENT DURING HIGH SOLAR ACTIVE YEAR AND LOW SOLAR ACTIVE YEAR FOR INDIAN REGION BASED ON IGS STATION GPS OBSERVABLES

Subrata Kundu, mcqmld@gmail.com

Indian Centre for Space Physics, KOLKATA, India Sudipta Sasmal, meet2ss25@gmail.com

Indian Centre for Space Physics, Kolkata, India Suman Chakraborty, suman.chakrabarty37@gmail.com Indian Centre for Space Physics, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

The Total Electron Content (TEC) is the ionospheric parameter that has the main effect on radio wave propagation. The dispersive nature of the ionosphere makes it possible to measure its TEC. Thus Global Positioning System (GPS), which uses dual-frequency radio signals is an ideal system to measure TEC. The International GNSS Service (IGS) has been continuously contributing to reliable IGS combined vertical total electron content (VTEC) maps in both rapid and final schedules. We figure out the percentage change of TEC during low and high solar activity over Indian landmass. The Total Electron Content (TEC) is computed from GPS from Bangalore (13.02°N, 77.57°E) and Hyderabad (17.417°N, 78.551°E) IGS stations for the low solar active year 2009 and the high solar active year for the period of 2014-2016. We compute both the slant TEC and vertical TEC for these two stations and compute the percentage change in TEC variation. We also compare our findings with existing IRI models.

The Advanced Mesospheric Temperature Mapper (AMTM) is a wide-field (120°) high-performance digital imaging system developed at Utah State University. The AMTM is capable of precision measurements of the OH(3,1) band intensity and rotational temperature (2K in < 30 sec) important for quantifying the effects of a broad-spectrum of gravity waves at the 87 km level, with periods ranging from several minutes to many hours. The nocturnal OH temperature data are also of high value for planetary wave (PW) and seasonal studies. Four AMTM's have been developed: two are currently operational at high latitudes, in Antarctica (McMurdo and South Pole), one in the Arctic (ALOMAR, Norway / Poker Flat, Alaska), and one recently sited in South America at Rio Grande, Argentina. This presentation highlights observations and results from several campaigns and illustrate the variety of the data often obtained in coordination with lidar and radar measurements. Selected studies include (a) gravity wave propagation and fluxes and PW temperature signatures at polar latitudes, (b) mountain wave breaking events at meospause heights, (c) opportune daytime observations of OH airglow structure during the 2017 Solar Eclipse, and (d) new coordinated AMTM and lidar observations under the largest gravity wave "hot spot" on Earth!

Experimental and modeling efforts show that small-scale gravity waves (GW) essentially affect large-scale circulations, thermal states, and dynamics from the surface to the middle atmosphere. In climate modeling and weather-forecasting applications the gravity-wave drag and its interaction with large-scale dynamics are referred to as sub-gridscale, i.e. unresolved processes and are the most uncertain aspect of these models. Another remaining uncertainties come from secondary gravity-waves. Such waves are generated in situ, propagate in different directions and transport energy. The lack of our knowledge about secondary GWs is because observation of such waves is challenging. One possibility to quantify secondary waves is observation of downward propagating gravity-waves.

Advances in lidar measurement techniques allow for experimental studies of GWs at very small spatial and temporal scales, which are not accessible by other means. The state of the art Doppler Rayleigh/Mie/Raman lidar at the ALOMAR research station located in Northern Norway (69N, 16E) provides an observational database of GWs at the edge of the polar vortex connected to global dynamics of the Earth atmosphere.

The Doppler Rayleigh Iodine System (DoRIS) provides horizontal wind measurements in addition to temperature observation. This gives us a unique possibility to obtain wave propagation direction, intrinsic frequency, and horizontal wavelength from the single station. Making use of the advantage of this system, we derive wave parameters precisely. In this paper we will demonstrate different methods for resolving downward propagating gravity waves. One method is based on 2D-FFT analysis and allows for general description of wave parameters. Another method is based on the hodograph technique and delivers detailed description of selected waves.

C2.1-0003-18 THE ROLE OF INERTIAL INSTABILITY AND THE QUASI 2-DAY WAVE IN COUPLING WINTERTIME PLANETARY WAVES WITH THE POLAR SUMMER MESOPAUSE

Jeff France, j.france@gats-inc.com

GATS, Johnstown, Colorado, United States Ruth S. Lieberman, r.s.lieberman@gats-inc.com GATS, Boulder, Colorado, United States

Recent work has documented the link between planetary waves in the winter stratosphere and the occurrence of polar mesospheric clouds (PMCs) through interhemispheric coupling. Breaking planetary waves in the winter hemisphere lead to warming in the low-latitude mesosphere and cooling in the stratosphere. These temperature anomalies lead to a weakening of the summer easterlies in the upper mesosphere and a strengthening of the summer easterlies in the stratosphere. These wind shifts can influence the occurrence of PMCs through a modification of gravity wave forcing in the upper mesosphere and subsequent weakening of the upper branch of the residual circulation. There is also a resulting enhancement to the wind shear near the equatorward flank of the summer jet, leading to enhanced baroclinic instability, and resulting growth of the 2-day wave. The 2-day wave can lead to a decline in PMCs by weakening the residual circulation, and forcing meridional advection and warming of the PMC region. The 2-day wave can also grow as a result of low-latitude inertial instability (negative EPV); inertial instability is associated with strong curvature of the mid-latitude summer easterlies, producing baroclinic and barotropic instability. This work considers inertial instability as a possible link between wintertime planetary waves and the growth of the summertime 2-day wave. Data from the Navy Global Environment Model (NAVGEM) and the Sounding of the Atmosphere Using Broadband Emission Radiometry (SABER) instrument are used to diagnose regions of inertial instability, identified as vertically stacked or "pancake" structures in temperature that occur in regions of anomalous EPV. Results suggest that low-latitude inertial instability may have contributed to the growth of the 2-day wave in 2014 which was responsible for the anomalous decline in PMCs in early August.

C2.1-0004-18 THE MOMENTUM BUDGET IN THE MIDDLE ATMOSPHERE BASED ON A WHOLE ATMOSPHERE MODEL SIMULATION OVER 11 YEARS

Kaoru Sato, kaoru@eps.s.u-tokyo.ac.jp The University of Tokyo, Tokyo, Japan

Ryosuke Yasui, yasui.ryosuke@eps.s.u-tokyo.ac.jp The University of Tokyo, Tokyo, Japan Yasunobu Miyoshi, miyoshi@geo.kyushu-u.ac.jp Kyushu University, Fukuoka, Japan

A momentum budget is examined in the middle atmosphere using simulation data covering a period of 11 years from a whole atmosphere model in terms of the respective contributions of gravity waves (GWs), Rossby waves (RWs) and tides. The GW forcing is dominant in the MLT region, as indicated in previous studies. However, RWs also cause strong westward forcing, described by Eliassen-Palm flux divergence (EPFD), in all seasons in the MLT region as well as in the winter stratosphere. In addition, despite the relatively coarse model resolution, resolved GWs with large amplitudes appear in the MLT region. The EPFD due to the resolved GWs is eastward (westward) in the summer (winter) hemisphere, similar to the parameterized GW forcing. These RWs and resolved GWs are likely generated in situ in the MLT region.

Previous studies suggested that a possible mechanism of in situ RW generation in the MLT region is the barotropic/baroclinic instability. This study revisits this possibility and examines causes of the instability from a potential vorticity (PV) viewpoint. The instability condition is characterized as the maximum of PV magnitude at middle latitudes on an isentropic surface. Positive EPFD for RWs is distributed slightly poleward of the PV maximum. This feature indicates that the RW radiation acts to reduce the PV maximum. The PV maximum is climatologically maintained by the parameterized GW forcing in both the winter and summer mesospheres.

A likely mechanism of the resolved gravity waves in the MLT region is shear instability. In the summer MLT region, the mean zonal winds have a strong vertical shear formed by parameterized gravity wave forcing. In addition, shear instability occurs in the low (middle) latitudes of the summer (winter) MLT region and is associated with diurnal (semi-diurnal) migrating tides.

These results strongly suggest that the forcing by gravity waves originating from the lower atmosphere causes the barotropic/baroclinic and shear instabilities in the mesosphere that, respectively, generate Rossby and gravity waves and indicate that the in situ generation and dissipation of these waves play important roles in the momentum budget of the MLT region.

C2.1-0005-18 FIRST SIMULTANEOUS NA DOPPLER AND FE BOLTZMANN LIDAR OBSERVATIONS OF THE UPPER ATMOSPHERE-SPACE AT ARRIVAL HEIGHTS NEAR MCMURDO, ANTARCTICA

After full seven years of observations with an Fe Boltzmann lidar in Antarctica, a new Na

Doppler lidar, named STAR (Student Training and Atmospheric Research), was successfully installed into the same lab as the Fe lidar at Arrival Heights Lidar Observatory (77.84°S, 166.67°E)

by the University of Colorado Boulder lidar group in the 8th season (2017-2018). Simultaneous Na Doppler and Fe Boltzmann lidar observations started in January 2018 and will continue through the Antarctic summer and winter. These two sophisticated resonance-fluorescence lidars provide unique opportunities to study the complex physical, chemical, neutral dynamical and electrodynamics processes in the Earth's atmosphere and space environment. In particular, we will explore the recently discovered thermosphere Fe and Na layers to the E-F region, explore the neutral temperature and vertical winds in the mesosphere and thermosphere, investigate high-frequency waves in addition to the persistent gravity waves, and measure the wave-induced heat, Na and Fe fluxes in the mesopause region.

Initial 48-hour continuous observations with the Na and Fe lidars in February 2018 have revealed interesting phenomena in the Fe and Na layers as well as polar mesospheric clouds, which deserve further studies. Nearly 8000 hours of Fe lidar data have been collected in the last seven years covering all 12 months of a year. Many new science discoveries have been resulted from the data. In this paper we will report the first simultaneous Na and Fe lidar observations in the Antarctic season 2018 and also highlight several discoveries emerged from the first seven years of Fe lidar campaign.

C2.1-0006-18 UNUSUAL CHANGES IN THE MESOSPHERIC DYNAMICS DURING 2017 MINOR SSW OVER THE TROPICAL REGION

Eswaraiah Sunkara, eswar.mst@gmail.com Chungnam National Univsersity, Daejeon, Korea

The observations from advanced meteor radar located at Tirupathi (13.63oN, 79.4oE), a tropical station India, has been used to investigate the 2017 minor Sudden Stratospheric Warming (SSW) effects on the tropical mesosphere and lower thermosphere (MLT) region. Two minor warmings were noticed on 1 and 26 February 2017 with the enhancement of 35 K in the polar stratospheric temperature followed by a weakening of eastward wind of 25 m/s. The observations show the large zonal wind shear at 75-80 km during SSW. The 14-16 day waves in the MLT zonal wind during the SSW, and the secondary waves (2-9 day) in the meridional wind after the SSW are noticed. Large enhancement (30 m/s) in the semi-diurnal tidal amplitude and reduction in diurnal tidal amplitude is observed during the SSW, and the possible reasons are discussed. The present results reveal entirely different features than that reported earlier and are in a similar manner to that observed during the major SSW.

C2.1-0007-18 HOW DO SSW SIGNATURES PROPAGATE OVER THE LATITUDES IN THE MLT REGION?

University of Western Ontario, London, Canada

The changes in the thermal and dynamical structure of the polar middle atmosphere brought about by sudden stratospheric warmings are found to significantly affect the mesosphere lower thermosphere region over high, middle as well as low latitudes. The signatures of SSW events over these regions have been examined individually in numerous studies. But, how these signatures propagate over the latitudes have not been explored in detail. Thus the high latitudelow latitude coupling associated with SSW events has to be addressed to gain deeper insights into the dynamics of the middle atmosphere. Using a network of meteor wind radars located from polar regions to low latitudes, the latitudinal propagation of changes in the MLT region in association with SSW events are examined in this study. The response of mean winds, diurnal and semidiurnal oscillations, quasi 2-day waves and quasi 16-day waves are investigated in detail. As a first step, climatologies of mean winds, tidal oscillations and planetary waves over each of the observational sites were constructed. Each individual SSW event was then studied with multi station observations to delineate the respective changes in the MLT region. The analysis clearly shows that the response of mean winds is most prominent in the high latitude MLT region in contrast to the low latitude counterparts. On the other hand, quasi 2-day waves over lower latitudes showed amplified responses compared to those over higher latitudes. Further, the temporal evolution of the different changes observed is also examined in detail. An attempt is also made to bring out the longitudinal asymmetry of the observed signatures, especially in the polar regions, with respect to the location of the polar vortex. The significance of the present study lies in investigating the changes of SSW signatures in the MLT region over the latitudes, right from polar to equatorial regions, using ground based observations.

C2.1-0008-18 ON HOW THE DYNAMICS COUNTERACTS THE DIRECT HEATING FROM THE SUN IN THE SUMMER MESOPAUSE DURING SOLAR MAXIMA.

Bodil Karlsson, bodil@misu.su.se Stockholm University, Stockholm, Sweden

Maartje Kuilman, maartje.kuilman@misu.su.se Sweden

The coldest place in the earth-atmosphere system is as good as constantly sunlit. Even during solar maxima, when the upper parts of the atmosphere are significantly warmer due to intensified physical and chemical processes, the summer high latitude mesopause temperature appears to be relatively unaffected by direct diabatic heating, particularly in the northern hemispheric summer. We show, using the nudged and extended version of the Canadian Middle Atmosphere Model (CMAM30), that the increased diabatic heating during the more active phase of the sun is counteracted by a strengthening of the meridional residual circulation, which cools the summer polar mesosphere adiabatically.

Water deposition in the Mesosphere and Lower Thermosphere (MLT) from space traffic can lead to significant variations in the energetics, composition and dynamics of the region. A variety of satellite and ground-based observations show that the fast global-scale plume transport from NASA's Space Shuttle launches can lead to the formation of Polar Mesospheric Clouds (PMCs), which typically appear in the summer near 85 km altitude. This is an important finding because PMCs have been implicated as possible indicators of long-term climate change. There has been a great deal of focus on the fate of concentrated water plumes in the MLT region, which is ordinarily extremely dry. The water plume phenomenon raises a number of important questions about lower thermospheric and mesospheric processes, ranging from dynamics and chemistry to PMC formation and climatology. The Super Soaker sounding rocket mission, funded by the NASA Heliophysics Technology and Instrument Development for Science (HTIDes) program, seeks to investigate the impact of a locally concentrated plume of water vapor on temperature and ice cloud formation as well as the resultant impact on water transport in the MLT. The mission explores this impact at high northern latitudes in the wintertime, when ambient conditions are unfavorable for PMC formation. Super Soaker successfully launched on January 26, 2016 from the Poker Flat Rocket Range (65 N) in Alaska and the mission included three sounding rockets; the first two carrying trimethyl aluminum tracers and the third rocket carrying 220 kg of liquid water. The experiment was designed to explosively distribute the water at 85 km from a rocket and observe the response of the atmosphere using a suite of ground-based instruments that included Rayleigh, sodium, and iron lidars, an Advanced Mesospheric Temperature Mapper, and the Poker Flat Incoherent Scatter Radar. In this paper we review the Super Soaker

souding rocket mission and describe initial numerical modeling results to provide a semi-quantitative view of the response of chemistry and energetics to the water plume deposition in the lower thermosphere.

C2.1-0010-18 NEW RESULTS FROM THE AIM AND SBUV SATELLITE MISSIONS: SOLAR FORCING OF POLAR MESOSPHERIC CLOUDS (PMC)

Gary Thomas, thomas@lasp.colorado.edu

Laboratory for Atmospheric and Space Physics, Boulder, Colorado, United States

The NASA satellite mission Aeronomy of Ice in the Mesosphere (AIM) has been in orbit for over ten years, and has produced a bonanza of scientific accomplishments which have greatly advanced our understanding of this upper atmospheric phenomenon. The series of NASA Solar Backscatter Ultraviolet (SBUV) satellite measurements, designed to measure middle atmospheric ozone has measured, as a by-product, a longer time series of PMC properties since 1979. Ozone satellite measurements with newer instrumentation are now in orbit, and will continue for the indefinite future. PMC are water-ice clouds occurring at the 'edge of space' during summer at high latitude, and serve as a tracer of atmospheric dynamics and chem- istry in this historically inaccessible region. This presentation will highlight some of the AIM achievements, and focus on recent results for long-term solar effects on PMC as measured by the SBUV experiments. This study illustrates the importance of PMC for the understanding of decadal changes in the entire mesosphere, and not just in the region of PMC occurrence in the cold summertime polar region.

Noctilucent clouds (NLC) at the edge of space (about 83 km) consist of tiny water ice particles of a few tens of nanometers in diameter. These clouds were first observed in 1885 and have been the only source of information from the upper atmosphere for a long time. NLC occur from high to mid-latitudes in summer, are linked to processes in the lower atmosphere and are affected from above through solar cycle effects and due to thermal tides. Long-term changes of the clouds are impacted by changes of water vapor, methane, and ozone in layers below the clouds. In the altitude range of ice particle existence small-scale dynamics is ubiquitous and plays a major role even for the thermal and dynamical structure on hemispheric scales. To understand the development of NLC, these small-scale processes are currently parameterized in models. In observations small-scale processes lead, for example, to the variance of particle sizes in a given atmospheric volume as seem by lidar. When looking at the clouds by naked eye or camera small scale structures are evident as wavy patterns. NLC exist in an altitude range where the multi-scale interaction of waves, e.g. tides, inertia gravity waves and small-scale gravity waves, is of importance for the global circulation. With new high resolution observations it has become evident that NLC are useful targets for studying multi-scale wave interactions and the transition to turbulence. We will present observations of the horizontal structure in NLC from observations by camera in combination with lidar and meteor radar measurements. Using this combination, partly with a time resolution of seconds, we quantify the vertical and horizontal structure of clouds and the underlying atmospheric dynamics.

C2.1-0012-18 NLC AND MSE AT A MIDLATITUDE SITE: ADVECTION VS. LOCAL PRODUCTION OF ICE PARTICLES

Michael Gerding, gerding@iap-kborn.de

Leibniz-Institute of Atmospheric Physics (IAP), Kühlungsborn, Germany Kathrin Baumgarten, k.baumgarten@iap-kborn.de

Leibniz-Institute of Atmospheric Physics (IAP), Kühlungsborn, Germany Marius Zecha, zecha@iap-kborn.de

Leibniz-Institute of Atmospheric Physics (IAP), Kuehlungsborn, Germany Franz-Josef Luebken, luebken@iap-kborn.de

Leibniz-Institute of Atmospheric Physics (IAP), Kuehlungsborn, Germany

Ice particles in the summer mesopause region can be observed either optically as Noctilucent Clouds (NLC) or by radar as (Polar) Mesosphere Summer Echoes ((P)MSE). These phenomena are directly related to atmospheric properties like temperatures, humidity and winds. Studying ice layers provides additional insight into an atmospheric region, where long-term visual observations of NLC exist, but records of other parameters are sparse. For the interpretation of the ice observations it is important to know whether the midlatitude clouds are formed locally during unusually low temperatures or whether they are advected from polar latitudes. Simultaneous observations of small (freshly formed) and large ice particles require the combination of radar and daylight-capable lidar techniques. This combination is quite rare, especially at midlatitudes. Since 2010 we operate a daylight capable Rayleigh-Mie-Raman lidar at our site at Kühlungsborn/Germany (54°N, 12°E) for optical observations of NLC independent from solar elevation. In combination with the co-located OSWIN VHF radar we are for the first time able to compare the occurrence and altitude structure of NLC and MSE at midlatitudes. The lower edges of simultaneously observed NLC and MSE typically agree, as expected from observations at polar latitudes. The top edge of MSE is on average nearly 500 m above the NLC edge, indicating the presence of ice particles being too small to be observed by lidar. Surprisingly, the height difference is much smaller than observed at polar latitudes. This hints at a lower abundance of small ice particles in the upper part of the ice layer, hence different growing conditions compared to high-latitude clouds. The data suggest that advection from polar latitudes plays a more prominent role for ice cloud occurrence at our site, compared to local formation. This is supported by, e.g., wind measurements showing a higher probability for ice occurrence during equatorward winds. Therefore, our findings indicate that midlatitude NLC do not only depict local mesospheric conditions, but also upstream (high-latitude) conditions. These results should be considered for, e.g., the evaluation of NLC in climate research.

C2.1-0013-18 UNDERSTANDING THE EFFECTS OF POLAR MESOSPHERIC CLOUDS ON THE ENVIRONMENT OF THE UPPER MESOSPHERE AND LOWER THERMOSPHERE

We use a version of the NCAR Whole Atmosphere Community Climate Model (WACCM) that includes a parameterization for polar mesospheric cloud (PMC) formation to consider the effects of PMC formation on the environment of the upper mesosphere and lower thermosphere. The formation of PMCs sequesters a significant fraction of the ambient water vapor causing a noticeable dehydration in the upper mesosphere above the cloud layer. This dehydration reduces the source of atomic hydrogen and thus the H abundance as measured by the Sounding of the Atmosphere by Broadband Emission Radiometry (SABER) instrument reveals a local minimum in H at mid-high latitudes each summer. In addition, as a result of the anticorrelation between HOx and Ox, this seasonal depletion in atomic hydrogen causes a localized maximum in ozone which has heretofore not been discussed. WACCM/PMC simulations as compared with Aeronomy of Ice in the Mesosphere (AIM) ice water content, SABER H and O3 agree well. There is a tendency to overestimate the dehydration compared with Solar Occultation for Ice Experiment (SOFIE) data, a problem which has been seen with other models as well. Finally, we consider how these seasonal variations in atomic H might propagate up into the thermosphere and be indicators of coupling between the stratosphere and the thermosphere.

C2.1-0014-18 THE SOLAR CYCLE RESPONSE OF THE POLAR MESOSPHERE, A LONG TERM PERSPECTIVE FROM MULTIPLE DATA SETS

It has long been considered that the 11-year solar cycle will impact the upper atmosphere by altering photochemistry, heating, and the circulation. Solar maximum should be characterized by higher temperatures and lower water vapor in the mesosphere, which in turn will reduce the amount of ice in polar mesospheric clouds (PMC). While the expected response is evident in PMCs during the 1980's and 90's, it appears to be absent from 2000 to present. The response of the polar upper mesosphere to the 11-year solar cycle is investigated using various observations during 1979 - 2017. Satellite observations from SBUV, HALOE, SABER, CIPS, and SOFIE are used to characterize PMCs, temperature, and water vapor. Apparent changes in the response to solar forcing are explored, with consideration of the potential roles of other mechanisms.

C2.1-0015-18 PROBABILITY DENSITY DISTRIBUTIONS OF NLC/PMC

Uwe Berger, berger@iap-kborn.de

Leibniz-Institute of Atmospheric Physics (IAP), Kuehlungsborn, Germany Gerd Baumgarten, baumgarten@iap-kborn.de

Leibniz-Institute of Atmospheric Physics (IAP), Kühlungsborn, Germany Jens Fiedler, fiedler@iap-kborn.de

Leibniz-Institute of Atmospheric Physics (IAP), Kühlungsborn, Germany Franz-Josef Luebken, luebken@iap-kborn.de

Leibniz-Institute of Atmospheric Physics (IAP), Kuehlungsborn, Germany

In this paper we present a new description about statistical probability density distributions (pdfs) of Polar Mesopheric Clouds (PMC) and noctilucent clouds (NLC) occurrence frequencies. The analysis bases on observations of maximum backscatter ratios measured by the ALOMAR RMR-lidar for all NLC seasons from 1997 to 2013. From these lidar data record we estimate an additional observational quantity of ice water density. For these two data sets we derive new classes of pdfs that describe the statistics of PMC/NLC events dierent from previously statistical methods using the approach of an exponential distribution commonly named g-distribution. The new theory is very successful in describing the probability statistic of ALOMAR lidar data. It turns out that the former g-function statistic is embedded in our new theory as a special case. In general the new theory allows to derive basic parameters of climatological ice particle distributions, namely mean ice radii and variances, and, secondly, the theory can be generally applied to many kinds of dierent observational data sets, e.g. measurements of albedo, ice water content, and ice water densities by satellite instruments, or backscatter signals by lidars, respectively.

C2.1-0016-18 SOLAR 27-DAY SIGNATURES IN STANDARD PHASE HEIGHT MEASUREMENTS ABOVE CENTRAL EUROPE

Christian Von Savigny, csavigny@physik.uni-greifswald.de

Ernst-Moritz-Arndt-Universitaet Greifswald, Greifswald, Germany Dieter H.W. Peters, peters@iap-kborn.de

IAP, Kuehlungsborn, Kuehlungsborn, Germany G Entzian, entzian@iap-kborn.de

Leibniz-Institute of Atmospheric Physics (IAP), Germany Jorge L. Chau, chau@iap-kborn.de

Leibniz-Institute of Atmospheric Physics (IAP), K, Germany Georg Teiser, georg.teiser@uni-greifswald.de

Ernst-Moritz-Arndt-Universitaet Greifswald, Greifswald, Germany

We report on the effects of solar variability at the 27-day and the 11-year time scale on standard phase height measurements carried out in central Europe. Using the superposed epoch analysis (SEA) method, we extract statistically highly significant solar 27-day signatures in standard phase heights. The 27-day signatures are anti-correlated to solar proxies. The sensitivity of standard phase height change to solar forcing at the 27-day time scale is found to be in good agreement with the sensitivity for the 11-year solar cycle, suggesting similar underlying mechanisms. Several findings are, however, unexpected. The amplitude of the 27-day signature in standard phase height is larger during solar minimum than during solar maximum, indicating that the signature is not only driven by photolysis of NO.

C2.1-0017-18 LONG-TERM OBSERVATIONS OF MESOSPHERE LOWER THERMOSPHERE DYNAMICS OVER THE LOW AND EQUATORIAL LATITUDES

Kishore Kumar Karanam, kishore_nmrf@yahoo.com Indian Space Research Organization, Trivandrum, India

The dynamics of the mesosphere and lower thermosphere region of the Earth's atmosphere is dominated by the myriad atmospheric waves of various spatial and temporal scales propagating from the lower atmosphere. In general, these waves are identified as gravity waves, tides and planetary waves. Most of the planetary waves observed in the earth's atmosphere correspond to normal-mode solutions for oscillations in an isothermal atmosphere. Apart from these waves, over low and equatorial latitudes, equatorial waves play a major role in shaping the structure and dynamics of MLT region. In the present study, long-term observations of MLT region over low and equatorial latitude are reported using meteor radar observations over Thumba (8.50 N, 770 E) and Kototabang (0.20S, 100.30E). Observations from TIMED/SABER and TIDI are also used to substantiate the radar observations as well as investigating the spatial variabilities. Apart from long-term changes in the mean winds and tides, climatology of planetary waves and gravity waves are constructed using meteor radar observations over the study regions. The gravity waves are quantified in terms of momentum flux and drag, whereas planetary waves are quantified in terms of amplitude and phases. The planetary waves with periods quasi 2-, 5- and 16-day are investigated and their contributions to observed variances in the background winds are quantified. A detailed discussion on the long term variability of these waves and their impact on the background MLT dynamics are presented. Significance of the present study lies in bringing out a comprehensive perspective of MLT dynamics over low and equatorial latitudes, which is envisaged to be helpful in evaluating the middle atmospheric models simulations.

C2.1-0018-18 VERTICAL VELOCITY IN THE HIGH-LATITUDE UPPER MESOSPHERE: ENERGETICS AND DYNAMICS

Leibniz-Institute of Atmospheric Physics (IAP), Kühlungsborn, Germany

More than 12 years of near continuous measurement of meteor radar data from two nearby station Andenes (16°E, 69°N) and Tromso (19°E, 70°N) were combined to derive horizontal winds and gradients in them. The gradient products, which were derived using a new concept called MMARIA (Multistatic Multifrequency Agile Radar for Investigations of the Atmosphere), were used to derive the horizontal divergence and vertical vorticity in horizontal winds. For the current investigation we derive the vertical velocity from the horizontal divergence measurements for all the years. Interestingly, we have found that the vertical velocity during summer is mostly positive (varies from 2 to 15 cms−1) and maximized near the mesopause suggesting upwelling and resulting adiabatic cooling. We found a positive relationship between our horizontal wind divergence and mesopause level temperature measured using the Earth Observing System (EOS) Microwave Limb Sounder (MLS) satellite data. We explain this relationship based on the mesospheric cooling due to upwelling and dynamics. The role of gravity waves will be discussed in the context of long term changes, and summer winter differences.

C2.1-0019-18 CHARACTERISTICS OF THE WIND AND AIRGLOW VARIABILITY IN THE POLAR MESOPAUSE REGION

William E. Ward, wward@unb.ca

University of New Brunswick, Fredericton, NB, Canada Samuel Kristoffersen, y6qk7@unb.ca

University of New Brunswick (Fredericton), Fredericton, Canada Christopher Vail, a0yqb@unb.ca

University of New Brunswick (Fredericton), Fredericton, Canada Dustin Gamblin, dustin.gamblin@unb.ca

University of New Brunswick (Fredericton), Fredericton, Canada

Observations of the wind and airglow above Eureka Nunavut (80 N, 85 W) have been taken during polar winter over the past 9 years at the Polar Environment Atmospheric Research Laboratory (PEARL) using the PEARL All Sky Imager (PASI, airglow images)) and the ERegion Wind Interferometer II (ERWIN2, wind, airglow irradiance and temperature). These instruments view the wind and airglow irradiance of hydroxyl (both) O2 (ERWIN2), sodium (PASI), and oxygen green line (both) in the meospause region. In this paper, the variability is characterized in terms of frequency and spatial scale where appropriate. It is found that much of the variability occurs in the range of 7 to 14 hours in the winds. The variability in the airglow is more difficult to characterize because of twilight effects but appears to peak at higher frequencies. Some of this variability can be attributed to wave effects. In this paper the nature of these variabilities are described and correlations between observations with the various emissions presented and interpreted.

C2.1-0020-18 THE POSSIBLE LINK BETWEEN THE NEUTRAL CONSTITUENTS IN THE MESOPAUSE REGION AND THE LOWER ATMOSPHERIC/SOLAR ACTIVITIES

Xianghui Xue, xuexh@ustc.edu.cn

University of Science and Technology of China, Hefei, China

The mesopause and lower thermosphere region is a transition region from the neutral atmosphere to the space plasma, which can be affected by the upward propagating waves from the lower atmosphere OR be coupled with the ionosphere under the modulation of the solar activities. The deposition of the meteors into the Earth’s atmosphere, on one hand forms the permanent metal layers in the mesopause region through the photo-chemical reactions, on the other hand generates trails of plasma which can be used as an indication of the neutral atmospheric dynamics. The ground-based remote-sensing techniques can obtain the information of the atmospheric paramters in the mesopause region through the measurements of the metal layers or the plasma in the meteor trails. Based on the ground-based optical and radio observations, we will report the possible link between the neutral constituents in the mesopause region and the lower atmospheric/solar activities. (1) The lidar observational results on a statistical basis showed evidence that thunderstorm activities can affect the metal layer, by identifying a statistically significant enhancement of the neutral metal Na layer above thunderstorms at Haikou, China (20.0N, 110.3E). The thunderstorm-generated gravity waves, and electric field effects could be the mechanisms responsible for the lightning-associated enhancement of Na layer.

The estimated atmospheric density in the mesopause region from a meteor radar chain from the North Pole to South Pole indicated a strong negative correlation with the geomagnetic kp index and suggested possible modulation from solar wind and solar stroms.

C2.1-0021-18 ROLE OF DYNAMICS AND CHEMISTRY FOR THE OCCURRENCE OF TROPICAL (10°N-15°N) MESOSPHERIC INVERSION LAYERS

Karanam Ramesh, karanamram@gmail.com

ABSTRACT

The inversion of temperature gradient from negative to positive superimposed upon the characteristically decreasing mesospheric thermal structure is known as Mesospheric Inversion Layer (MIL). Although MILs have been known for decades through all sorts of available techniques, their study is still of significant relevance for understanding of the energy and momentum budget of mesosphere and lower thermosphere (MLT) region. The suggested dominant causative mechanisms for the occurrence of MILs are: gravity wave (GW) breaking, planetary wave (PW) critical level interaction, GW-tidal interaction and chemical heating. In the present study, all these principal causative mechanisms have been addressed through a few case studies from Rayleigh lidar and TIMED-SABER (Thermosphere Ionosphere Mesosphere Energetics and Dynamics - Sounding of Atmosphere by Broadband Emission Radiometry) observations over Gadanki (13.5°N, 79.2°E) region. A large MIL has been observed at 79-84 km (ΔT 50

K and Δz 4.5 km) on the night of 24 January 2007 over Gadanki and it is attributed to large eddy diffusion by small scale (T 33 min, Λz 6.4 km) GW breaking. Further it is found that the chemical heating due to the exothermic reactions among H, O, O3, OH, HO2 played dominant role over dynamics for the occurrence of a few large MILs at 80-85 km during January-February 2011. In another special case study, a triple layered MIL event with three inversion layers at 70 km (11 K), 80 km (44 K), 90 km (109 K) has been observed in September 2011. The three inversion layers are found to be due to PW breaking, GW-tidal interaction and large chemical heating by the reaction, O+O+M→O2+M respectively.

C2.1-0022-18 ON THE ORIGIN OF VARYING NON-LTE CONTRIBUTIONS TO OH ROTATIONAL TEMPERATURES

Stefan Noll, stefan.noll@dlr.de

Institute for Environmental Physics, University of Bremen, Bremen, Germany

The departure of OH rotational level populations from the local thermodynamic equilibrium (LTE) can be an issue for the interpretation of the amount and variations of OH rotational temperatures Trot, which are an important diagnostic tool for the Earth's mesopause region. In order to improve our understanding of the impact and origin of such varying non-LTE effects, we performed a combined study which involved OH population and Trot measurements related to spectra of the high-resolution UVES spectrograph at the Very Large Telescope in Chile, OH emission layer and mesopause chemical composition data from the SABER radiometer on the TIMED satellite and the NRLMSISE-00 model, and a kinetic model of the relevant chemical reactions, collisional processes, and radiative transitions. We focussed our analysis on the vibrational level v = 9, which is the highest v that can be populated by the OH-producing reaction of hydrogen and ozone. We found significant non-LTE contributions to Trot in the observed and modelled data. The climatology of the variations of these effects appears to be mainly caused by their steep increase with altitude, the OH-specific weighting of the different altitudes depending on the emission rate, and the variability of the effective OH emission altitude. Moreover, our study resulted in rate coefficients for the rotational relaxation process by thermal collisions. In our presentation, we will also discuss the impact of these results for the non-LTE contributions to Trot of lower v, which are more frequently used for the analysis of temperature variations in the mesopause region.

C2.1-0023-18 NEW NON-LTE MODEL OF THE IR EMISSIONS OF HYDROXYL, OZONE AND CARBON DIOXIDE IN THE NIGHTTIME MLT

Ecole Polytechnique, Paris, France Diego Janches, diego.janches@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States Daniel Marsh, marsh@ucar.edu

NCAR, Boulder, Colorado, United States

We present a new non-LTE model which couples IR emissions of OH, O3 and CO2 bands in the nighttime MLT. The model treats a large number of vibrational levels and ro-vibrational bands of these three optically active molecules as well of N2(v) and O2(v), which all are coupled by a variety of interand intra-molecular collisionally induced exchanges of vibrational energy. We compare model calculations of limb emissions in the 1.6 and 2.0 μm OH Meinel bands, 9.6 μm O3 band and 4.3 μm CO2 band with nighttime limb radiances measured by SABER/TIMED. Particular attention is given to the effect of the recently discovered mechanism of OH(v) quenching by collisions with O(3P), subsequently producing O(1D), which further transfers its energy to the N2, CO2 and O3 vibrations, and therefore influencing OH, O3, and CO2 emissions. We also present a novel retrieval algorithm and show the application of the new model/algorithm to retrieving O(3P) and OH densities in MLT from the OH 1.6 and 2.0 μm Meinel band emissions measured by SABER. We compare retrieved densities with observations of other airglow emissions (WINDII, OSIRIS, SCIAMACHY), as well as model results of WACCM. Implications for the aeronomy and energy budget of the MLT are discussed.

C2.1-0024-18 A NEW LOOK AT THE TERTIARY OZONE MAXIMUM IN THE POLAR WINTER MESOSPHERE

Anne Smith, aksmith@ucar.edu

National Center for Atmospheric Research, Boulder, Colorado, United States Patrick Espy, patrick.espy@ntnu.no

Norwegian University of Science and Technology (NTNU), Trondheim, Norway Manuel Lopez-Puertas, puertas@iaa.es

Instituto de Astrofisica de Andalucia CSIC, Granada, Spain Olga Tweedy, otweedy1@jhu.edu

Johns Hopkins University, Baltimore, Maryland, United States

Observations from satellites and a ground-based station are combined to construct a global dataset for investigating the tertiary ozone maximum in the winter mesosphere for the period August 2004-June 2017. These give a comprehensive picture of this ozone maximum in latitude, pressure, and time. The location of the tertiary ozone maximum shifts in latitude and pressure with the evolving season; the ozone peak occurs at lower latitude and higher pressure around the winter solstice. Highest average nighttime ozone concentrations and greatest degree of interannual variability are seen in late winter in the Northern Hemisphere. The hemispheric differences and interannual variability in nighttime ozone are related to variations of temperature, H2O and OH associated with dynamical activity. Elevated stratopause events in the Northern Hemisphere winter are associated with transport of air that is depleted in H2O and high in OH; photochemistry then leads to downward displacement of the altitude of maximum ozone and enhancement in the ozone amount. Transport by planetary waves in the NH extends the region of high ozone further from the pole and leads to longitudinal variations. The analysis shows that, while the tertiary ozone maximum responds to a particular radiative situation as shown in previous studies, it also is the result of very dry air and high OH found in the winter polar mesosphere.

We investigate atomic hydrogen (H) variability from the mesopause to the upper thermosphere, on time scales of solar cycle, seasonal, and diurnal, using measurements made by the Sounding of the Atmosphere using Broadband Emission Radiometry (SABER) instrument on the Thermosphere Ionosphere Mesosphere Energetics Dynamics (TIMED) satellite, and simulations by the National Center for Atmospheric Research Whole Atmosphere Community Climate Model eXtended (WACCM-X). In the mesopause region (85 to 95 km), the seasonal and solar cycle variations of H simulated by WACCM-X are consistent with those from SABER observations: H density is higher in summer than in winter, and slightly higher at solar minimum than at solar maximum. However, mesopause region H density from the Mass-SpectrometerIncoherent-Scatter (NRLMSISE-00) empirical model has reversed seasonal variation compared to WACCMX and SABER. From the mesopause to the upper thermosphere, H density simulated by WACCM-X switches its solar cycle variation twice, and seasonal dependence once, and these changes of solar cycle and seasonal variability occur in the lower thermosphere (95 to 130 km); whereas H from NRLMSISE-00 does not change solar cycle and seasonal dependence from the mesopause through the thermosphere. In the upper thermosphere (above 150 km), H density simulated by WACCM-X is higher at solar minimum than at solar maximum, higher in winter than in summer, and also higher during nighttime than daytime. The amplitudes of these variations are on the order of factors of 10, 2, and 2, respectively. This is consistent with NRLMSISE-00.

C2.1-0026-18 THE RESULTS OF THE DETERMINISTIC-PROBABILISTIC MODELING OF THE D-REGION OF THE IONOSPHERE

Institute of Geospheres Dynamics RAS, Moscow, Russia

It has finally become clear that ionosphere influences propagation of almost all wavelength ranges being used in radio systems. Therefore, creating ionosphere models of various complexity levels is a very topical problem. Probabilistic-statistical modeling is the best way to describe such irregular environment as ionosphere, because output model's parameters are not the median values, but probability density functions, which provide us more complete and detailed information of ionospheric components behavior. The deterministic-probabilistic model is based on the five-component system of the ionization-recombination cycle of the D-region of the ionosphere. The modeling consists of experimental database processing of the input system's parameters and finding their probability density functions in various heliogeophysical conditions. Further, parameters' profiles are generated according to the obtained distributions and used to solve the system of differential equations to find electron density. The number of values is determined by the convergence of the solution. The resulting average values of the electron concentration demonstrate good agreement with the experimental database. So, obtained probability density functions of electron concentration can be used for radio wave propagation problems in considered conditions.

C2.1-0027-18 MODELING OF SIMULTANEOUS MULTIPLE PATH VLF OBSERVATION OF SOLAR FLARE USING ZENITH ANGLE PROFILE AND LWPC

New Zealand

Excess solar X-ray radiation during solar flares causes an enhancement of ionization in the ionospheric D-region and hence affects sub-ionospherically propagating Very Low Frequency (VLF) signal. It causes VLF signal amplitude perturbation (ΔA), phase perturbation (ΔP), amplitude time delay (Δt) and other associated characteristics. The nature of solar flare associated VLF perturbation events are strongly dependent on the characteristics of the signal propagation path, i.e. a given solar flare generally causes completely or partially different types of perturbative effects on VLF signals observed simultaneously across different propagation paths at different parts of the globe having different geophysical conditions. To study this phenomenon, we observe a C-class flare on 20th January 2016 simultaneously from a number of such paths, namely, VTX-Bharati, VTX-IERC, NWC-Bharati, NWC-Dunedin and NWC-Maitri. During these observations, the signal-to-noise ratio was significantly low at those observation stations. The amount of observed VLF amplitude perturbations at different paths are notably different. The diurnal solar flux profiles over the paths having different ground conductivity profiles are mainly responsible for it and so we model the zenith angle profile over the path. We have used the Long Wave Propagation Capability (LWPC) code to model the D-region including the zenith angle effects. The simulated VLF signals resemble with its observational counterpart. Finally, we performed a correlation analysis for a quantitative comparison.

Polar Mesosphere Winter Echoes (PMWE) are relatively strong coherent radar returns from 55-85 km altitudes, which primarily occur in the winter season at high latitudes. PMWE are also observed at mid-latitudes, although very much more rarely. Because of their extremely low occurrence rate, they are still poorly investigated. Consequently, the origin of these echoes is still under debate. Currently the most accepted explanation of PMWE formation mechanism suggests that the neutral air turbulence plays the key role. However, there are some features, which need additional players to explain this phenomenon. The most important among them is the background electron density, which is needed to make PMWE detectable for the radars. This explains why PMWE more often occur during daytime when the solar radiation ionizes the Earth's atmosphere. Another suggested important player in the formation of PMWE are the dust particles or the so-called Meteor Smoke Particles (MSP). Their importance was suggested by interpretation of the PMWE observations with the European Incoherent Scatter radar (EISCAT). The PMWE sounding rocket mission aims at in situ measuring the key parameters that may explain the formation mechanism of the winter radar echoes. The Middle atmosphere ALOMAR Radar System (MAARSY) is capable of measuring the echoes along the rocket's flight path and is used to define launch criteria. Two instrumented sounding rockets will be launched from the Andøya Space Center (ASC) in northern Norway during the first PMWE campaign scheduled for beginning of April 2018. In this paper we will present the first results of the PMWE-1 sounding rocket campaign.

C2.1-0029-18 AIRGLOW MONITORING AND THE PROJECT OF METEOR MAP FOR APPLIED RESEARCH

Kharkiv National University of Radio and Electronics, Kharkiv, Ukraine

Investigation of solar-terrestrial relations was a priority for the main geophysical projects of a global scale, starting from the 1957 International Geophysical Year, when the first artificial Earth's satellite was launched. When studying the influence of the Sun on the ionosphere, other factors of influence were taken into account, such as a meteoroid which enters Earth's atmosphere from outer space. During meteoroid passage, the atoms and molecules of the atmosphere become excited, therefore ionization processes occur. The meteoroid entry is accompanied by some other effects, which are the result of the interaction of a rapidly moving meteoroid and the Earth's atmosphere. An ionization trail appears behind the moving meteoroid. There is a special term "the meteor zone of the atmosphere" for the layers of the atmosphere on altitudes about 70-120 km, where meteors are mostly observed by astronomers. The chemical composition of the meteoroid affects the color of the meteor that are investigated by astronomers. Meteoroid passages can make their special contribution to the glow of the sky, as explained by atmospheric chemistry. The airglow (also called nightglow) is light emission from the Earth's upper atmosphere. This is studied by geophysicists. The airglow is observed in the altitude region between 80 and 110 km of the Earth's atmosphere. To see it needs long dark adaptation. Unlike the aurora, the airglow is visible all over the globe. Explanation of the origin of the glow is in debate. This can arise due to the interaction of the Sun and cosmic rays with the Earth's atmosphere. Meteoroid passages can play a role as well. Here the meteor map project for applied research is proposed. Such a map would be of particular interest to airglow researchers. The map will be filled with up-to-date information about meteor showers, indicating their activity and parameters of the possible composition of each shower (if the composition data are available). This will provide additional information to the researcher who assesses the effects of the Sun and cosmic radiation on processes that take place in the Earth's atmosphere.

C2.1-0030-18 QBO EFFECT ON THE MIGRATING DIURNAL TIDE IN THE MLT REGION

Hongping Gu, hongping.gu@louisville.edu

University of Louisville, Louisville, Kentucky, United States Jian Du, jian.du@louisville.edu

University of Louisville, Louisville, Kentucky, United States

The stratospheric quasi-biennial oscillation (QBO) effect on the migrating diurnal tide (DW1) is investigated using the extended Canadian Middle Atmosphere Model (eCMAM) 31.5-yr run (1979-2010). Composite analyses are conducted to identify the DW1 zonal wind response under the westerly QBO (WQBO) and easterly QBO (EQBO). The DW1 amplitude is found to be stronger in WQBO than EQBO and the difference exhibits a semi-annual variation (bigger difference during the equinoxes than the solstices). We then investigate in detail the physical causes for 1) the tidal difference during the two phases of QBO and 2) its seasonal variation through momentum budget analysis. Different terms in the momentum budget are compared and the most important terms are identified. We then dissect the terms further to examine the latitudinal and vertical wind shears under the two phases and the resulting difference in the tide - mean flow interaction and consequently the tidal amplitude.

Wavelet analysis on DW1 (the migrating diurnal tide) using data from the extended Canadian Middle Atmospheric Model (eCMAM30) run (1979-2010) and the sounding of the Atmosphere using Broadband Emission Radiometry (SABER) instrument on NASA's TIMED (Thermosphere Ionosphere Mesosphere Energetics Dynamics) satellite revealed strong short term tidal variability on time scales from few days to 1 month apart from the inter-annual, seasonal and intra-seasonal variabilities. Atmospheric tides have been observed to fluctuate on short-term time scales at the periods of planetary waves (few days to 30 days). In this research we investigate the tidal variability of DW1 as a function of the inter-annual variations such as solar flux, QBO, and ENSO, and seasonal harmonics (12, 6, 4 and 3 months) based on the regression model. We then further investigate the statistical properties (covariance, autocorrelation and time dependent probability density functions) of the short-term tidal variability with periods less than 30 days. The relative contributions from the quasi 23-day, quasi 16-day, and quasi 10-day waves to these statistical properties are noted.

C2.1-0032-18 STATISTICAL MODELING OF TIDAL WEATHER IN THE MLT REGION

Jian Du, jian.du@louisville.edu

University of Louisville, Louisville, Kentucky, United States XuWen Zhu, xuwen.zhu@louisville.edu

University of Louisville, Louisville, Kentucky, United States

We attempt to build a vector autoregression (VAR) model and an empirical statistical model to simulate day-to-day variability of the atmospheric tides. We will present some of the statistical properties of the day-to-day variability of the tides, and the process to build the models, what we can learn about the physical processes governing the variability from the models, and exam their predictability, pro and cons. This is a quite new approach to try to understand and simulate the complex tidal variability from a statistical point of view.

C2.1-0033-18 A MODEL STUDY OF THE DRIVERS OF PMC CHANGES USING A WHOLE ATMOSPHERE MODEL WITH PARAMETERIZED PMCS

Aimee Merkel, aimee.merkel@colorado.edu

LASP / University of Colorado, Boulder, Colorado, United States

Naval Research Laboratory, Washington, District of Columbia, United States Daniel Marsh, marsh@ucar.edu

NCAR, Boulder, Colorado, United States

Polar mesospheric clouds (PMC) are excellent monitors of mesospheric conditions due to their extreme sensitivity to temperature and water vapor. Both ground-based and satellite instruments have suggested changes in PMC abundance and brightness over the past several decades; however, the relative importance of the potential forcing terms is controversial. Possible sources of PMC change include changes in middle atmospheric structure due to anthropogenic CO2 and CH4, long-term change in global-scale dynamics, as well as solar irradiance changes. There is also the suggestion that PMCs respond to changes in ozone depleting substances such as chlorofluorocarbons (CFC). Temperature in the stratosphere responds to changes in stratospheric ozone, where decreasing O3 induces stratospheric cooling. Coupling of the stratosphere and mesosphere occurs through hydrostatic contraction, where a cooler stratosphere results in cooling near the mesopause, which in turn might enhance PMC formation. It is reported that cooling trends in the stratosphere became leveled off after 1995. This pause in cooling has been associated with slowly decreasing stratospheric concentrations of ozone-depleting substances. To study the influence of CFCs, we performed controlled numerical experiments with a version of the NCAR's Whole Atmosphere Community Climate Model (WACCM) that includes a parameterization for PMC formation. Rather than an overall trend analysis, where it may be difficult to disentangle the impacts of different forcing factors, we have more simply changed each term in isolation. For example, we will compare two runs, one with a background level of CFC abundance appropriate for earlier in the 20th century, to a run with present day values. Our results will enable subsequent trend analyses to more readily sort out the many possible causes of multi-decadal PMC variability. Acknowledgements: This work was funded by the NASA Heliophysics Supporting Research Program

C2.2-0001-18 FULL-WAVE MODELING STUDIES OF ATMOSPHERIC GRAVITY WAVES IN THE ATMOSPHERE

Michael Hickey, michael.hickey@erau.edu

Embry Riddle Aeronautical University, Daytona Beach, Florida, United States

Atmospheric gravity waves are a ubiquitous phenomenon in the terrestrial atmosphere and also in other planetary atmospheres. The importance of these waves to the terrestrial upper atmosphere is now reasonably well understood, based on a combination of observations and modeling over the last few decades. One type of model is the full-wave model. Here I will discuss this model and its variants, which have been used over the last two decades to simulation the propagation and dissipation of gravity waves in the atmosphere. This steady-state, single-gas Eulerian model solves the linearized Navier-Stokes equations subject to boundary conditions in a non-isothermal atmosphere, including height-dependent mean winds, viscosity, thermal conductivity, Coriolis force and ion drag. The model has been used to simulate gravity waves ducted in the terrestrial mesosphere and lower thermosphere, freely propagating gravity waves that dissipate in the terrestrial thermosphere, and gravity wave propagation and dissipation in planetary atmospheres (e.g., Jupiter, Mars) in order to examine wave influences on the mean state. A spectral version of the model, in which a few thousand individual monochromatic waves are simulated and then summed in a Fourier sense, has been used to simulate the response to a tsunami-like disturbance at the lower boundary. In spite of the fact that vertical advection of an air parcel should lead to fluctuations of gas properties such as molecular weight and specific heat, historically single gas steady-state models have never accounted for such effects in the thermosphere. Therefore, a second variant of the full-wave model was developed that treats the atmosphere as a single gas with a height-dependent mean molecular weight and also admits fluctuations of molecular weight and specific heat due to the effects of vertical advection. This increases by two the number of equations solved in the model. Earlier research suggests that this is an improvement over the standard single gas approach used in steady-state dynamical models. A third variant of the full-wave model treats the thermosphere as a binary gas. This model includes all the physical processes of the original full-wave model and also includes the effects of binary collisions in the momentum and energy equations, and mutual diffusion. Comparisons between simulations using this model with the second variant of the model, described above, suggest that including fluctuations of molecular weight and specific heat is the best approach for single gas steady-state models. Here, I will discuss the basic fullwave model and its variants, and present a number of model simulations that demonstrate the model's usefulness in improving our understanding of the effects of various physical processes on gravity wave propagation and dissipation. Vertical wavelengths and wave fluxes and their dependence on various physical processes will be discussed.

C2.2-0002-18 ATMOSPHERE-IONOSPHERE COUPLING DUE TO PLANETARY WAVES AND TIDES

Jeffrey M Forbes, forbes@colorado.edu

University of Colorado, Boulder, Colorado, United States

Over the past decade, first-principles whole-atmosphere models have revealed a lot about how planetary waves (PW) and tides determine the mean state and day-to-day variability of the quiet-time ionosphere. Some key elements of the atmosphere-ionosphere (A-I) coupling process include the dynamo generation of electric fields, wave-wave interactions, wave-mean flow interactions, and wave-induced composition changes. All of these produce different types of spatial and temporal variability, some over different time scales than others. An overview of these mechanisms is presented, with concrete examples for a few. Finally, open questions and remaining challenges regarding wave coupling in the A-I system are identified.

The Atmospheric Waves Experiment (AWE) plans to deploy a high-resolution infrared imager (based on the successful Utah State University Advanced Mesospheric Temperature Mapper) on the International Space Station (ISS) to gain a transformative set of gravity wave (GW)

-resolving temperature measurements using the OH nightglow emission (altitude 87 km). The ISS provides an ideal combination of altitude, geographic and local time coverage to accomplish our proposed science objectives, which seeks not only near-global measurements of GW characteristics in the mesopause region, but

also quantification of GW momentum and energy fluxes driving the Ionosphere-Thermosphere (IT) from below. Combined with state-of-the-art high-resolution models, the AWE mission will also assess the relative importance of sources versus propagation conditions in explaining the observed spatial and temporal variability of the GWs.

The AWE mission is currently in a "Phase A" study as part of the NASA 2016 Heliophysics Explorers Mission of Opportunity (MO) Program. In this presentation, we describe the primary goals of this program and introduce our proposed research methods using proven IR instrument technology. AWE's exceptional capabilities are illustrated with recent discoveries in observing GWs from the ground and from aircraft during the NSF DEEPWAVE campaign, promising a major step forward in understanding how troposphere weather translates to space weather.

C2.2-0005-18 ATMOSPHERE-IONOSPHERE COUPLING AND EQUATORIAL SPREAD-F

This paper discusses about the influence of Stratospheric Sudden Warming (SSW) events in modulating the occurrence time of the Equatorial Spread-F (ESF) through enhanced Planetary Wave (PW) activity during the winter months. The analysis based on the data from a Digital Ionosonde and Proton Precession Magnetometer over Trivandrum (8.5o N, 77o E, 0.5o N dip lat.), revealed that the PWs of quasi-16 day periodicity influence the start time of the ESF to a significant extent during the SSW years. On the other hand, during a normal year such effect is not very evidently present. It has been observed that the quasi-16 day wave propagate to ionospheric dynamo region from the atmosphere below and modify the electrodynamical processes like the Equatorial Electrojet and Pre-Reversal Enhancement, which is more pronounced during both the SSW periods. Such a modification in the electrodynamics can modulate the equatorial plasma fountain and influence the F-region neutral dynamics, which in turn can affect the occurrence of ESF by modifying the seeding conditions.

C2.2-0006-18 ATMOSPHERIC WAVE OBSERVATIONS AND PREDICTIONS FOR THE NASA IONOSPHERIC CONNECTION EXPLORER

Thomas Immel, immel@ssl.berkeley.edu

High Altitude Observatory, NCAR, Boulder, Colorado, United States

Earth's ionosphere varies from one day to the next in ways that cannot be predicted. The Ionospheric Connection Explorer (ICON) is set to launch in the Summer of 2018 with a mission to discover the causes of this variability. Since the decision by NASA in 2013 to develop the mission, there have been a number of research results that predict the presence of a number of science targets that are now better-defined. These include a remarkable variety of atmospheric waves and products of wave-wave interactions that may may be expected and identifiable in the ICON data products, including wind and temperature profiles in the lower E-region (90-140 km altitude). Here we will describe those potentially important drivers of ionospheric variability and how they may appear in the ICON data products. We use a TIEGCM model analysis of the ionosphere where large spatial and temporal scale waves are introduced along with atmospheric tides to elucidate these potential effects.

C2.2-0008-18 MODELING AND OBSERVATIONS OF LITHOSPHERE-ATMOSPHERE-IONOSPHERE COUPLING DRIVEN BY EARTHQUAKE SURFACE WAVES

Pavel Inchin, inchinp@my.erau.edu

Embry-Riddle Aeronautical University, Daytona Beach, Florida, United States Jonathan Snively, snivelyj@erau.edu

Embry Riddle Aeronautical University, Daytona Beach, Florida, United States Matthew Zettergren, zettergm@erau.edu

Embry-Riddle Aeronautical University, Daytona Beach, Florida, United States

It is known that earthquakes generate acoustic and gravity waves that drive ionospheric perturbations [Shuanggen et al., ESR, 2015; Komjathy et al., Radio Sci., 2016]. Rayleigh waves travel along the surface (3-5 km/s) of the Earth from epicenter creating vertical displacements. These displacements are a source of upward-propagating acoustic waves, with amplitudes growing exponentially with altitude due to the conservation of energy. Plasma density fluctuations with periods of 5mHz were observed and reported after several severe earthquakes using GNSS Total Electron Content (TEC) measurements [e.g. Ducic et al., GRL, 2003; Galvan et al., JGR, 2011; Tulasi Ram et al., JGR, 2017]. Observed fluctuations and their velocities are consistent with time of propagation of the acoustic wave signal to the ionospheric F2 layer (10 min), carrying the "imprint" of Rayleigh waves phase speeds. Rolland et al. [JGR, 2011] performed modeling of TEC perturbations driven by Rayleigh waves based on lithosphere-atmosphere coupling of normal modes [Lognonne et al., GJI, 1998; Artru et al., GJI, 2004], demonstrating this mechanism. In this work, we investigate the propagation of acoustic waves in atmosphere and ionosphere induced by Rayleigh waves after severe earthquakes. Case studies for Sichuan 7.9 Mw 2008, Tohoku-Oki 9.1 Mw 2011 and Nepal 7.8 Mw 2015 earthquakes are examined. We use the normal mode summation technique implemented in the 1D PREM Earth model [Dziewonski et al., PEPI, 1981] to simulate the propagation of Rayleigh waves from the earthquake's epicenter based on centroid moment tensor information about seismic source. Surface perturbations are then impose as a lower boundary condition for nonlinear 2D simulations using the Model for Acoustic-Gravity wave Interactions and Coupling (MAGIC) and the Geospace Environment Model for Ion-Neutral Interactions (GEMINI) [Zettergren and Snively, JGR, 2015] to study the propagation of acoustic waves to ionospheric altitudes. Modeling captures the primary features of lithosphere-atmosphere-ionosphere coupling, and reveals the spatial and temporal evolutions of acoustic waves in the atmosphere driven by fast surface waves, providing new insight into their generation and propagation. We also assess their detectability in data relative to other wave processes occurring above the epicenter.

C2.2-0009-18 SATELLITE OBSERVATIONS OF GRAVITY WAVES

Thai Trinh, t.trinh@fz-juelich.de Forschungszentrum Juelich, Juelich, Germany Manfred Ern, m.ern@fz-juelich.de Forschungszentrum Juelich, Juelich, Germany Eelco Doornbos, e.n.doornbos@tudelft.nl

Delft University of Technology, Delft, Netherlands Peter Preusse, p.preusse@fz-juelich.de Forschungszentrum Juelich, Juelich, Germany Martin Riese, m.riese@fz-juelich.de Forschungszentrum Jülich, Jülich, Germany

Vertical coupling by atmospheric gravity waves (GWs) from the lower atmosphere plays an important role in the energy and momentum balance of the thermosphere/ionosphere (T/I). However, the penetration of GWs into the T/I system is not fully understood in modeling as well as in observations. For a better understanding of this vertical coupling, satellite observations of GWs at different altitude levels can be utilized as a guidance. We here analyze observations of GWs at different layers of the atmosphere. In the middle atmosphere (30-90 km) GW momentum fluxes are extracted from temperature measurements of the Sounding of the Atmosphere using Broadband Emission Radiometry (SABER) satellite instrument. In the T/I, at altitudes of 220 km and 400 km, respectively, GW induced fluctuations are derived using mass density from the Gravity field and Ocean Circulation Explorer (GOCE) and CHAllenging Minisatellite Payload (CHAMP) satellites. We found similar features in GW horizontal distributions at the different altitude levels considered. Further, spatial correlations between these horizontal distributions are generally positive. These findings demonstrate the importance of the vertical coupling by GWs between lower atmosphere and T/I. Two coupling mechanisms may contribute: (1) fast GWs generated in the troposphere and lower stratosphere propagate directly to the T/I and (2) primary GWs having their origins in the lower atmosphere dissipate while propagating upwards and generate secondary GWs, which then penetrate up to the T/I and maintain the spatial patterns of GW distributions in the lower atmosphere. In addition to the mountain-wave related hot spot over the Andes and Antartic Peninsula, we found latitude-longitude variations in the summer midlatitudes in observations of all instruments. This, together with positive correlations in the summer midlatitudes, suggest the propagation of GWs with convective origins into the T/I. In addition, we estimate for the first time GW momentum fluxes using observations of GOCE and CHAMP. Limitations of the observations and of our research approach are discussed.

Between 2013 and 2016 the DLR-Institute of Atmospheric Physics has conducted a series of three coordinated ground based and air borne field campaigns to study the life cycle of gravity waves from their excitation in the troposphere to their dissipation in the mesopause region. Two of these field campaigns were carried out in in Northern Scandinavia (Northern hemisphere winter 2013/14 and 2015/16) and we also participated in the NSF-led DEEPWAVE mission in New Zealand in Austral winter 2014. Ground based observations comprised Rayleigh lidar temperature measurements between 20 - 90 km as well as OH airglow measurements. Airborne in-situ observations of momentum and energy fluxes were used to characterize the propagation characteristics of the waves across the tropopause, a topic which was further investigated using airborne wind lidar measurements. In this paper we present the major results of these campaigns focusing on 1) the role of the tropopause in determining the fraction of tropospheric waves that reach the middle atmosphere, 2) the refraction and horizontal propagation of waves by the background wind, and 3) the dissipation and wave mean flow interaction in the mesopause

region. Finally, we will also briefly introduce our plans for a combined ground based and airborne field campaign focusing on the Southern hemisphere gravity wave hotspot in the Southern Andes that is currently planned for September - December 2019.

C2.2-0011-18 GRAVITY WAVE DISSIPATION IN THE UPPER ATMOSPHERE

Richard Walterscheid, richard.walterscheid@aero.org Aerospace Corporation, Los Angeles, California, United States

A question of fundamental importance is the altitudes to which gravity waves originating in the lower atmosphere can propagate. It is well known that high frequency quasi-monochromatic waves that are initially small amplitude may propagate to great heights before they dissipate, while slower stronger waves are damped at lower altitudes. Less well known are effects on wave packet attenuation related to their spectral nature, specifically dispersion and scale-dependent dissipation. Dispersive wave packets launched in the lower atmosphere may suffer strong attenuation by dispersion alone before they propagate great distances from their sources. Dispersion combined with dissipation has a strong effect on the spectra of wave packets and this affects their propagation and dissipation. For highly dispersed wave packets, the component of the packets with long vertical wavelengths (the component with rapid vertical propagation) reaches the dissipative regions of the thermosphere first. This depletes the fast waves first and causes a shift in the central wavenumber toward shorter slower waves and causes wave packets to slow down. On the other hand, if minimal dispersion occurs before wave packets reach strongly dissipative regions, scale-dependent dissipation depletes the shorter slower waves and the opposite effects are seen. The effects of dispersion are greatest for broadband disturbances. The spectral nature of wave packets has significant implications for wave packet trajectories, amplitudes and wave drag (including drag parameterizations). The theory and modeling of wave packet propagation subject to dispersion and viscous dissipation will be reviewed.

C2.2-0012-18 OBSERVATION OF ATMOSPHERIC COUPLING AND INTERNAL WAVES BY AIRGLOW IMAGERS

Kazuo Shiokawa, shiokawa@nagoya-u.jp

Institute for Space-Earth Environmental Research, Nagoya University, Nagoya, Aichi, Japan Yuichi Otsuka, otsuka@isee.nagoya-u.ac.jp

Institute for Space-Earth Environmental Research, Nagoya University, Nagoya, Japan Satoshi Tsuchiya, tsuchiya.satoshi@isee.nagoya-u.ac.jp

Institute for Space-Earth Environmental Research, Nagoya University, Nagoya-shi, Aichi-ken, Japan

Aysegul Ceren Moral, acmoral@isee.nagoya-u.ac.jp

Institute for Space-Earth Environmental Research, Nagoya University, Nagoya, Japan

We will review our recent progress on the observation of atmospheric coupling processes through gravity waves using multi-point all-sky airglow imagers of Optical Mesosphere Thermosphere Imagers (OMTIs). Three-dimensional Fourier analysis of airglow images makes it possible to analyze long-term airglow imaging data to see the short-period gravity wave activities. Using this method, Takeo et al. (JGR, 2017) studied 16-year variation of horizontal phase velocity and propagation direction of mesospheric and thermospheric waves in airglow images observed by an airglow imager at Shigaraki (34.8N), Japan. We also extend this 16-year analysis to another station at Rikubetsu (43.5N), Japan to investigate latitudinal difference/similarity of the gravity wave characteristics. We show yearly, seasonal, and local time variation of gravity wave propagation characteristics as well as their relation to the stratospheric sudden warming. We also show gravity wave characteristics in the thermosphere based on statistical study of medium-scale traveling ionospheric disturbances (MSTIDs) in the 630-nm airglow images and through simultaneous observations of the MSTIDs by an airglow imager and the CHAMP satellite over Indonesia at a latitude of 0.2S. We observed thermospheric neutral density variations by the CHAMP satellite associated with the southward-propagating MSTIDs in the 630-nm airglow images over Indonesia, indicating that these MSTIDs are caused by gravity waves penetrating into the thermosphere. We also show geomagnetic conjugacy and non-conjugacy of ionospheric and thermospheric variations accompanied by a midnight brightness wave at low latitudes reported by Fukushima et al. (EPS, 2017) using airglow imagers, ionosondes and an Fabry-Perot interferometer at Thailand and Indonesia.

C2.2-0013-18 INTERACTIONS OF SMALL AND MEDIUM-SCALE GRAVITY WAVES IN THE MESOSPHERE AND LOWER THERMOSPHERE.

Christopher Heale, healec@erau.edu

Embry-Riddle Aeronautical University, Daytona Beach, Florida, United States Jonathan Snively, snivelyj@erau.edu

Embry Riddle Aeronautical University, Daytona Beach, Florida, United States

Gravity Waves play an important role in transporting energy and momentum from the lower to upper atmosphere. However, their propagation, evolution, and momentum deposition depend highly upon the prevailing atmospheric conditions (Fritts and Alexander., Geophys. Rev., 41, 103, 2003). High-frequency, small scale waves in particular are suggested to carry large momentum flux into the Mesosphere and Lower Thermosphere (MLT) region (Fritts et al., JGR, 119, 2014). However, temporal variances in atmospheric winds and temperatures caused by other, longer period waves can significantly influence their progress into the dissipative region. Currently, wave dynamics at these scales are often parameterized using linear, steadystate approximations in General Circulation Models (GCMs).

In this study, numerical simulations are used to explore linear and nonlinear interactions between small (10s km, sub hour periods) and medium-scale (100km, hour periods) gravity waves in order to understand and characterize the dominant dynamical effects at these scales. Doing so will be important for the next generation of high-resolution GCMs, which will partially resolve and partially parameterize the gravity wave spectrum (e.g. Liu et al., GRL, 41, 2014). It is found that small-scale wave breaking can occur along preferential phases of the medium scale wave. This breaking can induce a mean flow and shear which in turn influences the medium-scale wave. At finite amplitudes, both the medium-scale and small-scale waves are nonlinearly and time-dependently depositing energy into the mean flow causing self, and 'mutual accelerations' between the two waves (when the time dependent acceleration of the mean flow by one wave also acts to accelerate the other wave). Results suggest that time-dependent dynamics are required in order to properly describe these nonlinear wave-wave interactions. Next-generation GCMs will require parameterization schemes that can account for these effects between resolved (medium scale) and unresolved (small scale) gravity waves of relatively fast group and phase velocities.

C2.2-0014-18 IMPLEMENTATION OF A GRAVITY WAVE PARAMETERIZATION INTO A WHOLE ATMOSPHERE GCM AND SIMULATION OF THERMOSPHERIC GRAVITY WAVE EFFECTS

Yasunobu Miyoshi, miyoshi@geo.kyushu-u.ac.jp Kyushu University, Fukuoka, Japan

Erdal Yiğit, eyigit@gmu.edu

George Mason University, Space Weather Lab, Fairfax, VA, Virginia, United States

Using a general circulation model (GCM), the effects of gravity wave (GW) drag on the general circulation in the thermosphere is examined. A whole atmosphere GCM developed by Miyoshi and Fujiwara (2003) is used in this study. A GW parameterization specifically designed for thermospheric heights developed by Yigit et al (2009) is implemented in the GCM. The horizontal resolution of the GCM is 2.8 degrees longitudes by 2.8 degrees latitudes. Therefore, the GW drag in the model is mainly estimated by the GW parameterization. Comparing the results obtained by the GCM with and without the GW parameterization, we first examine the effects of the GW drag on the zonal mean zonal wind and meridional circulation in the thermosphere. Next, the impacts of the GW drag on the upward propagating tides from below. In particular, the interaction between the GW drag and the migrating diurnal and semidiurnal tides is investigated in detail. Our results indicate that the GW drag modulates the vertical and latitudinal structure of the migrating tidal amplitude in the thermosphere.

C2.2-0015-18 MODELING THE QUANTIFIABLE SIGNATURES AND EFFECTS OF GRAVITY WAVES IN THE MESOSPHERE AND LOWER THERMOSPHERE: NONLINEAR EVOLUTIONS AND HYDROXYL AIRGLOW LAYER RESPONSES

Jonathan Snively, snivelyj@erau.edu

Embry Riddle Aeronautical University, Daytona Beach, Florida, United States

Imaging of the hydroxyl (OH) airglow layer provides one of the most promising capabilities to assess gravity wave propagation and processes in the mesosphere and lower thermosphere (MLT). Filtered imaging techniques to derive OH rotational temperature can enable measurements of gravity wave perturbations, for quantification of their energy and momentum fluxes and subsequent effects [e.g., Fritts et al., JGR, 119(24), 2014; Pautet et al., App. Opt., 53(26), 2014]. In this talk, we provide additional modeling basis for the quantitative interpretation of gravity waves in the MLT region. The 3D Model for Acoustic-Gravity wave Interactions and Coupling (MAGIC) [e.g., Snively and Pasko, JGR, 113(A6), 2008; Zettergren and Snively, JGR, 120, 2015, and references therein] is applied to investigate the evolutions of short-period, small-scale gravity wave packets as they impact the MLT at large amplitude under varied ambient conditions. The comprehensive nonlinear evolutions of the gravity waves are simulated from ground to thermosphere, while also capturing their perturbations to major (N2, O2, O) and minor (e.g., H, O3, OH(v)) species and resulting signatures in OH(3,1) emission rate, integrated intensity, and brightness-weighted temperature [e.g., Snively et al., JGR 115(A11), 2010, and references therein]. We assess the quantitative estimation of fluxes and effects from these synthetic data, in comparison with the underlying physical quantities, and find promising agreement using present techniques especially when the ambient atmospheric state can be characterized. We also consider the effects of the simulated gravity waves above the MLT in the thermosphere, with implications for the overlying ionosphere (IT). Results demonstrate new opportunities towards the interpretation of MLT and IT observations using comprehensive numerical simulations.

C2.2-0016-18 TIDES, PLANETARY WAVES, AND ATMOSPHERIC COUPLING

Ruth Lieberman, rlieberm@nsf.gov

National Science Foundation, Alexandria, Virginia, United States

A growing number of studies report linkages between disparate stratospheric and upper atmospheric phenomena. For example, stratospheric warmings correlate with ionospheric perturbations, and with reductions in polar mesospheric cloud occurrence. Understanding these so-called teleconnections is important for ionospheric prediction, and interpreting global change proxies. This presentation will focus on the roles of tides and planetary waves in transmitting tropospheric and stratospheric variability into the thermosphere and ionosphere. I will review several key studies demonstrating strategies that will inform NASA's upcoming ICON and GOLD missions.

C2.2-0017-18 COUPLING BETWEEN TIDAL AND PLANETARY WAVE MODES IN THE MLT-I SYSTEM

Patrick Espy, patrick.espy@ntnu.no

Norwegian University of Science and Technology (NTNU), Trondheim, Norway Nora Stray, nora.stray@teknova.no

Teknova AS, Kristiansand, Norway Robert Hibbins, robert.hibbins@ntnu.no

Norwegian University of Science and Technology (NTNU), Trondheim, Norway

Individual spatial modes from tidal and planetary waves are known to structure the ionosphere. However, wind observations from a single station, even those that image over scales much smaller than these waves, produce a time-series from which only the net period and phase of the total superposed spatial wavenumber components can be derived. Thus, neither the amplitudes of the individual wave modes nor the interactions between them can be observed. While satellite data can give both temporal and spatial components, the time and spatial information is generally not separable without assuming stationarity. Here, hourly mean meteor wind data from a longitudinal chain of 8 high-latitude northern hemisphere SuperDARN radars have been combined in order to provide the spatial tidal and planetary wave components as a function of time. This has been used to extract the migrating and non-migrating components of the semidiurnal tide, as well as the S1 and S2 planetary wave components in the lower thermosphere meridional wind between 1995 and 2016. We find that the semidiurnal tide is dominated by the migrating (W2) component, though substantial W1 and W3 contributions to the semidiurnal tide occur, especially around the equinoxes. Similarly, the S1 planetary wave amplitudes in the northern hemisphere are generally largest, but there are periods where the S2 mode becomes dominant. Due to their large amplitudes in the northern hemisphere, these planetary wave modes can couple into individual tidal components and may enhance their presence in the ionosphere. Data analysis and validation will be presented, together with initial results on the inter-annual variability of the tidal and planetary wave components and their possible coupling to the ionosphere.

C2.2-0018-18 INTERACTION BETWEEN SMALL-SCALE GRAVITY WAVES AND MIGRATING DIURNAL TIDE IN EARTH'S MIDDLE AND UPPER ATMOSPHERE

Erdal Yiğit, eyigit@gmu.edu

George Mason University, Space Weather Lab, Fairfax, VA, Virginia, United States Alexander S. Medvedev, medvedev@mps.mpg.de

Max Planck Institute for Solar System Research, Gottingen, Germany

Gravity (buoyancy) waves (GWs) and solar tides of lower atmospheric origin are important for the energy and momentum budget of the middle and upper atmosphere [Yiğit and Medvedev, 2015]. Here, the effects of subgrid-scale GWs on the diurnal migrating tides are investigated from the mesosphere to the upper thermosphere during equinox, using a general circulation model coupled with the whole atmosphere nonlinear GW parameterization of Yiğit et al. [2008]. Systematical simulations show that GWs appreciably impact the mean circulation and cool the thermosphere by up to 18%. GWs significantly affect the winds modulated by the diurnal migrating tide, in particular, in the low-latitude mesosphere and lower thermosphere and in the high-latitude thermosphere. These effects depend on the mutual correlation of the diurnal phases of the GW forcing and tides: GWs can either enhance or reduce the tidal amplitude. In the low-latitude MLT, the correlation between the direction of the deposited GW momentum and the tidal phase is positive due to propagation of a broad spectrum of GW harmonics through the alternating winds. In the Northern Hemisphere high-latitude thermosphere, GWs act against the tide due to an anticorrelation of tidal wind and GW momentum, while in the Southern high-latitudes they weakly enhance the tidal amplitude via a combination of a partial correlation of phases and GW-induced changes of the circulation. The variable nature of GW effects on the thermal tide can be captured in GCMs provided that a GW parameterization scheme (1) considers a broad spectrum of wave harmonics, (2) properly describes their propagation, and (3) correctly accounts for the physics of wave breaking/saturation [Yiğit and Medvedev, 2017].

Gravity waves (GWs) play a crucial role for the understanding of the circulation in the Earth's atmosphere. The propagation of these waves is strongly affected by the slowly varying background wind, which is modulated by tidal and planetary waves. These large scale waves are also influenced by GWs. Such wave-wave interactions are rarely observed and they are also not adequately implemented in many circulation models. Exceptional weather conditions in May 2016 allowed for an unprecedented 10-day continuous sounding with the daylight-capable Rayleigh-Mie-Raman (RMR) lidar at the midlatitude station Kühlungsborn (54° N, 12° E). The lidar operates independently from daylight conditions and typically provides temperature profiles in an altitude range between 30 and 75km with a temporal resolution of 2h or relative density profiles with 10min resolution. The data set shows a large variability of GWs and tides on time scales of days. GWs and tides are separated using a 1-dimensional spectral filtering technique, and their temporal evolution is studied. During the measurement period a strong 24h-wave is detected mainly between 40 and 60km and vanishes after a few days. The disappearance is related to an enhancement of GWs with periods of 4-8h. Short periodic GWs with periods of a several minutes to 4h are extracted by using the high resolution lidar raw data instead of temperature data. These waves show a similar enhancement during the last days. Wind data provided by ECMWF are used to analyze the meteorological situation above the station. The local wind structure changes during the observation period, which leads to a strong GW activity in the last days of the measurement. The analysis indicates a further change in wave-wave interaction resulting in a minimum of the 24h tide. The observed variability of tides and GWs on timescales of a few days clearly demonstrates the importance of continuous measurements with high temporal and spatial resolution to resolve this short-term variability.

C2.2-0020-18 ATMOSPHERIC GRAVITY WAVE PROPAGATION ACROSS THE STRATOSPHERE, MESOSPHERE, AND THERMOSPHERE OVER ALASKA, AND THE ROLE OF THERMAL GRADIENTS IN THE POLAR REGIONS ON VERTICAL GRAVITY WAVE PROPAGATION

Kim Nielsen, kim.nielsen@uvu.edu

A broad spectrum of atmospheric waves is responsible for transporting energy across atmospheric layers from the troposphere and deep into thermosphere. Recent developments in general atmospheric circulation modeling are allowing for analysis of coupling mechanisms between these atmospheric layers in terms of wave activity. One of the difficulties are implementing the role of small-scale gravity waves with wavelengths less than 100 km and periods in the orders of minutes. These short-period gravity waves are known to be a major contributor to transporting momentum fluxed across atmospheric regions. As these waves propagate vertically through the atmosphere, they are subject to dispersion and dissipation due to varying winds and temperature, as well as eddy diffusion in upper atmosphere and lower thermosphere. A collaborative project between Utah Valley University, University of Alaska, Fairbanks, and Utah State University involved gravity wave measurements in the stratosphere, mesosphere, and thermosphere during the 2011-2014 period. In this presentation, we highlight new results of this study and discuss impacts of mesospheric thermal gradients as observed by SABER on the wave propagation and coupling between atmospheric layers in the Polar regions.

C2.2-0021-18 GRAVITY WAVES GENERATED IN THE IONOSPHERE DURING 21 AUGUST 2017 TOTAL SOLAR ECLIPSE AS SEEN THROUGH GPS-TEC OBSERVATIONS

Chinmaya Nayak, physics642@gmail.com

George Mason University, Fairfax, Virginia, United States Erdal Yiğit, eyigit@gmu.edu

George Mason University, Space Weather Lab, Fairfax, VA, Virginia, United States

The present work investigates ionospheric effects of the 21 August 2017 total solar eclipse, particularly targeting eclipse-generated gravity waves in the ionosphere. Ionospheric total electron content (TEC) derived from Global Positioning System (GPS) data obtained from a number of stations located both along and across the path of eclipse totality has been utilized for this purpose. Distinct gravity wave-like signatures with wave periods around 20-90 min (with dominant peak at 25-30 min wave period) have been observed at all locations both in the path of totality and away from it. The observed gravity waves are more intense at locations closer to the path of totality, and the wave amplitudes decrease gradually with increasing distance from the path of totality. Our result highlights the manifestation of eclipse-generated waves in the variability of the terrestrial ionosphere.

C2.2-0022-18 ON SOME EFFECTS OF UPPER ATMOSPHERE COOLING OVER GWS PROPAGATION

CONICET - Universidad Nacional de Tucuman, San Miguel De Tucuman, Argentina

The study of cooling and trends in general in the upper atmosphere has gained interest since the early 1990's as a consequence of the great concern about the global warming observed in the troposphere. Since then it has become a significant topic in global change investigations. Some research works link these trends to the increase in greenhouse gases concentration, and others to natural causes. Based on many observational and model results a global pattern of trend emerged with the dominant driver of upper atmosphere trends being the increasing concentration of greenhouse gases. At these heights, a cooling effect is expected, and also observed, together with a decrease in neutral concentration. The propagation of gravity waves (GWs) in the thermosphere depends strongly on neutral temperature and total mass density, so changes should also be expected in GW propagation and dispersion characteristics. In order to analyze these changes, a GW ray tracing method, which take into account kinematic viscosity and thermal diffusivity was applied. NRLMSISE-00 and HWM14 models were used to assess the parameters needed for the ray tracing code. As result of decreasing the temperature and neutral density background values, the heights reached by the GWs are lower, as expected from theoretical analysis. Although the assessed variations are small, upper atmosphere cooling effect over GWs behavior are a challenging and topical scientific issue worth of deep study and comprehension which can become more noticeable in the future if the increase in greenhouse gases continues.

C2.2-0023-18 MODELING IONOSPHERIC TEC AND MAGNETIC FIELD SIGNATURES OF LARGE-AMPLITUDE ACOUSTIC AND GRAVITY WAVES GENERATED BY NATURAL HAZARD EVENTS

Matthew Zettergren, zettergm@erau.edu

Embry-Riddle Aeronautical University, Daytona Beach, Florida, United States Jonathan Snively, snivelyj@erau.edu

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Ocean and solid earth responses during earthquakes are a significant source of large amplitude acoustic and gravity waves (AGWs) that perturb the overlying ionosphere-thermosphere (IT) system. IT disturbances are routinely detected following large earthquakes (M > 7.0) via GPS total electron content (TEC) observations, which often show acoustic wave (3-4 min periods) and gravity wave (8-15 min) signatures with amplitudes of 0.05-4 TECU. In cases of very large earthquakes (M > 8.0), persistent acoustic waves are estimated to have 100- 300 m/s compressional velocities in the conducting ionospheric E and F-regions and should generate detectable dynamo currents and magnetic field signatures. Indeed, some recent reports (e.g. Hao et al, 2013, JGR, 118, 6) show evidence for magnetic fluctuations, which appear to be related to AGWs, following recent large earthquakes. Physical processes, including both ionospheric and oceanic dynamos, responsible for generating the magnetic field perturbations are not yet well-understood to the point that we can characterize their dominant physical source mechanisms nor their detailed spatial and temporal structure. TEC responses, while betterunderstood, still cannot be modeled and predicted to the extent necessary to interpret their natural hazard AGW sources.

This work investigates spaceand time-dependent behavior of both TEC and magnetic fluctuations following recent large earthquakes, with the aim to improve physical understanding of these perturbations via detailed, high-resolution, twoand three-dimensional modeling case studies with coupled neutral atmospheric and ionospheric models, MAGIC (Model for AcousticGravity wave Interactions and Coupling) and GEMINI (Geospace Environment Model for Ion Neutral Interactions) as described by Zettergren and Snively (2015, JGR, 120, 9). We focus on the recent 2011 Tohoku-Oki earthquake, which has a well-characterized ocean surface response (e.g. Mikumo et al, 2013,

JGR, 118) and published examples of magnetic field perturbations, and also perform modeling for recent large Chilean earthquakes in 2010 and 2015. AGW sources for MAGIC-GEMINI are chosen, for each event, based on available information from ocean buoy, seismometer data, and TEC data. Simulations reveal the 3D structure of plasma density and currents, and TEC latitude and longitude structure, and provide fundamental insight into the degree to which the ionosphere contributes to magnetic perturbations following natural hazards. Comparisons of simulation results against available TEC and magnetic field data from these events provide evidence supporting the processes identified in these spatially-resolved simulations.

New experiments and results of sensitivity simulations performed with a mechanistic circulation model are presented. The study is focused on possible effects of a localized gravity wave (GW) breaking region on the large-scale circulation and transport and, more generally, a possible influence of the spatial distribution of gravity wave activity on middle atmospheric dynamics. The analysis was originally inspired by Sacha et al. (2015) describing a localized area of enhanced gravity wave activity and breaking in the lower stratosphere of the east Asian-northwestern Pacific region.

The results indicate the important role of the spatial distribution of GW activity for the polar vortex stability, formation of planetary waves, and for the strength and structure of the zonalmean residual circulation. Furthermore, the zonally asymmetric forcing plays an important role in the longitudinal variability of the circulation in general and Brewer-Dobson circulation in particular. The first results were described by Sacha et al. (2016). Here we present results of new experiments that were focused on the impact of various spatio-temporal characteristics of the localized GW activity, and potential coupling with tropospheric climate oscillations like ENSO and NAO.

C2.2-0025-18 A MODELING STUDY OF NON-MIGRATING TIDAL EFFECTS ON IONOSPHERIC STRUCTURE DURING BOREAL WINTER

Sarah McDonald, sarah.mcdonald@nrl.navy.mil

Computational Physics, INC., Springfield, United States

Non-migrating tides of lower atmospheric origin have a dramatic impact on the large-scale longitudinal structure of the low latitude ionosphere. For example, wave-3 and wave-4 features associated with DE2, DE3, DW4, among others, are typically observed in the equatorial ionization anomaly (EIA). Day-to-day ionospheric structure is continually changing due to the varying amplitudes of the non-migrating tides. Studies with coupled atmosphere-ionosphere models have been able to capture such day-to-day variability. Recently, we have used SAMI3 coupled with the Specified Dynamics Whole Atmosphere Community Climate Model, extended version (SD-WACCM-X) to show that the model captures much of the observed day-to-day variability in the ionosphere. We also found that non-migrating tides are modulated during a stratospheric warming period in January 2010. In this study, we extend our modeling studies to simulate three boreal winter seasons (January - February 2010, 2013 and 2016). We characterize non-migrating tidal variability that impacts the ionospheric structure. Specifically, we address whether or not the non-migrating tidal variations we identified in January 2010 are unique to the stratospheric warming event, or simply characteristic of the season. The Navy atmospheric analysis from the High-Altitude Navy Global Environmental Model (HA-NAVGEM) is used to constrain the meteorology of the numerical simulations up to 90 km.

C2.2-0026-18 GLOBAL DISTRIBUTION OF MEDIUM SCALE TRAVELING IONOSPHERIC DISTURBANCES SEEN BY SWARM AND CHAMP SATELLITES

Hyosub Kil, hyosub.kil@jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, United States Woo Kyoung Lee, wklee@kasi.re.kr

Applied Physics Laboratory, Laurel, Maryland, United States

This study investigates the activity of medium-scale traveling ionospheric disturbances (MSTIDs) on a global basis by analyzing the measurements of the electron density and magnetic fields by Swarm and CHAMP satellites. The combination of the CHAMP (2001-2008) and Swarm (2014-2017) observations provides us an opportunity to identify the variation of the MSTID activity during a solar cycle. Because the irregularities produced by MSTIDs are not distinguishable from the irregularities produced by plasma bubbles (equatorial region) and by particle precipitation or horizontal plasma convection (high latitudes), our investigation focuses on the MSTID distribution in middle latitudes. Several studies derived the MSTID distribution from satellite observations, but notable discrepancies exist among the results derived using different parameters. Our study determines the appropriate parameters for the detection of MSTIDs from satellite observations by comparing with ground-based observations. We report the variation of the MSTID activity with local time, season, latitude, magnetic activity, and solar cycle and use this knowledge for the identification of the onset condition of MSTIDs.

C2.2-0027-18 WAVE DYNAMICS OF THE WHOLE ATMOSPHERE MODELS: TIDAL VARIABILITY AND ITS EFFECTS IN THE ITM

The paper presents comparative analysis of tidal variability, as simulated by two whole atmosphere models, WAM and WACCM-X, constrained by the meteorological analyses of NASA/GMAO in the troposphere and stratosphere. Both models with the meteorology of the lower atmosphere reproduce the main features of the day-to-day, annual and year-to-year variability of diurnal and semidiurnal tides, as deduced from the multi-year (2009-present) space-borne observations and middle atmosphere data assimilation case studies. As observed and simulated by models, the March-April semiannual maxima of the 24-hr tidal amplitudes and their strong quasi-biennial modulations can represent a good illustration for strong wave coupling and interactions of tidal and gravity waves with prevailing flow in the equatorial middle atmosphere. Sensitivity of the mean flows and tides simulated by WAM and WACCM-X to the model gravity wave physics will be highlighted. The influence of the mid-winter Arctic sudden stratospheric warming dynamics on the global tidal structures and the low-latitude anomalies of electrodynamics and plasma transport will be discussed and compared with the data.

C2.2-0029-18 QUASI-6 DAY PLANETARY WAVES AND UPPER ATMOSPHERIC EFFECTS

Yosuke Yamazaki, yamazaki@gfz-potsdam.de

GFZ German Research Centre for Geosciences, Potsdam, Germany Claudia Stolle, cstolle@gfz-potsdam.de

University of Colorado, Boulder, Boulder, United States

The ionosphere is under the influence of various forcing mechanisms and its electrodynamic state varies significantly from day to day. This ionospheric variability results not only from solar radiation and magnetospheric forcing, but also from atmospheric waves that propagate to the ionosphere from the lower layers of the atmosphere. Previous studies mainly focused on the role of atmospheric tides, which have large amplitudes (several 10 m/s) in the dynamo region of the ionosphere (90-150 km). At dynamo region heights, tidal winds serve as a source of ionospheric variability, as they drive electric fields and currents. Similar ionospheric effects may be expected from planetary waves, Kelvin waves, and gravity waves, which can also partly penetrate into the dynamo region. In this light, we examine the variation of the equatorial electrojet derived from the magnetic field measurements by the Swarm and CHAMP satellites. The equatorial electrojet is a relatively strong zonal ionospheric current flowing along the magnetic equator at approximately 110 km. Case studies are presented, in which the equatorial electrojet intensity at a fixed longitude shows an oscillatory variation with a period of approximately six days. We discuss the possible contribution of the quasi-6 day planetary wave.

C2.2-0030-18 HORIZONTAL WIND'S FACTOR IN FORMATION OF SPORADIC E UNDER INFLUENCE OF ATMOSPHERIC WAVES

Goderdzi Didebulidze, didebulidze@iliauni.edu.ge

E Kharadze Abastumani Astrophysical Observatory, Ilia State University, Tbilisi, Georgia Giorgi Dalakishvili, giorgi.dalakishvili@iliauni.edu.ge

Ilia State University, Tbilisi, Georgia Lekso Toriashvili, ltoriashvili@gmail.com Ilia State University, Tbilisi, Georgia

An importance of meridional and zonal background wind for formation the sporadic E under the influence of atmospheric gravity waves (AGWs) and shear excited vortical type perturbations (shear waves) are considered. It is shown, that the mid-latitude northward horizontal wind influences downward motion of the long-lived heavy metallic ions (e.g., Fe+) and can cause their density increase at lower thermospheric heights, where their vertical diffusive displacement is comparatively smaller. In the similar way, the combined action of ions collision with zonal neutral wind particles and Lorentz Forcing also influence on the ions vertical drift, which can provide an additional convergence or divergence of their density at mid-latitude and equatorial regions as well. The values of northward wind velocity providing the ions vertical convergence into a horizontal layer and the location of region of additional convergence under influence of zonal wind are estimated. It is shown that AGWs along with horizontal homogeneous/inhomogeneous wind can cause additional convergence of ions and formation multilayered sporadic E. The numerical results describing formation sporadic E under an influence of horizontal wind and its multilayered structure caused by the declined propagation AGWs and shear waves are demonstrated. Acknowledgement: This study is supported by Georgian Shota Rustaveli National Science Foundation Grant no. FR17-357.

C2.2-0031-18 INVESTIGATION ON 15-DAYS OSCILLATIONS IN THE EQUATORIAL SPREADF

An intensive study on the start time of equatorial plasma bubble, observed by an all sky imager deployed at São João do Cariri (7.4°S, 36.5°W), and equatorial spread-F, observed by a coherent back scatter deployed at São Luís (2.5°S, 44.2°W) was conducted from 2001 to 2009. Oscillation of 14.5 days was clearly observed in three month (September 2003, October 2005 and January 2008) in the airglow images with amplitudes of 45-60 min. Furthermore, using the data from the radar range time integration (RTI) maps, several events were observed with dominant period of 14.5 days in September 2001, November 2002, January-February 2003, October-December 2005 and November 2008. In such case, the amplitudes of the oscillations were from 3 min up to 60 min. This oscillation could be related to the semidiurnal lunar tide, which appear as an important contributor to the time of occurrence of equatorial spread-F.

C2.2-0032-18 COMPARISON OF ATMOSPHERIC FIELDS IN THE TROPICAL UPPER STRATOSPHERE AND LOWER MESOSPHERE BETWEEN MULTIPLE REANALYSIS DATA

Several kinds of meteorological reanalysis data have been used for climate and atmospheric science studies. Their accuracy and reality depend on the forecast model and data assimilation method used therein, but they have never been quantitatively evaluated. In order to overcome this problem, the SPARC Reanalysis Intercomparison Project (S-RIP), which is a coordinated activity to compare all reanalysis data sets, was established in 2012. In this presentation, we will introduce an S-RIP activity on the evaluation of atmospheric fields in the tropical upper stratosphere and lower mesosphere.

C2.2-0033-18 SIMULATING MSTIDS GENERATED FROM TROPOSPHERIC WEATHER

Katherine Zawdie, kate.zawdie@nrl.navy.mil

Naval Research Laboratory, Washingto, District of Columbia, United States Sarah McDonald, sarah.mcdonald@nrl.navy.mil

Naval Research Laboratory, Washington, District of Columbia, United States Stephen Eckermann, stephen.eckermann@nrl.navy.mil

Naval Research Laboratory, Washington, District of Columbia, United States Fabrizio Sassi, fabrizio.sassi@nrl.navy.mil

Naval Research Laboratory, United States

It is well known that gravity waves generated from deep convection and jet instabilities can propagate into the ionosphere and generate structures such as Medium Scale Traveling Ionospheric Disturbance. (MSTIDs). In this study, a high resolution, first-principles ionosphere model, SAMI3/ESF is driven by new specifications of the neutral atmosphere that include forcing from below to quantify the effect of the wave perturbations on the ionosphere. Gravity waves predicted by an extended altitude version of the Navy's mesoscale numerical weather prediction system, COAMPS (Coupled Ocean-Atmosphere Mesoscale Prediction System) are propagated to ionospheric altitudes using gravity-wave ray models. The perturbed thermospheric gravity wave fields are used to examine the effects of the neutral density, temperature and wind gradients on the ionosphere.

C2.2-0034-18 RECENT RESULTS ON THE WAVE CHARACTERISTICS IN THE LOW-LATITUDE UPPER ATMOSPHERIC REGION OBTAINED BY OPTICAL AND RADIO TECHNIQUES

Duggirala Pallamraju, raju@prl.res.in

Physical Research Laboratory, Ahmedabad, India Subir Mandal, subir@prl.res.in

Physical Research Laboratory, Ahmedabad, India Deepak Karan, deepak@prl.res.in

Physical Research Laboratory, Ahmedabad, India Ravindra Pratap Singh, ravindra@prl.res.in Physical Research Laboratory, Ahmedabad, India

The importance of neutral wave dynamics in the upper atmosphere is well-known. Recent results of optical emission measurements obtained over large spatial extents (latitudes/ longitudes) and multiple wavelengths yielded information on different aspects of horizontal and vertical coupling in the low-latitude upper atmospheric regions. Some of the results include deriving the first three dimensional wave characteristics in the daytime, obtaining their propagation characteristics during geomagnetic quiet and disturbed conditions, and their dependence on the equatorial driving sources. These results were obtained through measurements of oxygen dayglow emissions at 557.7, 630.0, and 777.4 nm that originate from around 130, 230, and 300 km, respectively. These measurements were enabled by a high spectral resolution imaging spectrograph operating from a low-latitude location, Hyderabad (Geographic: 17.50 N, 78.50 E; Geomagnetic: 8.60 N, 151.80 E), in India. This spectrograph enables information on these three daytime airglow emission intensities simultaneously over a large FOV. New insights on the coupling aspects in the equatorialand low-latitude regions obtained from these investigations will be presented. While such measurements of neutral wave characteristics are conventionally obtained using optical airglow emissions in both the day and nighttime, as the thermospheric waves affect the ionospheric species as well, in this paper we will also describe the use of a radio technique that provides information on the thermospheric wave behaviour. This technique is used to derive neutral wave characteristics in the ionosphere-thermosphere region.

C2.2-0035-18 ESTIMATION OF THE QBO FORCING OF EQUATORIAL WAVES USING THE TIMED/SABER DATASET

Zeyu Chen, z.chen@mail.iap.ac.cn

Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing, China

The Equatorial quasi-biennial oscillation (QBO) is driven by the wave-drag of the equatorial waves. In this work, the temperature data collected by the SABER/TIMED mission in 2002- 2016 are used to investigate the equatorial waves activities. The Fast Fourier Synoptic Mapping (FFSM) method is applied to delineate planetary wave components with the zonal wavenumber spanning over -6 to +6, hereby, positive (negative) wavenumber is assigned to westward (eastward) propagating waves. The vertical shear of zonal wind is derived by using the rawinsonde data at Singapore. Results show that in height range 70-10 hPa, Kelvin waves of wavenumber 1 to 3 are prominent. At 50 hPa level, wave 1 component exhibits amplitude spectral peak at three kinds of period, 8, 11 and 20 day. Meanwhile, shifting to shorter period is seen in amplitude spectra as wave number increases,for example, the 20-day period spectrum is attenuated substantially for wave 2 and wave 3 components. Although with small amplitude, mixed Rossby-gravity waves of wavenumber 4 and 5 with shorter periods of 4-7 days are discernable. Zonal forcing of the Kelvin waves attains maxima along with the downward propagation of the maximum positive shear zone (corresponding to that the Westerlies are above the Easterlies), the magnitude is 0.1 m/s/ day. Contrast to the Kelvin waves, the mixed R-G wave activity is substantially weak.

C2.2-0036-18 A RECORD BREAKING DURATION OF THE EASTWARD PHASE OF THE STRATOSPHERIC QBO AT 20 HPA: SOME NEW INSIGHTS INTO THE RECENT QBO DISRUPTION

Kishore Kumar Karanam, kishore_nmrf@yahoo.com Indian Space Research Organization, Trivandrum, India Sneha Susan Mathew, snehamavila@yahoo.com

Indian Space Research Organization, Thiruvananthapuram, India

K.V. Subrahmanyam, kv_subrahmanyam@vssc.gov.in

Space Physics Laboratory, VSSC, ISRO, Trivandrum, Trivandrum, India

The equatorial stratospheric interannual variability is dominated by the presence of the Quasi Biennial Oscillation (QBO), which is a spectacular long-period oscillation with the alternating eastward and westward winds every year in the 20-40 km height domain. The period of the QBO varies between 22-36 months with mean period of 28 months. In the present communication, a recorded breaking duration (23 months) of the eastward phase of the QBO at 20 hPa is reported and details of the tropical wave activity during the recent anomalous QBO (2015/2016) are discussed. The Modern-Era Retrospective analysis for Research and Applications-Version 2 (MERRA-2) reanalysis dataset has been used for the present study along with radiosonde observations over Singapore (1.350 N, 103.810 E). A detailed analysis of day-to-day variability of zonal winds revealed that the deceleration of eastward winds at 40 hPa started in the month of November, 2015. The zonal wind perturbations have revealed the presence of eastward propagating waves with 10-12 day time period during JulyAugust 2015 and a long period westward propagating oscillation with 30-40 day time period and zonal wave number 1 from November, 2015 onwards. These results are confirmed using two-dimensional Fourier analysis, which also revealed the presence of westward propagating 10-15 day waves. The time evolution of 30-40 day oscillation provided a clue on the sustainable forcing observed during the QBO disruption event. A combination of the mid-latitude Rossby waves and the 30-40 day oscillations seems to be most probable mechanism for observed disruption of the QBO. However, the uniqueness of this combination and the interaction between the 30-40 day oscillations and midlatitude Rossby waves over the tropics are yet to be investigated. The significance of the present study lies in reporting the record breaking duration of the eastward phase of the QBO at 20 hPa and providing new insights in to the recent QBO disruption.

C2.2-0037-18 POSSIBLE "TROPICAL CYCLONES -IONOSPHERE" COUPLING MECHANISMS

Liudmila Vanina-Dart, vandart@seeingear.org

(1) The Seeingear LTD, Battle, United Kingdom (vandart@seeingear.org), (2) Space Research Institute RAN, Moscow, Russia, St Leonards On Sea, United Kingdom

The objective of this topic is to put new facts into understanding of the coupling processes in the atmosphere-ionosphere system during the tropical cyclone (TC) action. Advanced international investigations of the correlation between tropical cyclones (TCs) and the ionosphere are connected with extreme difficulties of proving the action of possible mechanisms of TC (greatest troposphere hazard) effect on the ionosphere. There are two of the possible "TC-Ionosphere" coupling mechanisms - the Gravity Waves and the electric. GWs generated at tropospheric altitudes propagate to the F-region. Middle atmospheric dynamics, and particularly atmospheric waves, play a leading role in determining the variability of the atmosphere-ionosphere system. GWs generated from storms break near 100 km and produce secondary waves that continue to propagate upward GWs modulate the E-region plasma producing polarization fields that map to F-region altitudes. Strong convection cells produce a wide spectrum of GWs. GWs increase in amplitude within creasing altitude and may become unstable. Only waves propagating at the certain angles and with the correct amplitude can reach thermospheric altitudes. Once in the thermosphere, only those waves oriented to the magnetic field in a particular manner may produce ionospheric disturbances (dr.Rebecca Bishop, PSL/SSAL, 30 March 2012). An effect of external electric currents on the global atmosphere-ionosphere electric circuit may be one of possible mechanisms of interaction between atmospheric and ionospheric components. External currents with a horizontal scale of about one hundred of kms may be related to the vertical large - scale convection of the cloudy atmosphere in the zone of a TC and to the charge separation in this region. The electric field disturbance arises due to perturbation in the atmosphere - ionosphere electric circuit generated by the upward transport of charged water drops and aerosols in TC convection zone (Sorokin et al, 2005). In this paper authors analyze the ionospheric data from South hemisphere during TC action for the last century years.

Sorokin, V., Isaev, N., Yaschenko, A., Chmyrev, V., Hayakawa, M., 2005. Strong DC electric field formation in the low latitude ionosphere over typhoons. J. Atmos. Sol. Terr. Phy. 67 (14), 1269 - 1279.

C2.2-0038-18 EXCITATION OF ZONAL FLOW AND MAGNETIC FIELD BY FINITE-AMPLITUDE COUPLED ELECTROMAGNETIC PLANETARY WAVES IN THE E IONOSPHERIC REGION

Laila Kahlon, lailakahlon192@gmail.com

FC College (A Chartered University) Lahore, Lahore, Pakistan Tamaz Kaladze, tamaz_kaladze@yahoo.com

GC University, Lahore, Pakistan

The excitation of zonal flow and magnetic field by finite-amplitude coupled electromagnetic (EM) planetary waves in the Earth's E ionospheric region is reviewed. Coupling of diverse EM low-frequency electromagnetic modes under the typical conditions of ionospheric E layer is revealed. Propagation of different coupled internal-gravity-Alfvén (CIGA), coupled RossbyKhantadze (CRK) and coupled Rossby-Alfvén-Khantadze (CRAK) waves is shown and studied. Appropriate nonlinear equations describing the interaction of such waves with sheared zonal flow is derived. The instability of short wavelength turbulence of such coupled waves with respect to the excitation of low-frequency and large-scale perturbation of the sheared zonal flow and sheared magnetic field is inferred. This nonlinear instability's mechanism is caused by the parametric excitation of triple finite-amplitude coupled waves leading to the inverse energy cascade towards the longer wavelength. The possibility of the intense mean magnetic field's generation is shown. The obtained growth rates are discussed for each considered coupled waves.

C2.2-0039-18 IONOSPHERIC F2 REGION VARIABILITY ASSOCIATED WITH SUDDEN STRATOSPHERIC WARMINGS

Sumedha Gupta, sumedha88@gmail.com

National Physical Laboratory India, New Delhi, India Arun Kumar Upadhayaya, upadhayayaak@nplindia.org National Physical Laboratory India, New Delhi, India

The ionospheric F2 region response to sudden stratospheric warming (SSW) has been extensively analyzed for the major event of year 2009, apart from a few reports on other major and minor events. Morphology of ionospheric response during SSW can be better comprehended by analyzing such warming events under varying solar, geomagnetic, and meteorological conditions. In view of this, we investigate the features of F2 region variability following the SSW events of 2010, 2011, 2012, 2013, 2014, 2015, and 2016, using ionosonde data from the Asian region covering a broad latitudinal range from 26.6°N to 45.1°N. We find perceptible ionospheric variations in electron densities during these warming events which is accompanied by a large variation of 117% within enhancements, as compared to a meagre variation of 11% within depressions, during these events. Further, the maximum and minimum variations in F2 layer critical frequency are observed during each SSW period when analyzed for six months. The influence of quasi-stationary 16-day planetary waves is seen during these SSW events. It is also found that a recently proposed parameter, "SSW integrated strength" by Vieira et al. (2017), to characterize SSW event with respect to ionosphere, does not fit well for these seven SSW events at these latitudes and longitudes.

C2.2-0040-18 GLOBAL IONOSPHERIC RESPONSE TO SUDDEN STRATOSPHERIC WARMING EVENTS

Irfan Azeem, iazeem@astraspace.net

ASTRA LLC., Boulder, Colorado, United States

Recent studies have shown variations in the low latitude ionosphere that are linked to Sudden Stratospheric Warming (SSW) events. Although previous studies have provided important information on the ionospheric response to SSW events, they have been fairly localized. Therefore, broader observational capabilities and data are required that can unambiguously reveal the instantaneous global response of the ionosphere to SSW events. In this paper, we present results from the Ionospheric Data Assimilation Four-Dimensional (IDA4D) algorithm to describe a global view of the ionospheric variability during the Northern Hemisphere SSW events in 2009, 2010, and 2013. We will present the dynamical response of the ionosphere to SSWs and the global structure of lunar semi-diurnal tides in the ionosphere during these events. We will show the ability of the data assimilation technique to successfully delineate a time-dependent structure of the lunar semidiurnal tide in the ionosphere during SSW events. These results enable us to identify the evolution, on a global scale, of the enhanced lunar semi-diurnal tides during SSWs.

C2.2-0041-18 PLANETARY WAVE-GRAVITY WAVE INTERACTIONS DURING MESOSPHERE TEMPERATURE INVERSION EVENTS OVER TROPICS (10°N-15°N)

ABSTRACT

The nightly temperatures from Rayleigh lidar and TIMED-SABER (Thermosphere Ionosphere Mesosphere Energetics and Dynamics - Sounding of Atmosphere by Broadband Emission Radiometry) observations show a few large mesospheric inversion layer (MIL) events at 75-85

km during 20-26 January 2007 over a tropical region, Gadanki (13.5°N, 79.2°E). The MIL

amplitudes in SABER temperature averaged for 10°N-15°N and 70°E-90°E show a clear 2 day modulation during 20-26 January 2007. The two dimensional spectrum of SABER temperatures confirms the dominant presence of 2-day planetary wave (PW) with zonal wave numbers, k=2, 3 at inversion height. It is evident from the wavelet spectrum of SABER temperatures that the 2-day wave propagates with increasing amplitudes and dissipated in the MIL region above 80 km. Further the FFT spectrum of lidar temperatures show the gravity wave (GW) activity with periods 18 min, 38 min, 38 min, and vertical wavelengths 6.4 km, 4.0 km, 6.4 km respectively on 20, 22, and 24 January 2007. The eddy diffusion due to the GW breaking could cause the MILs between 75 km and 85 km. Further eddy momentum flux of 2-day PWs and drag forces of GWs are calcualted using medium frequency radar winds over (8.7°N,77.8°E). It is inferred that the MILs are caused mainly due to gravity wave breaking and the inversion amplitudes got modulated by the background 2-day PW. Further the eddy diffusion associated with the gravity wave force drag caused the suppression of 2-day planetary wave in the inversion region.

C2.2-0042-18 SOLAR AND LUNAR TIDAL VARIABILITIES IN GPS-TEC AND GEOMAGNETIC FIELD VARIATIONS: SEASONAL AS WELL AS DURING THE SUDDEN STRATOSPHERIC WARMING OF 2010

Sridharan Sundararajan, susridharan@narl.gov.in National Atmospheric Research Laboratory, Pakala, India

The Global Positioning System (GPS) deduced total electron content (TEC) data at 15°N (geomagnetic), which is the northern crest region of equatorial ionization anomaly, are used to study solar and lunar tidal variabilities during the years 2008 and 2009 and also during the 2009-2010 winter, when a major sudden stratospheric warming (SSW) event has occurred. The diurnal and semidiurnal tidal amplitudes show semiannual variation with maximum amplitudes during February-March and September-November, whereas terdiurnal tide is larger during April-September. They show significant longitudinal variability with larger (smaller) amplitudes over 250°E-150°E (200°E-250°E). Lunar semidiurnal tidal amplitudes show sporadic enhancements during northern winter months and negligible amplitudes during northern summer months. They also show notable longitudinal variabilities. The solar migrating tides DW1 and SW2 show semiannual variation with larger amplitudes during spring equinox months, whereas TW3 maximizes during northern summer. DW2 shows larger amplitudes during summer months. During the SSW, except TW3, the migrating tides DW1 and SW2 show considerable enhancements. Among solar nonmigrating tides, SW1, TW2, and DS0 show larger enhancements. Solar tides in TEC and equatorial electrojet strength over Tirunelveli vary with the time scale of 60 days during October 2009-March 2010 similar to ozone mass mixing ratio at 10 hPa, and this confirms the vital role of ozone in tidal variabilities in ionospheric parameters. Lunar tidal amplitudes in changes in horizontal component of geomagnetic field (H) are larger over Tirunelveli, a station near dip equator. Solar semidiurnal tides in H have larger amplitudes than lunar tides over polar stations, Mawson and Godhavn.

C2.2-0043-18 NEAR-INFRARED CAMERA OBSERVATIONS OF MESOSPHERIC GRAVITY WAVES IN PATAGONIA

Airglow imaging has been widely used for the detection of gravity wave in the upper atmosphere since the 1990s owing to the development of highly sensitive charge-coupled device detectors. This imaging technique is useful for investigating the two-dimensional horizontal characteristics of small-scale (horizontal wavelength less than 100 km) gravity wave motions in the mesosphere and lower thermosphere (MLT). Gravity waves are known to contribute greatly to MLT dynamics through their dissipation, which is accompanied by the momentum transfer into the MLT mean flow.

The ANtarctic Gravity Wave Instrument Network (ANGIWN) project has started in 2011 to understand gravity waves over the Antarctic and the effects on general circulation. It is known that the southern Andes is a hot spot of gravity waves and would also contribute significantly to the dynamics in the upper atmosphere in the southern hemisphere. We installed an all-sky airglow camera in November 2017 at Rio Gallegos station (51.6S, 69.3W), Patagonia, Argentina, as an extension the ANGWIN network. The Patagonia camera has an InGaAs array sensor, which is sensitive to the near-infrared (900-1700 nm), and can image OH Meinel band airglow (height: 85 km) without interference filter, obtaining an OH airglow image every 5 s with an exposure time of 2 s. The system is similar to the imagers of ANGWIN network at Davis,

McMurdo, Halley, Syowa and the south-pole. We expect that the airglow imaging at this site would contribute to reveal the characteristic of gravity waves generated around the hot spot at Andes and Antarctic Peninsula.

In this presentation, we will share details of the airglow imaging observation in Patagonia and some initial results.

C2.2-0044-18 EFFECTS OF HORIZONTAL WIND STRUCTURE ON THE GRAVITY WAVE ENERGY IN THE UPPER STRATOSPHERE OVER SYOWA, THE ANTARCTIC

Gravity waves (GWs) transport their momentum and energy from the lower atmosphere to the upper atmosphere and drive the general circulation, which significantly changes the temperature in the middle atmosphere [Fritts and Alexander, 2003]. To understand this role quantitatively will improve the modern general circulation models. GW activities and its seasonal variations have been studied at various places all over the world. Nowadays, some studies have shown global maps of the typical activities from satellite observations. However, what causes a shorter temporal and local variations of the activities are poorly understood, especially above the upper stratosphere.

To understand this cause, we estimated the potential energy of GW (Ep) over Syowa Station (69°S, 40°E) from a Rayleigh/Raman (RR) lidar observation between 2011 and 2015. We found a clear enhancement of the Ep during 8th-21st August 2014. The Ep values in this period were about two and five times as large as the winter mean in the other years at 50 and 60 km, while the ones between 20 and 40 km were as small as the winter mean. One of possibility is that some source would exist around 45 km, but there seemed no specific source within the Modern-Era Retrospective analysis for Research and Applications (MERRA) [Rienecker et al., 2011]. The second one is that the GWs would converge from the lower atmosphere at various latitudes due to the meridional gradient of the westerly wind [Dunkerton, 1984]. The polar night jet around

40°E during the enhancement period slanted to 70°S from 50°S and the gradient was larger. In such condition, the GWs with west-ward wavenumber can converge to Syowa. We estimated paths of GWs in order to examine whether the GWs could converge to Syowa. The estimation shows that the large-scale GWs could converge to 50-55 km altitudes over Syowa in that period. We conclude that the

enhancement could be caused by the convergence of the GWs. In this presentation, we will show the potential energy, the wind field and the paths of the GWs during the enhancement period, and highlight an importance of the wave's horizontal propagation.

Ionospheric seismology, which was at most seen as an exotic way to record doubtful signals in the early 2000 has gain maturity, especially after the worldwide observations made during the Tohoku 2011 earthquake and tsunami. These ionospheric signals have been detected by a variety of technics: GPS, Doppler sounders, Over-the-horizon radars and airglow camera from either ground instruments or spaceborne instruments. In many cases, these observations systems are by nature dual, offering both scientific and security/defense applications. We compare and illustrate the different observation techniques available today, with a focus on ground, air-based and space-based GPS measurement and airglow and illustrate the later with data recorded during the Tohoku 2011

and Haida Gwai earthquake and tsunamis. We then discuss the physics enabling the conversion of seismic waves into electron perturbation (for GPS data) and light emission (for airglow). This allow us to model these signals and to discuss the sensitivity of the coupling between seismic or tsunami waves and acoustic or gravity waves to the atmosphere structure, the subsurface and crust structure, the ocean thickness and local time, ionospheric state and magnetic latitude. We then show that these signals can already be inverted and used to predict with very high accuracy the amplitudes of tsunami at the sea level and a characterization of the seismic source of large earthquake, enabling important perspective for the future improvement of the global and regional tsunami warning systems.

C2.2-0046-18 IONOSPHERIC TILT MEASUREMENTS AS A PROXY OF TID CLIMATOLOGY AND CHARACTERISTICS

Ionospheric vertical incidence sounders are capable of measuring ionospheric "tilts", which are a measure of horizontal gradients in the ionosphere. Digisondes routinely make skymap measurements, which represent a set of angles of arrival for each reflection point of the ionosphere, from which tilts are derived by computing a representative "mean" point of reflection of HF waves. We illustrate the reliability of the digisonde tilt measurements by comparing the expected angles of arrival (AoA) measurements calculated using simple "mirror model" as well as 3D raytracing to the real AoA measurements on a corresponding HF link. The accuracy of the AoA prediction and sources of errors are discussed. Digisonde at Ebro Observatory in Spain routinely measures ionospheric plasma drift and tilts. Analysis of the tilt measurements made in 2012-2015 is presented. Spectral analysis with Lom-Scargle method is used to identify the presence and exact periods of the wavelike disturbances that we associate with the Travelling Ionospheric Disturbances (TIDs). The tilts are represented in terms of North-South and East-West components with the biases and daily trends removed. Using several years of observations a climatological distribution of the TIDs is established. Most of the TIDs occurrence is determined by the solar terminator passage and the most frequently observed periods are from 30 min to 1.5 hour. These characteristics are typical for middle-scale TIDS (MSTIDS). Summertime appears to have the most frequent occurrence of the disturbances in the tilts. Variations in tilt intensity appear to moderately increase with the increase in solar activity and geomagnetic disturbances. Direction of propagation is also analyzed and compared to the neutral wind direction calculated with the TIEGCM model. There is a noticeable correlation between the two, although the agreement is not perfect. This is also an indication that most of the observed TIDs originate in the troposphere. We also present a comparison of the ionosonde tilts and those derived from the GNSS TEC measurements and discuss under what conditions the latter ones are reliable.

Gravity waves transport momentum and energy from the lower atmosphere to the upper atmosphere, and drive the general circulation, which significantly changes the temperature in the middle atmosphere [Fritts and Alexander, 2003]. Understanding this role quantitatively will improve the modern general circulation models.

The polar night jet is known to contain regions of high gravity wave (GW) activity. However, their source, propagation and intermittency are only poorly understood because of a lack of observations. To understand their source and propagation, our group has observed the gravity waves over Syowa (69°S, 40°E) using some instruments (e.g., lidar, OH imager and MF radar). We also compared the gravity waves over Syowa and Davis (69°S, 79°E), at which terrain and meteorological conditions are similar, to investigate their horizontal variation over the east Antarctic. We found, from the lidar temperature observations, that the vertical profile of gravity wave potential energy is similar between Syowa and Davis, except for a clear enhancement around 30-40 km over Davis [Kogure et al., 2017]. Horizontal propagation characteristics are more clearly observed by airglow imaging measurements of 90 km altitude. The comparison of four imagers' results between April-May 2013 have indicated that the major propagation directions were westward at three station (Syowa, McMurdo, Halley), but at Davis GWs seems to propagate all the directions, which is totaly different from the other three. [Matsuda et al., 2017]. It seems like the GWs over Davis did not experience the same wind filtering in the middle atmosphere.

The goal of this study is to compare the gravity waves over Syowa and Davis in many different ways and with more observational data. In this presentation, we will show the ground-based horizontal phase speed spectrum over the two stations derived from OH imagers in more detail. We analyzed the OH airglow imager data obtained for eight months (from March to October in 2016) over the two stations with M-transform [Matsuda et al., 2014]. We analyzed the data without clouds and aurora contaminations continuously for at least one hour. The numbers of nights with such data sets are 40 at Syowa and 55 at Davis. The seasonal variations of the nightly mean variance were very similar with winter maximum, but the variance over Syowa was significantly larger than that over Davis in September. The reason for a larger variance over Syowa in September was the existence of southward propagating gravity waves with the phase speed of 10 - 80 m/s. In 2016, clear sky and aurora free data were available at both station on ten nights. Comparison of phase velocity spectra obtained on the same night showed similarity on only one night out of ten. On five nights, the spectra were quite different. On the other four nights, the spectral peaks with slow westward phase velocity (> 50 m/s) were commonly observed but additional spectral peaks were found over Davis and not over Syowa. We calculated transmission diagram, which indicates the GW phase speeds for which a GW would encounter turning and critical level [Tomikawa, 2015], and we found that the diagrams over both stations were similar. These results suggest that the difference was not caused by wind filtering or reflection. We will show these spectra and transmission diagrams, and discuss what causes the different spectra. We will, moreover, present paths of gravity waves and discuss where the gravity waves were generated.

C2.2-0048-18 SIMULATION RESULTS AND PERFORMANCE ANALYSIS OF PHASE VELOCITY SPECTRAL ANALYSIS SOFTWARE (M-TRANSFORM) FOR AIRGLOW IMAGING DATA

National Institute of Polar Research, Tachikawa,Tokyo, Japan

Airglow imagers have been deployed in various locations to study the atmospheric gravity waves (AGWs) in the last few decades, which provide a huge amount of data. This groundbased imaging observation has been proven to be very effective to study energy and propagation characteristics of AGWs. However, the lack of sophisticated analysis methods prevented quantitative studies using huge data that have been collected over such long period of observation. Matsuda et al. [2014] developed a new phase velocity spectrum analysis method based on 3D FFT algorithm (M-transform) to address this issue. This algorithm can efficiently deal with extensive amounts of imaging data without bias and treat dynamical/physical effect of AGWs by precisely reflecting amplitude, area and lifetime of each AGW event. Based on Matsuda et al. [2014] method, we have developed a simple and user-friendly function to be used in IDL. The input of this program is a three dimensional array of a time series of 2-D image array where the wave parameters (e.g. horizontal wavelength (h), wave period (), phase speed (c), image resolution in space (dx, dy) and time (dt)) can be customized by the user in one-line command to execute the program. Various simulations by using artificial wave images as test data have been done in order to exhibit the new program's performance and the characteristics/interpretation of the spectral analysis. The simulation was done by using test data with different time resolution (dt=1 min, 3 min, 5 min and 7 min), image size (256x256, 512x512), duration (30 min, 60 min, 90 min, 120 min) and by changing the horizontal wavelength and wave periods with a fixed phase speed (40 m/s). In addition, by using observational data from Syowa station we conducted an investigation how waves with different horizontal wavelengths behave independently. We divided the horizontal wavelength into three categories: 5< h <20 km, 20< h <100 km and 5< h <100 km. We found that propagation direction for small scale, close to ripple scales (5< h <20 km), showed omni-directional feature, as previously suggested by Nakamura et al. [1999]. Beside the detail discussion on the simulation results and performance test, this presentation also aims to guide how to use the program within a practical computation time.

The atmospheric lunar tide is excited by gravitational action in the lower atmosphere and by the movement of the oceans and Earth's surface. Due to the fact that the source of the lunar tide does not change, the determination of this oscillation in the ionosphere is an excellent tool for understanding the coupling mechanism between the neutral and ionized atmospheres. The lunar tide has been studied in the mesosphere-thermosphere-ionosphere in different longitudinal sectors and using different observational techniques and simulations. However, there are some aspects of lunar tide that still need explanation, for example, the temporal variability of this oscillation. So, in this work, the diurnal and semidiurnal lunar tides are investigated in the ionosphere using ionosonde data over Brazil. The ionosonde measurements were collected at Cachoeira Paulista (22.7° S; 45.0° W) and São Luis (2.6° S; 44° W) from 2001 to 2009 with a temporal resolution of 15 minutes. Using these data, it was possible to extract the characteristics of the lunar tide. Salient features of this oscillation are presented and discussed in this work. For instance, the semidiurnal lunar tide is dominant comparing to the diurnal tide and had amplitude of 0.6 MHz in foF2 and 7 km in hmF2.

C2.2-0050-18 LIGHTNING INDUCED IRREGULARITIES IN THE LOWER IONOSPHERE, MEASURED BY GLOBAL NAVIGATION SATELLITE SYSTEM

Yaser Rahmani, yaserrahmani@email.kntu.ac.ir K.N.Toosi University of Technology, Tehran, Iran M.Mahdi Alizadeh, alizadeh@kntu.ac.ir

K.N.Toosi University of Technology, Tehran, Iran

Atmosphere is divided into two layers with respect to electrical charge of the medium; namely Troposphere from above the Earth surface up to approximately 60 km altitude and Ionosphere from 60 to 1000 km and higher altitudes. There are some interactions between these two layers, which are referred to as Troposphere/ Ionosphere coupling. Lightning is an electrical discharge that occurs within Troposphere and can cause upward propagation of electric field into lower Ionosphere (60-100 km altitude) and makes some variations in electron density, Total Electron Content (TEC) and conductivity of such medium. These variations in the Ionosphere parameters affect propagating of radio signals travelling through this medium. Thus, it is important to investigate the influence of lightning on the Ionosphere parameters e.g. Vertical Total Electron Content (VTEC). In this paper, we have investigated the VTEC variations in lower Ionosphere due to lightning activity during a geomagnetic quiet day (with geomagnetic activity index of day Ap<4). To achieve this purpose, we used data from the Worldwide Lightning Location Network (WWLLN) data for detecting time and location of the lightning events and also we used the Global Navigation Satellite Systems (GNSS) data for VTEC calculations. After calculating the VTEC values in both lightning and non-lightning days we compared them to obtain the lightning effects on VTEC.

The mean age of stratospheric air (AoA) is a useful transport diagnostic and one of the best tools for accessing the Brewer-Dobson circulation (BDC) change. Analyzing AoA output from CCMI REFC2 model simulations we found a remarkable agreement among majority of models in projecting the largest mean age-of-air (AoA) negative trends and changes in localized regions in the extratropical LS on both hemispheres (approximately between 200000 and 250000gpm and 20°- 40°N and 20°- 40°S). The occurrence of those regions are a direct function of the climatological AoA distribution, upward shifting trend of the circulation and of widening of the AoA izolines due to a negative trend in aging by mixing. The negative trend in aging by mixing is primarily caused by the speeding up of the residual circulation in the shallow BDC branch, which is connected with an interplay (not only compensation) between spatial structures and magnitudes of gravity and resolved wave drag leading to strengthening trend of the total drag.

Gravity waves play a momentous role in shaping the observed thermal and dynamical structure of the middle atmosphere. Over polar regions, they have myriad effects such as controlling the general circulation of the middle atmosphere, affecting the formation of polar stratospheric clouds, thereby controlling the chemistry of the stratosphere and so on. Atmospheric general circulation models employ parameterizations to represent gravity waves. The Antarctic stratosphere is consistently found to have a cold bias in model representations for which improper parameterization of gravity wave drag is considered to be the reason. Thus more realistic observations of gravity waves are required in order to provide physical constraints for these models. In this regard, a study was conducted to characterize gravity waves in the Antarctic lower stratosphere using balloon borne radiosonde observations. Balloon soundings were carried out in campaign mode from the Indian research base at Antarctica, Bharati (69S, 76E) during the austral summers of 2014-15, 2015-16 and 2016-17. Gravity wave potential energy, being a proxy for wave activity, was estimated from the vertical profiles of temperature. The average potential energy densities in the lower stratosphere were found to be less than 1 J/kg. There were small but significant variabilities in the potential energy densities between the three austral summers. The wavelet based approach was employed to extract individual gravity wave packets from the vertical profiles of horizontal winds. The extracted packets were subjected to Stokes Parameter analysis to infer propagation characteristics. Further, to extend the analysis to larger spatial and temporal scales, an attempt is made to validate the MERRA-2 Reanalysis datasets using the available observations. It was seen that the broad features are captured well by the MERRA-2 datasets. The momentum flux values obtained from radiosonde as well as MERRA-2 datasets are compared. The significance of the present study lies in extracting

the gravity wave parameters by employing wavelet analysis and utilizing MERRA reanalysis datasets for the study of gravity waves over the Antarctic.

C2.2-0053-18 RELATIONSHIPS BETWEEN THE CHARACTERISTICS OF THE HAYASHI WAVES IN THE NORTHERN STRATOSPHERE WITH CLIMATE VARIABILITY INDICES IN WINTER

Vladimir Guryanov, vv@kpfu.ru

Kazan Federal University, Kazan, Russia Alexey Eliseev, eliseev@ifaran.ru

Kazan Federal University, Russia

By using the winter (from November to March) ERA-Interim reanalysis geopotential data in the troposphere and stratosphere (up to the 1 hPa isobaric level) for 1979-2016, an analysis of the Hayashi spectra for wave disturbances with zonal wave numbers 1 k 10 and with periods from 2 to 156 days is performed. In this, contributions of the eastward traveling (E), westward traveling (W), and stationary (S) waves are estimated. We found statistically significant positive correlations of the W-waves energy EW and, to a smaller extent, of the S-waves energy ES in the upper stratosphere with the index of sudden stratospheric warmings (SSWs). The latter index was defined in our previous papers and based on the number of SSWs of different types (with specific weight factors for each SSW type) during given winter. In turn, the E-waves energy EE is negatively correlated with thus defined SSW index. We also found the strong positive correlation waves energy EW and ES with the conventional indices of the North Atlantic and the Arctic Oscillations in the mid-latitudinal troposphere and stratosphere. E-wave energy is also positively correlated with those indices, but only in the troposphere and in the lower stratosphere. In the tropical and subtropical troposphere as well as in the subtropical lower stratosphere E-waves energy is correlated with the indices of the Southern Oscillation and El Nino/La Nina-related sea surface variability (EE increases during El Nino events and decreases during La Nina ones). The spatial domain of the strongest correlation co-locates with the region of the tropopause break. This suggests a possibility of the E-waves-related mechanism of the El Nino-Southern Oscillation influence on the troposphere-stratosphere exchange. In turn, Wand S-waves and negatively correlated with the El Nino/La Nina-related sea surface variability indices in the troposphere and lower stratosphere of the mid-latitudes as well as in the tropical upper troposphere.

C2.2-0054-18 WAVE ACTIVITIES AND TURBULENCE INFLUENCING STRATOSPHERE TROPOSPHERE EXCHANGE (STE) OF OZONE OVER COSTA RICA DURING 2016

High vertical resolution radiosondes and ozonesondes are launched every week from stations in Southern Hemisphere ADitional OZonesondes (SHADOZ) network. We have analyzed the data of winds, temperature, ozone mixing ratio and relative humidity of a tropical station Costa Rica (10° N, 83.4° W) for the year 2016 to study transport of ozone between stratosphere and troposphere (STE/TSE). Five STE and three TSE events could be identified in the data. The intrusion are normally shallow with a maximum of 5.7 DU in the month of August. Transport of ozone is observed to occur mostly during May to August when convection prevails in the region. Spectral analyses and correlation results confirm the gravity wave and Inertia/Rossby gravity wave activities to be responsible for the transport. Exchange of ozone between stratosphere and troposphere is found to be associated with Kelvin wave near the tropopause and Madden-Julian oscillation in the troposphere. Eddy diffusivity computed by using simultaneous radiosonde measurements display high values of turbulence, particularly, below the tropopause, where laminar structures are mostly observed. Wind shear is also high in the region. We conclude that a combination of wind shear, wave activity and local turbulence is responsible in the transport of minor constituents between troposphere and stratosphere.

C2.2-0055-18 EXPLORING LIMITS OF THE DOWNWARD CONTROL PRINCIPLE

The Downward Control Principle (DC) in the form that was formulated in Haynes et al. (1991) is one of the most popular concepts in current research of wave-induced forces impacts on the global-scale circulations, namely on the stratospheric Brewer-Dobson circulation (gyroscopic pumping). It is also often used for separating relative roles of the resolved and gravity waves driving. However, this principle relies on zonally symmetric basic states and forces and it has been argued even in the original paper that the longitude-dependent force would set-up a secondary Rossby wave - a situation that has been confirmed by numerical simulations described in Sacha et al. (2016). Thus, by definition the principle should not be used for gravity wave driving, which is inherently zonally asymmetric.

In this study we use circulation model sensitivity simulations with different distributions of wave forcings to quantify the deviations from DC as measured by a difference in the net upward mass flux across 70 hPa computed directly from the stream function and using the DC. We artificially add wave drag perturbations and modify their longitudinal distribution between the simulations, while always adding the same net zonal mean force, which is added also symmetrically for a reference. We also investigate the validity of the DC in terms of addition of the same value of zonally symmetric force but at different altitudes above the turnaround latitude position at 70 hPa (following angular momentum curves) so that the DC integral remains the same, but the induced acceleration differs significantly according to the altitude of the perturbation. To conform the DC concept we analyze steady state results only.

C2.2-0056-18 SIGNATURE OF A SECONDARY WAVE IN THE BRAZILIAN EQUATORIAL IONOSPHERE

In the past decade, understanding of the day-to-day variability of the ionosphere induced by waves propagating from bellow has considerably been advanced. More recently, several studies have pointed out that the secondary waves arising from the nonlinear interaction between tides and planetary waves could significantly impact the ionosphere. From the meteor radar wind at Cariri (7.4°S, 36.5°W) and ionossonde measurements at Fortaleza (3.9°S, 38.4°W) we investigated the presence and effects of secondary waves in the Brazilian equatorial MLT and ionosphere. We found an evidence of the nonlinear interaction between an ultra-fast Kelvin wave and the diurnal tide in the MLT wind. We identified a 1.3-day secondary wave arising from this interaction and found it to propagate upward with a relatively long vertical wavelength (44 km), which may allow it to penetrate into the ionosphere. From the ionossonde measurements at Fortaleza we found indications of the modulation of the F-layer height by the 1.3-day secondary wave. In this paper, we will present and discuss details of this study.

Atmospheric gravity waves play an important role in transporting energy and momentum between atmospheric spheres and drive circulations that affect key processes such as formation of the ozone hole and the cold summer polar mesosphere. One of the reasons that still avoid the full understanding and description of gravity waves is the lack comprehensive observations over the Antarctic region. The ANtarctic Gravity Wave Instrument Network (ANGWIN) is a highly successful grassroots programme that was started in 2011. It seeks to use a network of observations to measure gravity waves continent wide and through all levels of the atmosphere, in order to fully understand their impact and constrain modelling work. Although ANGWIN initially focused on the Antarctic, the group is now aiming to develop collaborations in both polar regions.

Current member countries of ANGWIN are Australia, Brazil, Japan, South Korea, the United Kingdom and the United States of America. The objective of ANGWIN network include; Qualify the longitudinal variations in gravity waves and determine causes; Characterize wave propagation and influence; Relate observed gravity waves to sources throughout the atmosphere; Study interactions of gravity waves with planetary scale waves; Compare polar wave observations to model parameterizations; Determine the effects of gravity waves on polar stratospheric cloud formation.

The ANGWIN network, its objectives and some recent results will be presented in the poster.

The National Institute of Polar Research (NIPR) is leading a prioritized project of the Antarctic research observations. One of sub-project is entitled the whole atmosphere system revealed by precise profiling over the Antarctic. Profiling dynamical parameters such as temperature and wind, as well as minor constituents is the key component of observations in this project, together with a long term observations using existent various instruments at Syowa, Antarctica (69S). As a part of the sub-project, a new resonance scattering lidar system with frequency-tunable alexandrite laser was developed. The lidar has a capability to observe temperature profiles and variations of minor constituents such as Fe, K, Ca+, and aurorally excited N2+. The lidar system was installed at Syowa Station by the 58th Japan Antarctic Research Expedition (JARE 58) and successfully received the first light from K layer in March 2017. From July to October in 2017, the MLT temperature profiles were derived from K or Fe resonance scatter signals. Also we challenged to receive some resonance scatter signals from Ca+ and N2+. This presentation will report preliminary results of the lidar observations at Syowa.

C2.2-0059-18 OBSERVATIONS OF SUPERDARN GLOBAL TIDES IN THE MLT AND THEIR RESPONSE TO SUDDEN STRATOSPHERIC WARMING EVENTS

Coastal Carolina University, United States

Meteor wind data derived from a longitudinal chain of eight SuperDARN radars are used to determine the mean response of the migrating semidiurnal tide to the chemical and dynamical changes driven by sudden stratospheric warmings (SSWs). The radars span a limited range of latitudes around 60 degrees N and are located over nearly 180 degrees of longitude allowing the different zonal wavenumbers of the tide in the mesosphere and lower thermosphere to be distinguished. The migrating tide is extracted from the non-migrating components observed in the meridional wind, and climatologies of the different components are presented. The composite response of the amplitude of the components of the tide over 13 SSWs are presented and the drivers of the variability are discussed with the aid of corresponding WACCM-SD simulations.

We study atmospheric gravity waves (AGWs) in the mesopause region and medium-scale traveling ionospheric disturbances (MSTIDs) in the thermosphere from 1999 to 2014, by applying a three-dimensional spectral analysis technique to airglow images at wavelengths of 557.7 nm (emission altitudes: 90-100 km) and 630.0-nm (200-300 km) obtained at Rikubetsu (43.5N, 143.8E) and Shigaraki (34.8N, 136.1E), Japan. Such a long-term multipoint analysis of AGWs and MSTIDs using airglow images has not been reported previously. The propagation direction of mesospheric AGWs seen in 557.7-nm airglow images is northeastward in summer and southwestward in winter at both stations, probably due to wind filtering of these waves by the mesospheric jet. In winter, the propagation direction of AGWs shifted from southwestward to northwestward as time progresses from evening to morning at both stations, which can also be explained by the wind filtering effect. The propagation direction of AGWs changed from southwestward to northeastward at Rikubetsu on the day of the zonal wind reversal at 60N at 10 hPa by the stratospheric sudden warming (SSW), while such a SSW-associated change was not identified at Shigaraki, indicating that the effect of SSW wind reversal reached only to the Rikubetsu latitudes. For MSTIDs, the major propagation

direction is southwestward with a minor northeastward peak in all seasons at both stations. A negative correlation is found between yearly variation of power spectral density and solar F10.7 flux. This negative correlation can be explained by considering the linear growth rate of the Perkins instability. We have also applied this 3D FFT spectral analysis technique to the 557.7 nm and 630.0 nm airglow images obtained from 2005 to 2017 at Athabasca, Canada (54.7N, 246.7E before 25 September, 2012 and 54.6N, 246.3E after 27 September, 2012). We discuss similarities and differences of the propagation characteristics of AGWs and MSTIDs over Japan and Canada.

C2.2-0061-18 VARIABILITIES OF LOW-LATITUDE MIGRATING AND NONMIGRATING TIDES IN GPS-TEC AND TIMED-SABER TEMPERATURE DURING THE SUDDEN STRATOSPHERIC WARMING EVENT OF 2013

Sridharan Sundararajan, susridharan@narl.gov.in National Atmospheric Research Laboratory, Pakala, India

The Global Positioning System deduced total electron content (TEC) data at 15°N (geomagnetic), which is the crest region of equatorial ionization anomaly, are used to study tidal variabilities during the 2013 sudden stratospheric warming (SSW) event. The results from space-time spectral analysis reveal that the amplitudes of migrating diurnal (DW1) and semidiurnal (SW2) tides are larger than those of nonmigrating tides. After the SSW onset, the amplitudes of DW1, SW2, SW1, and DS0 increase. Moreover, they show 16 day variations similar to the periodicity of the high-latitude stratospheric planetary wave (PW), suggesting that the nonmigrating tides (SW1 and DS0) are possibly generated due to nonlinear interaction of migrating tides with PW. Similar spectral analysis on temperature at 10°N obtained from the Sounding of Atmosphere by Broadband Emission Radiometry (SABER) shows that the SW2 enhances at stratospheric heights and the SW2 is more dominant at 80-90 km, but its amplitude decreases around 100 km. The amplitudes of nonmigrating tides become comparable to those of SW2 around 100 km, and their contribution becomes increasingly important at higher heights. This suggests that the nonlinear interaction between migrating tides and PW occurs at low-latitude upper mesospheric heights, as SW2 exhibits 16 day periodicity in SABER temperature at 100 km as observed in TEC. Besides, it is observed that the eastward propagating tides are less dominant than westward propagating tides in both TEC and SABER temperatures.

SPACE STUDIES OF THE UPPER ATMOSPHERES OF THE EARTH AND PLANETS INCLUDING REFERENCE ATMOSPHERES (C)

ADVANCES IN EXTERNAL FORCING STUDIES FOR THE MIDDLE ATMOSPHERE AND LOWER IONOSPHERE (C2.3)

C2.3-0001-18 CONTRIBUTION OF ENERGETIC PARTICLE PRECIPITATION TO ANTARCTIC OZONE VARIABILITY

Alessandro Damiani, alecarlo.damiani@gmail.com Chiba University, Chiba, Japan

In polar regions, the natural variability of the upper stratospheric and mesospheric ozone is expected to be affected by energetic particle precipitation (EPP). Indeed, EPP boosts the concentration of odd nitrogen (NOx) and odd hydrogen (HOx) species which efficiently destroy ozone. Since ozone change has the potential to further influence atmospheric dynamics and regional climate, the evaluation of the EPP impact on long time scales is a critical issue. Nevertheless, the assessment is complicated by constraints in satellite observations and by the other drivers of ozone variability. This talk deals with the ozone response to EPP by analyzing satellite observations from Solar Backscatter Ultraviolet Radiometer and Microwave Limb Sounder. We focus on the Antarctic region where the reduced inter-annual variability of the vortex dynamics, compared with the Arctic, makes easier to distinguish EPP effects. Overall, during the austral winter we found an average EPP-induced ozone depletion larger than 10 % in both mesosphere and upper stratosphere, the latter caused by an indirect impact of EPP-NOx produced at upper altitudes. Such changes are coherent with forcings from different EPP populations and are coupled with enhancements in HOx and HNO3. This confirms the necessity of taking the EPP forcing into account in climate models as recently recommended for the ongoing Coupled Model Intercomparison Project Phase 6 (CMIP6).

C2.3-0002-18 IMPACT OF MEDIUM-ENERGY ELECTRON PRECIPITATION ON POLAR OZONE OVER DECADAL TIME SCALES

FMI Finnish Meteorological Institute, Helsinki, Finland

One of the key challenges in polar middle atmosphere research is to quantify the total forcing by energetic particle precipitation (EPP) and assess the related response over solar cycle time scales. This is especially true for electrons having energies between about 30 keV and 1 MeV, so-called medium-energy electrons (MEE), because there has been a persistent lack of adequate description of MEE ionization in chemistry-climate simulations. The most recent solar forcing recommendation for the Coupled Model Intercomparison Project (CMIP) includes EPP for the first time, with MEE represented as daily zonal mean using a proxy model driven by the geomagnetic Ap index. Here we use the Whole Atmosphere Community Climate Model (WACCM) and include EPP forcing by solar proton events, auroral electron precipitation, and MEE precipitation. We contrast our results from an ensemble of simulations (147 years in total) with those from the fifth phase of CMIP in order to show the importance of the recommended MEE forcing to the middle atmospheric ozone, odd hydrogen, and odd nitrogen over decadal time scales. In addition, over shorter time periods, we demonstrate the importance of detailed lower ionospheric chemistry as represented in the WACCM-D variant as well as the importance of considering the MEE dependence on magnetic local time. We further discuss how these, if included, might affect our results and conclusions from the 147-year simulation.

C2.3-0003-18 EMPIRICAL MODEL OF NITRIC OXIDE IN THE MESOSPHERE FROM SCIAMACHY/ ENVISAT SATELLITE OBSERVATIONS

Stefan Bender, stefan.bender@ntnu.no

Norwegian University of Science and Technology (NTNU), Trondheim, Norway Miriam Sinnhuber, miriam.sinnhuber@kit.edu

Norwegian University of Science and Technology (NTNU), Trondheim, Norway John Burrows, burrows@iup.physik.uni-bremen.de

Institute of Environmental Physics, University of Bremen, Bremen, Germany

Solar, auroral, and radiation belt electrons as well as soft solar X-rays produce nitric oxide (NO) in the mesosphere and lower thermosphere (MLT, 50–150 km). NO downward transport, in particular during polar winters, influences the lower atmosphere by, for example, catalytically reducing ozone. These changes in the NO and ozone chemistry also change the dynamics of the mesosphere and can impact the stratosphere.

We present ten years of daily global NO number density measurements obtained by the satellite instrument SCIAMACHY on board Envisat. The densities are derived from UV limb scans of the mesosphere for altitudes from 60 km to 90 km. From this data set, from 08/2002 to 04/2012, we construct an empirical model of NO in the mesosphere. In particular, we link NO production and its lifetime to geomagnetic disturbances (given by the AE index) and to the solar UV radiation (using the Lyman-α index).

The derived parameters constrain how solar and geomagnetic activity influence the NO content in the mesosphere. Our model will help to fill gaps in measurements and to validate and improve chemistry climate models; it complements similar work done using AIM/SOFIE data (90–140 km) and Odin/SMR data (85–115 km). In the longer term, including additional dynamical effects in the model would help to distinguish between direct production and transport processes.

In this study 30–1000 keV energetic electron precipitation (EEP) data from low Earth orbiting POES satellites were processed in two improved ways, compared to previous studies. Firstly, all noise-affected data were more carefully removed, in order to provide more realistic representations of low fluxes during geomagnetically quiet times. Secondly, the data were analyzed dependent on magnetic local time (MLT), which is an important factor affecting precipitation flux characteristics. We developed a zonally averaged EEP model, and a new model dependent on MLT, which both provide better modeling of low fluxes during quiet times. The models provide the spectrum of EEP assuming a power-law gradient. Using the geomagnetic index Ap with a time resolution of 1 day, the spectral parameters are provided as functions of the L-shell value relative to the plasmapause. Results from the models compare well with EEP observations over the period of 1998–2012. Analysis of the MLT-dependent data finds that during magnetically quiet times, any significant fluxes are only observed around local midnight. As disturbance levels increase, the flux increases at all MLT. During disturbed times, the flux is strongest in the dawn sector, and weakest in the late afternoon sector. The MLT-dependent model emulates this behaviour. The results of the models can be used to produce ionization rate datasets over any period of time for which the geomagnetic Ap index is available (recorded or predicted). This ionization rate dataset will enable simulations of EEP impacts on the atmosphere and climate with realistic EEP variability.

C2.3-0005-18 SOFIE OBSERVATIONS AND MODELLING OF NITRIC OXIDE IN THE POLAR MESOSPHERE AND LOWER THERMOSPHERE

Koen Hendrickx, koen.hendrickx@misu.su.se Stockholm University, Stockholm, Sweden Linda Megner, linda@misu.su.se

Stockholm University, Stockholm, Sweden Daniel Marsh, marsh@ucar.edu

NCAR, Boulder, Colorado, United States

Christine Smith-Johnsen, christine.smith.johnsen@gmail.com University of Bergen, Bergen, Norway

A reservoir of Nitric Oxide (NO) in the lower thermosphere efficiently cools the atmosphere after periods of enhanced geomagnetic activity. Transport from this reservoir to the stratosphere within the winter polar vortex allows NO to deplete ozone levels and thereby affect the middle atmospheric heat budget. As more climate models resolve the mesosphere and lower thermosphere (MLT) region, the need for an improved representation of NO related processes increases.

We use NO observations made by the Solar Occultation for Ice Experiment (SOFIE) instrument onboard the Aeronomy of Ice in the Mesosphere (AIM) satellite in the Antarctic MLT region and compare them to simulations performed by the Whole Atmosphere Community Climate Model with Specified Dynamics (SD-WACCM). The morphology of the simulated NO is in agreement with observations though the long term mean is too high and the short term variability is too low. The NO production and transport processes are investigated using multiple linear regressions and superposed epoch analyses in the SOFIE observations. A similar approach on SD-WACCM data allows us to determine how well these processes are represented in the model and identify possible improvements.

C2.3-0006-18 CHEMICAL IMPACTS OF ENERGETIC PARTICLE PRECIPITATION IN THE POLAR MESOSPHERE-LOWER THERMOSPHERE

Energetic particle precipitation generates perturbations in the abundance of various neutral and ionic species in the mesosphere-lower thermosphere, partly through a complex ion cluster chemistry. In particular, mesospheric polar nitric acid enhancements have been attributed to energetic electron precipitation (EEP), but this phenomenon is not reproduced in current wholeatmosphere chemistry-climate models. We investigate such nitric acid enhancements following a series of EEP events during April and May 2010 with WACCM-D, a recently developed variant of the Whole Atmosphere Community Climate Model (WACCM) that includes a sophisticated ion chemistry tailored for the D-layer of the ionosphere (50-90 km). Whereas the standard WACCM includes only 5 positive ions, WACCM-D comprises 21 negative ions and 20 positive ions. Using the specified-dynamics mode, i.e. nudging dynamics in the troposphere and stratosphere, we perform a one-year long simulation (July 2009-July 2010) and contrast WACCM-D with the standard WACCM. Both WACCM and WACCM-D simulations are performed with and without a parametrization of the medium-to-high energy electron precipitation, allowing a better representation of the energetic electrons penetrating in the mesosphere. We demonstrate the effects of the EEP events on nitric acid and on key ion cluster species, as well as other key species of the nitrogen family. The one-year long simulation allows placing the event-related changes on key neutral and ionic species in the context of their annual cycle. We especially highlight the important role played by medium-to-high energy electrons in triggering ion cluster chemistry in the mesosphere and lower thermosphere.

C2.3-0007-18 RELATIVISTIC ELECTRON MICROBURST EVENTS: FROM OCCURRENCE TO ATMOSPHERIC IMPACT

Emma Douma, emmadouma@gmail.com University of Otago, Dunedin, New Zealand Annika Seppala, annika.seppala@otago.ac.nz University of Otago, Dunedin, New Zealand

C. J. Rodger, crodger@physics.otago.ac.nz University of Otago, Dunedin, New Zealand Pekka T. Verronen, pekka.verronen@fmi.fi

UCLA, Los Angeles, California, United States

Relativistic electron microbursts are short-duration (< 1 second), high-energy (>1 MeV) precipitation events that are thought to be an important loss mechanism for radiation belt particles. Previous work by Turunen et al. (2009, JASTP) to estimate their atmospheric impacts found no significant changes in atmospheric chemistry, but these were based on rough estimates of the intensity of a typical microburst event. In fact, only a single monoenergetic microburst of 100

el cm–2 sr–1 s–1 was used in their simulation. We use an automated relativistic microburst detection algorithm [O'Brien et al., 2003, JGR; Blum et al., 2015, JGR; Douma et al., 2017, JGR] on low-altitude SAMPEX HILT >1 MeV electron flux observations. This algorithm provides both event detection and precipitating intensity measurements. This database of relativistic microbursts reveals that both the fluxes and frequency of microbursts are much higher than previously thought. During a 6 hour storm we are likely to see 0.0513 microbursts per second with a mean flux of 1,733.5 cmcm–2 sr–1 s–1 and a median flux of 963 cm–2 sr–1 s–1 of > 1

MeV electrons. We test the seasonal range of atmospheric impacts using this latest microburst information as input forcing to the Sodankylä Ion and Neutral Chemistry model (published in Seppälä et al., 2018, GRL). A modelled 6 h microburst storm increased mesospheric HOx by 15-25%/800-1,200% (summer/winter) and NOx by 1,500-2,250%/80-120%. Together, these drive 7-12%/12-20% upper mesospheric ozone losses, with a further 10-12% longer-term middle mesospheric loss during winter. Our results suggest that existing electron precipitation proxies, which do not yet take relativistic microburst energies into account, are likely missing a significant source of precipitation that contributes to the atmospheric ozone balance.

C2.3-0008-18 ROLE OF EQUATORIAL FOUNTAIN FOR THE DELAYED RESPONSE OF THERMOSPHERE O1D 630.0 NM DAYGLOW OVER THE DIP EQUATOR DURING AN X-CLASS FLARE

Vineeth Chandrasekharan Nair, cnvins@gmail.com

Indian Space Research Organization, Thiruvananthapuram, India
Pant Tarun Kumar, tkpant@yahoo.ca

Space Physics Laboratory, Vikram Sarabhai Space Centre, 695022, India

This paper reports, for the 'first time', the delayed response of O1D 630.0 nm dayglow emissions over Trivandrum (8.5o N, 77o E, 0.5o N dip lat.), a geomagnetic dip equatorial station in India, to the X class solar flare event of July 30, 2005. The dayglow measurement has been made using dayglow photometer operating at three wavelengths. The Equatorial Electrojet (EEJ) induced magnetic field, measured using a proton precession magnetometer, showed a magnetic crochet of 90 nT enhancement during this flare with a time delay of 7.2 minutes. Noteworthy observation is, unlike to the conventional belief, the O1D 630.0 nm dayglow over the dip equator exhibits a fourfold enhancement during the noontime flare after a time delay of 45 minutes. These observations show that the thermospheric O1D 630.0 nm dayglow emission over the dip equatorial region is primarily driven by the electrodynamics, rather than the direct solar control. This finding is new, unique and very important for the studies related to plasma-neutral coupling and also modeling the equaorial thermosphere-ionosphere region.

C2.3-0009-18 UPPER AND MIDDLE ATMOSPHERIC RESPONSE TO HARD X-RAY/GAMMARAY IONIZATION: INVESTIGATION WITH OBSERVED AND SIMULATED IONIZATION IMPULSES OR SPIKES

Sourav Palit, souravspace@gmail.com

Universidade Presbiteriana Mackenzie/CRAAM, São Paulo, Brazil
Jean-Pierre Raulin, raulin@craam.mackenzie.br

Universidade Presbiteriana Mackenzie/CRAAM, São Paulo, Brazil

A significant part of the celestial and terrestrial sources of radiation is the X-rays (soft and hard) and γ-rays, which modify the ionosphere and middle atmosphere of earth by ionization of the neutral molecules. The sources of such ionizing radiation and hence the modulating effects on upper and middle atmosphere may vary in a large range of time scales, starting from few milliseconds for GRB, SGR bursts etc.to few minutes and hours (solar flares). The usual signature of such events is the sudden enhancement of free electrons and ions and gradual decay of those due to atmospheric recombination processes. The Very Low Frequency (VLF) propagation between a pair of transmitter and receiver is effected by such atmospheric modulation and has been studied for decades. The investigation of such VLF response is very informative in terms of both determining the atmospheric chemistry and dynamics as well as the source characteristics. Exact understanding of such modulations is challenging, owing to the fact that the VLF radio wave propagation is multi-parametric in nature and can only be described by rigorous theory, like mode theory of propagation in earth-ionosphere waveguide. In-situ computer simulation starting from ionization rate determination, chemistry evolution and application of programs like Long Wave Propagation Capability (LWPC), based on mode theory, is a viable option. Most simplest ionizing profile in time, such as a spike or ionization impulse is an ideal candidate to start with. Here we present the study of the effect of spike like ionization profiles on the atmosphere and VLF propagation, with both an observed SGR X-ray burst and numerically simulated sources. Numerical investigation with various source and propagation characteristics enables us to explore how the response should vary and also the possibility that whether an actual ionizing X-ray or gamma ray source with arbitrary complicated time profile may be approximated by series of such consecutive spike sources.

C2.3-0010-18 IMPACT OF INTERACTIVE CHEMISTRY OF STRATOSPHERIC OZONE IN PALEOCLIMATE AND GLOBAL WARMING SIMULATIONS

Shigeo Yoden, yoden@kugi.kyoto-u.ac.jp Kyoto University, Kyoto, Japan

KU-MRI PSTEP team

Shigeo Yoden, Satoshi Noda, Kunihiko Kodera, Yukimasa Adachi, Makoto Deushi, Akio Kitoh, Ryo Mizuta, Shigenori Murakami, and Kohei Yoshida

Several series of numerical simulations on paleoclimates and global warming conditions were performed by using an Earth System Model of the Meteorological Research Institute of the Japan Meteorological Agency to investigate the impact of interactive chemistry of stratospheric ozone on the climate system including the surface conditions. The stratospheric ozone profile can be modulated by the changes of solar insolation at the top of the atmosphere due to variations of orbital parameters of the Earth, and CO2 concentration through associated temperature changes. Time slice runs over 100 years for the Mid-Holocene (MH; 6 kyr B.P. solar insolation and 280 ppm CO2 concentration), Last Glacial Maximum (LGM; 21 kyr B.P. and 185 ppm), PreIndustrial period (PI; 1850 C.E. and 285 ppm), and abrupt quadrupled CO2 concentration (4xCO2; 1850 C.E. and 1140 ppm), were done under interactive ozone chemistry to obtain quasi-equilibrium climates and compared with those of the corresponding experiments with a prescribed ozone profile for the PI condition, respectively.

Comparisons of the results of interactive ozone chemistry calculations for MH and PI with those of the corresponding experiments in CMIP5, in which the ozone distribution was prescribed to the 1850 C.E. level, show that the contribution of the interactive ozone chemistry in a quasiequilibrium state reveals a significant anomaly of up to +1.7 K in the Antarctic region for the annual mean zonal mean surface air temperature (Noda et al., 2017; JGR). This impact on the surface climate is explained by a similar mechanism to the cooling influence of the Antarctic ozone hole in spring but opposite in sign, through the Southern Annular Mode variations and associated weakening of equatorward ocean surface current and sea ice retreat. Seasonal variation in solar insolation modulated with the variations of Earth's orbital parameters has the predominant role in the interactive chemistry in the MH experiment with similar values of CO2 concentration compared with the PI condition.

Comparisons of the simulations for LGM and PI conditions also show the impact of interactive chemistry of stratospheric ozone with significant anomaly of +0.5 K (approximately 20 %) in the tropics and up to +1.6 K in high-latitudes for the annual mean zonal mean surface air temperature, compared with those of the corresponding experiments with a prescribed ozone distribution for the PI simulations in CMIP5 (Noda et al., 2018; under revision). In the tropics, this mitigation of global cooling is related to longwave radiative feedbacks associated with circulation-driven increase in lower stratospheric ozone and related increase in stratospheric water vapor. The relationships are opposite signs to and consistent with those of 4xCO2 simulation. In high-latitudes, the polar amplification of the mitigation of cooling is associated with the sea ice retreat that is the same sign to and consistent with our previous MH simulation.

Biases of sea surface temperature in both MH and LGM simulations in CMIP5 models with the prescribed ozone are reduced in our simulations by using interactive ozone chemistry. We recommend that climate models include interactive sea ice and ozone distribution that are consistent with paleo solar insolation.

C2.3-0011-18 RECENT ADVANCES AND OUTSTANDING ISSUES IN SOLAR EUV IRRADIANCE

Francis G. Eparvier, frank.eparvier@lasp.colorado.edu University of Colorado, Boulder, Colorado, United States

Solar EUV spectral irradiance is a necessary piece in the understanding of the thermosphere, ionosphere, geosphere system. We are currently in a time where there are several missions measuring the solar EUV over multiple wavelength ranges, with different spectral resolutions and cadences, and even from different locations in the solar system. I will present an overview of the observations from TIMED-SEE, SDO-EVE, and GOES-16 EXIS in Earth orbit and MAVEN-EUVM in Mars orbit. These missions have addressed many of the questions originally posed when the TIGER program started. I will take a look at the limitations of the current measurements and the still open questions regarding the important EUV input to the upper atmosphere. In addition, I will also discuss the planned future of solar EUV irradiance monitoring.

C2.3-0012-18 TROPICAL MIDDLE ATMOSPHERE OZONE RESPONSE TO THE SOLAR ROTATIONAL CYCLE IN OBSERVATIONS AND CHEMISTRY-CLIMATE SIMULATIONS

Laboratoire Atmosphères, Milieux, Observations Spatiales, Paris, France Mustapha Meftah, mustapha.meftah@latmos.ipsl.fr

CNRS, Guyancourt, France

Alain Hauchecorne, alain.hauchecorne@latmos.ipsl.fr LATMOS/IPSL/CNRS/UVSQ, Guyancourt, France

Solar spectral irradiance fluctuations associated with the Sun's 27-day rotational cycle can significantly influence ozone variability in the tropical middle atmosphere. In the stratosphere, previous observational studies based on different instruments and time periods revealed however large disparities in the magnitude of the ozone response to the 27-day solar signal. For the mesosphere, only few observational estimates of the ozone response to the 27-day solar cycle are available. This is partly due to the relative paucity of ozone measurements and the considerable amplitude of the ozone diurnal variations at these altitudes which both make the detection of solar signals in ozone difficult. The results presented here summarize the main findings of two studies that used satellite ozone data (UARS-MLS, Aura-MLS and ENVISAT-GOMOS) and chemistry-climate simulations of LMDz-REPROBUS and HAMMONIA models in order (i) to understand the discrepancies in previous estimates of the stratospheric ozone solar rotational signal and (ii) to quantify the mesosphere/lower thermosphere ozone response to the solar rotational cycle. Observational ozone response to solar irradiance variations are identified and quantified from linear correlation and regression methods combined with non-parametric statistical tests. Observational results are then compared with the results from chemistryclimate model simulations which are driven with realistic and/or idealized solar irradiance forcings. The analysis of stratosphere MLS ozone data and their comparison with LMDzReprobus results show that the dynamical variability modulates the ozone solar rotational signal, which partly explain the discrepancies found in previous observational studies. This dynamical variability masking effect can be overcome by considering long timeseries; we found that a minimum of a 3 year time window is needed for the 1 uncertainty estimate of the ozone solar rotational signal to drop below 50%. The analysis of mesosphere/lower thermosphere GOMOS data allowed us to derive the first observation-based night-time ozone response to the solar rotational cycle in the range [50,110] km. The vertical distribution of this ozone response exhibits

a maximum at 80 km and an abrupt increase above 100 km. Although qualitatively consistent with GOMOS observations, the results from HAMMONIA simulations significantly underestimates the magnitude of the ozone response. Possible causes for these discrepancies will be discussed.

C2.3-0013-18 STUDY OF LONG TERM EFFECTS OF SOLAR UV AND X-RAY RADIATIONS ON VLF SIGNAL CHARACTERISTICS.

Suman Ray, sumanray07@gmail.com Gobardanga Hindu College, Gobardanga, India Dipak Sanki, dip.vupbc@gmail.com

Indian Centre for Space Physics, Kolkata, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

We study long term effects of high energy solar UV and X-ray radiations on the Very Low Frequency (VLF) signals which propagate through the earth-ionosphere wave-guide. We used the transmitted signal at 24 KHz from NAA (Cutler, Maine) which is received at Moore Observatory in Brownsboro, Kentucky between 2007-2014. To study long term effects of UV and X-ray radiations we used solar X-ray and solar UV data of the same period. We consider diurnal peak amplitude of the VLF signal on each day and compare it with solar UV and X-ray radiation components. We found that the correlation coefficient of diurnal peak VLF signal amplitude with both solar X-ray and UV radiations is 0.7, which indicates a strong relationship between the VLF signal amplitude and solar radiation components. We carry out the same analysis with average VLF signal amplitude during day and night time separately and found that the correlation coefficient to be high with day time data while it is very weak with night time VLF signal amplitude.

C2.3-0014-18 SPORADIC VLF AMPLITUDE PERTURBATIONS IN THE HIGH LATITUDE D-REGION IONOSPHERE

Edith Macotela, edith.macotelacruz@oulu.fi

Sodankylä Geophysical Observatory / Univ. of Oulu, Sodankylä, Finland Mark Clilverd, macl@bas.ac.uk

British Antarctic Survey, Cambridge, United Kingdom Jyrki Manninen, jyrki.manninen@sgo.fi

University of Oulu, Finland

The propagation of very low frequency (VLF) radio waves permit us to study the response of the lower ionosphere (60-90 km) to sporadic space weather events such as solar proton events (SPEs) and energetic electron precipitation. In this study, we use the 37.5 kHz VLF signal transmitted from NRK (Iceland, L=5.5) recorded at Sodankylä (Finland, L=5.5) since 2010 till 2016. We compare the observed variations in the VLF amplitude measurements with changes in AE index, solar wind velocity, solar proton events and nitric oxide (NO) concentration. The analysis was divided in to positive and negative variations of the VLF perturbations with respect to the quiescent level. We found that the positive variations are mainly associated with SPEs and NO concentration enhancements. The observed large negative daytime perturbations are currently unexplained

C2.3-0015-18 ABOUT COSMIC FACTOR COUPLING WITH CLOUDLESS DAYS AND OZONE CONTENT VARIATIONS BY OBSERVATIONS FROM ABASTUMANI

Goderdzi Didebulidze, didebulidze@iliauni.edu.ge

E Kharadze Abastumani Astrophysical Observatory, Ilia State University, Tbilisi, Georgia Tekle Didebulidze, tekle.didebulidze@gmail.com

Ilia State University, Tbilisi, Georgia Maya Todua, mayatodua@iliauni.edu.ge

E Kharadze Abastumani Astrophysical Observatory, Ilia State University, Tbilisi, Georgia

We consider possible coupling of geomagnetic disturbances and galactic cosmic rays (GCRs) flux changes with inter-annual and long-term variations of the cloudless days and total ozone content (TOC) observed at Abastumani Astrophysical Observatory during 1957-1993. The observations were carried out during cloudless conditions which allows us to investigate TOC and cloud covering possible coupling with cosmic factors. According to these data the annual and seasonal mean TOC and GCRs flux have negative trends. The tendency of decrease of the TOC is greater for geomagnetically disturbed days, which is evident for planetary geomagnetic indices Ap8 and Ap12. The TOC and corresponding number of cloudless days, observed on geomagnetically disturbed days, show their seasonal peculiarities. The TOC and GCRs flux decreases mainly during strong geomagnetically disturbed days (Ap50), except summer, when in June, in spite of GCRs flux decreases, there is a tendency of its increase and decrease in the number of cloudless days. The observed sensitivity of TOC inter-annual distribution on cosmic factor are important for the troposphere-stratosphere coupling processes which may influence inter-annual variations of dayand night-time cloud covering processes. The different behavior of TOC at spring equinox and summer time on magnetically disturbed days could be coupled with different inter-annual distributions of numbers of cloudless days and nights and the presence of semi-annual variations in it. It is also noted that the observed cloud covering and ozone content sensitivity on cosmic factors is important for climate change. Acknowledgement: This study is supported by Georgian Shota Rustaveli National Science Foundation Grant no. FR17-357.

C2.3-0017-18 OBSERVATION OF COMBINED EFFECTS OF LUNAR OCCULTATION OF A SOLAR FLARE DURING THE GREAT AMERICAN TOTAL SOLAR ECLIPSE OF 2017

The Great Amerian Total Solar Eclipse of August 2017 had a pleasant surprise stored for VLF observers in that some of the locations could witness VLF amplitude perturbation due to the eclipse superposed by a C 3.0 flare activity partly blocked by the lunar disc. We analyse one such observation and compare it with a similar observation we had in 2010 during the annular solar eclipse over India when the VLF amplitude variation clearly recorded a C1.3 flare being partly occulted by the lunar disc. We also studied other paths during TCE2017 where the flare was fully blocked. In both the cases, the flare increased the amplitude significantly on the top of the general dip profile due to the Eclipse. We discuss how we reproduced the observed signal variation and computed the spatio-temporal variation of the electron number density.

C2.3-0018-18 MID-LATITUDE IONOSPHERIC RESPONSE TO THE SUPER GEOMAGNETIC STORM OF MARCH 2015

Sushanta Kumar Mondal, sushskbu@gmail.com

Sidho Kanho Birsha University, WB, India, Purulia, India Sujay Pal, amisujaypal@gmail.com

Indian Centre for Space Physics, Kolkata, India Mahbub Rahaman, mahbubrahaman3@gmail.com

Sidho Kanho Birsha University, WB, India, Purulia, India

We have shown the response of the mid-latitude D-region ionosphere to the super geomagnetic storm of 17th March, 2015 using radio remote sensing technique. This geomagnetic storm, resulted from the coronal mass ejection on 15th March, was the strongest storm of 24th solar cycle. We analysed radio signal of the NAA transmitter at 24.0 kHz from four receiving stations across the north Atlantic region in Europe. The storm enhanced the entire diurnal signal during the course of the storm. The amplitude of the radio signal recovered to its pre-storm level almost after two weeks. We have observed similar type of response in all the propagation paths. We estimated the enhancement of electron density in the D-region ionosphere during this period with the help of a radio propagation model.

C2.3-0019-18 A EUV REFERENCE DATA SET FOR SOLAR CYLCLE 24 (2008-2018) BASED ON ISS-SOLACES AND OTHER INSTRUMENTS

Robert Schaefer, robert.schaefer@ipm.fraunhofer.de Fraunhofer IPM, Freiburg Im Breisgau, Germany Raimund Brunner, raimund.brunner@ipm.fraunhofer.de Fraunhofer IPM, Freiburg, Germany

Gerhard Schmidtke, gerhard.schmidtke@t-online.de Germany

In 2017 the SolACES Team published the Level 4 EUV data set, consisting of approximately 1600 spectra, ranging from 16 - 56 nm, over the total ISS-SOLAR-SolACES mission time (2008 - 2017). Even though the measurement cadence of spectral data acquisition is roughly only once a month, additional solar EUV spectra could be generated from ionization chamber measurements, by a modelling process. By combining true spectral measurements and spectra based on ionization chamber measurements, a total of about 1600 solar EUV spectra were accumulated during the mission time of 9 years.

The calibrated SolACES spectra are combined with data from other experiments to fill up the (time) gaps caused by the orbital and logistical conditions of the International Space Station. The extended data set covers almost one full solar cycle in the spectral range from 17 nm to 134 nm, and is intended to be used as a standard data set for solar cycle 24.

SPACE STUDIES OF THE UPPER ATMOSPHERES OF THE EARTH AND PLANETS INCLUDING REFERENCE ATMOSPHERES (C)

SMALL SATELLITE MISSIONS FOR AERONOMY AND IONOSPHERE STUDIES (C2.4)

C2.4-0001-18 SMALL SATELLITE MISSIONS: CREATING A NEW OPPORTUNITIES FOR THE COMMUNITY

Larry Paxton, larry.paxton@jhuapl.edu

Applied Physics Laboratory, Laurel, Maryland, United States

Our community stands at a critical juncture. We have the opportunity to embrace the new capabilities offered to us by lower cost, more widely available, access to space or we can choose the more familiar path of doing "business as usual". With the revitalization of the space program brought about by commercial participation and the greater number of nations that can access space, we can now begin to develop a systematic understanding of the Sun-Earth system. That critical juncture consists of two elements: 1) can we embrace new technologies?

2) can we work together in a broad, trans-national, multidisciplinary way to address gaps in our understanding? The advantage of a collaborative and diverse system is that we gain many different perspectives on this complex system that enable us to better constrain our models. Models have many free parameters and/or parameterized processes. They also have limitations on their ability to specify the state vectors of the upper atmosphere and their drivers. I stress models because, I would assert, we are not able to address a fundamental question: do we have a complete understanding of the physics that drives the system? It may be that our parameterizations of some processes hide the fact that we aren't aware of some of the processes. Some of these questions can be best addressed by combining spaceand groundbased instruments to test hypotheses about mechanisms and processes. I will describe some of the many ways that groundand space-based techniques can be used to explore the ionosphere and, in particular, why cubesats and other small satellites are so important. By combining our approaches and incorporating the space-, groundand modelingcommunity into the design of scientific investigations, we can advance our understanding of this amazing physical system.

C2.4-0002-18 DOPPLER SCANNING WITH GAS FILTERS (DSGF): A GATEWAY TO OBSERVING UPPER ATMOSPHERE DYNAMICS

Larry Gordley, l.l.gordley@gats-inc.com GATS, Newport News, Virginia, United States Benjamin Marshall, tom@gats-inc.com

GATS, Newport News, Virginia, United States

A technique for measuring upper atmosphere winds and temperature was describe by Gordley and Marshall (2011) and presented at the 2012 COSPAR meeting in Mysore, India. The method, called the Doppler Wind and Temperature Sounder (DWTS), images gas filtered earth limb emission, from low earth orbit, perpendicular to the orbit velocity vector. The change in signal due to the effective Doppler scanning by the gas filter as the limb scene passes through the FOV can be used to infer temperature and wind components. Although a major advance over current methods, the DWTS wind and temperature come from limb observations that are intrinsically limited to 100 km or more in horizontal resolution along the observation path. This talk briefly reviews the DWTS technique and then demonstrates how the DSGF limb observations can be extended with nadir observations to mitigate the limb resolution problem. The result is the ability to retrieve the upper atmosphere wave dynamics in 3 dimensions with horizontal resolution of 10 to 20 km and vertical resolution ranging from 3 to 8 km over the altitudes from cloud-top to 100 km. This now enables quantification of the key dynamical mechanisms connecting the lower to upper atmosphere.

Gordley, L. L., Benjamin T. Marshall, "Doppler Wind and Temperature Sounder: A new approach using gas filter correlation radiometry", JARS, Vol 5, 2011.

C2.4-0003-18 SOSWEET-SOUP (SOLAR, SPACE WEATHER EXTREME EVENTS AND STRATOSPHERIC OZONE ULTIMATE PROFILES) DUAL CONSTELLATION MISSION

Luc Damé, luc.dame@latmos.ipsl.fr

Laboratoire Atmosphères, Milieux, Observations Spatiales, Guyancourt, France Mustapha Meftah, mustapha.meftah@latmos.ipsl.fr

CNRS, Guyancourt, France SoSWEET-SOUP Team

A. Hauchecorne, S. Bekki, P. Keckhut, A. Irbah, A. Sarkissian, M. Marchand, R. Thiéblemont, J.-P. Duvel, D. Bolsée, N. Pereira, D. Sluse, G. Cessateur, et al.

SoSWEET-SOUP is an innovative small satellites constellation which aims to measure on complementary platforms the solar influence on climate, namely on one part solar activity and spectral variability and, on the other, the different components of the Earth radiation bud- get, energy input and energy re-emitted at the top of the Earth atmosphere, with a particular focus on the UV part of the spectrum and on the ozone layer, which are most sensitive to solar variability. The far UV (FUV) is the only wavelength band with energy absorbed in the high atmosphere (stratosphere), in the ozone (Herzberg continuum, 200-220 nm) and oxygen bands, and its high variability is most probably at the origin of a climate influence. A simultaneous observation of the incoming FUV and of the ozone (O3) production, would bring an invaluable information on this process of solar-climate forcing. Space instruments have already measured the different components of the Earth radiative budget but this is, to our knowledge, the first time that all instruments will be operated simultaneously on coordinated platforms. This characteristic guarantees by itself obtaining new significant original scientific results.

SoSWEET-SOUP is an evolution of the SUITS/SWUSV and SUMO proposed missions, acknowledging the scientific advantages of associating a constellation of 10 to 12 small satellites of some 20 to 30 kg (12 "U" or so nanosatellites) on equatorial orbits (+/- 20° in latitude) to a small polar satellite of 100 to 120 kg on a OneWeb like platform for an almost continuous solar following (a polar orbit is also essential to the understanding of the relation between solar UV variability and stratospheric ozone on arctic and antarctic regions).

SoSWEET-SOUP definition's options are still under assessment but will include, on the polar satellite, SUAVE (Solar Ultraviolet Advanced Variability Experiment), an optimized heavyduty thermally stable SiC telescope for FUV (Lyman-Alpha) and MUV (200-220 nm Herzberg continuum) imaging (sources of variability, extreme events detection), and SOLSIM (SOLar Spectral Irradiance Monitor), a newly designed double-monochromator instrument covering the 170-340 nm ultraviolet spectral range and in within a limited mass-power budget. Other instruments include a small coronagraph, UV and ozone radiometers, Earth radiative budget assembly, Electron-Proton detectors and a vector magnetometer. The constellation of small satellites includes, on its side, precise ozone profiles measurements (miniGOMOS experiment with dual Sun and stars occultations) and detailed energy radiative budget monitors. Science objectives, mission profiles and model payloads will be presented and opportunities of missions and potential collaborations discussed.

C2.4-0004-18 PRELIMINARY RESULTS OF ADVANCED IONOSPHERIC PROBE ONBOARD FORMOSAT-5 SATELLITE

Chi-Kuang Chao, ckchao@jupiter.ss.ncu.edu.tw

National Central University, Chung-Li, Taiwan, Taiwan, China

A remote sensing satellite, FORMOSAT-5, was launched by a SpaceX Falcon 9 launch vehicle from Vandenberg Air Force Base Space Launch Complex 4E at 2:51 25 August 2017 CST into a 98.28° inclination sun-synchronous circular orbit at 720 km altitude along 1030/2230 local time sector. Advanced Ionospheric Probe (AIP) is a piggyback science payload developed by National Central University for FORMOSAT-5 satellite to explore space weather/climate and seismic precursors associated with strong earthquakes. The AIP is an all-in-one plasma sensor that measures ionospheric plasma concentrations, velocities, and temperatures in a time-sharing way and is capable of measuring ionospheric plasma irregularities at a sample rate up to 8,192 Hz over a wide range of spatial scales. Validation on retarding potential analyzer mode has been performed in Space Plasma Simulation Chamber at lab, in a flight test on sounding rocket, and during in-orbit checkout phase of the FORMOSAT-5 satellite. No significant hysteresis on measured current-voltage curves indicates that the AIP grids are almost free of contamination and could make an accurate measurement of ionospheric plasma parameters. Meanwhile, some typical ion density profiles measured by the FORMOSAT-5/AIP in night-side orbits with a geographic latitude coverage from -60° to 60° will be presented. Ion density maxima near equator and mid-latitude troughs near 40°-60° geographic latitude are helpful to identify AIP performance in the future.

The Advanced Ionosphere Probe (AIP) aboard the FORMOSAT-5 mission is an all in one in-situ plasma sensor combining retarding potential analyzer, ion trap, ion drift meter, and planar Langmuir probe modes in a time-sharing manner, providing measurements of ion density, temperature, composition, and drift velocity, as well as electron temperature. Launched in August 2017 into a 720 km Sun-synchronous repeating orbit, AIP is actively providing observations of the aforementioned parameters in the low to mid latitudes around 22 hours local time. The coverage provided by FORMOSAT-5 AIP will be extended through the upcoming INSPIRESat-1 and IDEASSat (Ionosphere Dynamics Explorer and Attitude Subsystem Satellite) CubeSat missions. The spacecraft are respectively 6U+ and 3U CubeSats carrying the Compact Ionosphere Probe (CIP) - a miniaturized version of AIP, as payload. Both spacecraft are being developed with international partners as part of the International Satellite Program in Research and Education (INSPIRE) consortium, with IDEASSat being developed by National Central University in Taiwan and funded in part by the National Space Organization (NSPO). With both spacecraft operational in high inclination Sun synchronous orbits following the expected IDEASSat launch in 2020, comprehensive in-situ measurements of ionospheric variability and irregularities can be obtained to further extend the AIP ionospheric observations to high latitudes, additional local times and altitudes.

The hydrogen exosphere constitutes the uppermost atmospheric layer of the Earth, and its shape may reflect the last stage of the atmospheric escape process. The distribution of hydrogen in the outer exosphere remains unobserved because outer geocoronal emissions are difficult to observe from within the exosphere. In this study, we used the Lyman Alpha Imaging Camera (LAICA) onboard the Proximate Object Close Flyby with Optical Navigation (PROCYON) spacecraft, located outside the exosphere, to obtain the first image of the entire geocorona that extends to more than 38 Earth radii. The observed emission intensity distribution can be reproduced using our analytical model that has three parameters: exobase temperature, exobase density, and solar radiation pressure, which implies that hot hydrogen production in the magnetized plasmasphere is not the dominant process shaping the outer hydrogen exosphere. However, the role of the magnetic effect in determining the total escape flux cannot be ruled out. In this report, we show the first high-quality, and wide-field-of-view (FOV) image of Earth's hydrogen corona obtained by the first interplanetary microspacecraft. Hydrogen geocorona has not been observed by wide FOV imager since Apollo 16 in 1972, which observed only up to 10 R of FOV. The field of view of our observation is 10 times wider than that in past. Furthermore, since the advancement in deep UV detection technology in the last four decades is very large, the improvement in data quality is also very large. In fact, our newly obtained data strongly support a different picture for geocorona distribution. More specifically, we found that the observed ecliptic north-south symmetrical distribution can be reproduced by a simple analytic model and is not consistent with past results. Our result strongly suggests a combination between a compact science instrument and a flexible interplanetary microspacecraft allows us to measure important scientific observables not readily accessible with conventional large-scale spacecraft missions.

C2.4-0007-18 ADDRESSING CLIMATE ISSUES WITH SMALL SATELLITES: RADIATIVE BALANCE AND TEMPERATURE

Philippe Keckhut, keckhut@latmos.ipsl.fr

Université de Versailles Saint Quentin, Guyancourt, France Mustapha Meftah, mustapha.meftah@latmos.ipsl.fr

CNRS, Guyancourt, France

Alain Hauchecorne, alain.hauchecorne@latmos.ipsl.fr LATMOS/IPSL/CNRS/UVSQ, Guyancourt, France Slimane Bekki, slimane.bekki@latmos.ipsl.fr CNRS/INSU, LATMOS-IPSL, Guyancourt, France Alain Sarkissian, alain.sarkissian@latmos.ipsl.fr LATMOS / UVSQ - IPSL - CNRS, Guyancourt, France

Atmospheric temperatures result of the radiative balance between Earth emission and Solar irradiance. To resolve such an issue it is required to insure global measurements of vertical temperature profiles, IR Earth emissions and solar irradiance on a long term basis. IR emissions and UV-Visible solar flux are related to composition and albedo that need to be performed simultaneously with temperature because of their space and time variability. Solar irradiance required to be observed on the UV part of the spectrum that exhibit the largest changes and having the largest atmospheric impact. Actual instruments are not numerous and suffer from discontinuities. Such measurements can be performed by miniaturized instruments and conducted on board small satellites. A possible strategy consist in having a constellation to insure a global survey. Continuity can be access with successive instruments if instrument drifts can be reduced.

C2.4-0008-18 DEVELOPMENT OF PHYSICS-BASED GLOBAL MODELS OF THE THERMOSPHERE AND IONOSPHERE FOR SATELLITE DRAG DETERMINATION

George Bowden, g.w.bowden@gmail.com

University of New South Wales Canberra, Campbell, Australia Melrose Brown, melrose.brown@adfa.edu.au

University of New South Wales Canberra, Canberra, Australia Lewis Freeland, lewis.freeland@student.adfa.edu.au

University of New South Wales Canberra, Canberra, Australia James Gilmore, james.gilmore@unsw.edu.au

University of New South Wales Canberra, Campbell, Australia Russell Boyce, russell.boyce@adfa.edu.au

University of New South Wales Canberra, Canberra, Australia

Accurate determination of the properties of the upper atmosphere is vital for orbit prediction. The drag experienced by objects in low Earth orbit (LEO) is primarily dependent on neutral species density and to a lesser extent wind velocity. However, recent research at UNSW Canberra suggests that charged species may affect drag more strongly than previously believed. These quantities can be computed using physics based models, such as the Global Ionosphere Thermosphere Model (GITM) developed at the University of Michigan. This presentation details progress in modelling the LEO environment using GITM for various solar and geomagnetic conditions.

The influences that various improvements to the physical models in GITM have on thermospheric and ionospheric conditions are investigated. The effects of changes to models which describe thermal conductivity, NO cooling and plasmasphere transport on densities and velocities in the thermosphere are assessed. Various levels of solar and geomagnetic activity are considered. Results are compared with the empirical NRLMSISE-00 and IRI-2012 models. Moreover, the results are also compared with accelerometer measurements from the CHAMP satellite.

GITM is applied to predict thermosphere and ionosphere conditions relevant to the Buccaneer CubeSat. This satellite has an elliptical, quasi-sun synchronous orbit which allows investigation of spacecraft environment interactions across a range of altitudes. Circumstances in which charged drag is likely to become important for this satellite are identified. Outcomes from this research will contribute to precise orbit reconstruction and propagation, charge drag determination and manoeuvring using differential drag on planned UNSW satellite missions, including M1 and M2.

C2.4-0009-18 EARTH ENERGY IMBALANCE EXPLORER (EAGER)

Margit Haberreiter, margit.haberreiter@pmodwrc.ch PMOD/WRC, Davos Dorf, Switzerland

Christoph Jacobi, jacobi@uni-leipzig.de

University of Leipzig, Institute for Meteorology, Leipzig, Germany

In the science community there is growing need to measure the Earth's energy imbalance (EEI). We propose the EArth enerGy imbalance ExploreR (EAGER) mission, which will - for the first time - determine the EEI through measuring both incoming Total Solar Irradiance (TSI) and Solar Spectral Irradiance (SSI) as well as the outgoing thermal and reflected solar radiation at the TOA with the same instrument type. To further ensure the highest possible accuracy and stability for the EEI observations, in-flight calibration of the solar observations will be enabled through applying very stable DARA-type TSI sensors in combination with transfer filters as a reference for the SSI observations, complemented by ionisation chambers for the calibration in the EUV wavelength range. Similarly, for the Earth observations, the fast bolometric sensors will be calibrated by a stable Earth-pointing DARA instrument. Ultimately, using the DARAtype TSI as calibration facility in space will allow us to determine the EEI with the required precision.

C2.4-0010-18 THE OCCULTATION WAVE LIMB SOUNDER (OWLS) ON INSPIRESAT-3

Edward Thiemann, thiemann@lasp.colorado.edu

LASP / University of Colorado, Boulder, Colorado, United States

Solar occultations served as an early work-horse for characterizing the temperature and density of Earth's thermosphere because of the technique's capability of making self-calibrated measurements of thermospheric density from roughly 90 to 400 km. However, solar occultations have been abandoned in recent decades, and few, if any, satellite-borne solar occultation instruments designed specifically for characterizing the thermosphere have ever flown. Meanwhile, few other methods have been proven capable of profiling the 120-300 km region of the thermosphere, leading some authors to label this region the "Thermospheric Gap" due to its lack of measurements. The Occultation Wave Limb Sounder (OWLS) instrument scheduled to fly on the INSPIRESat-3 small-sat aims to fill the Thermospheric Gap by making solar occultation measurements from 90 to 400 km, spanning from the mesopause to the exobase. OWLS is capable of measuring major neutral species (O2, N2 and O) density and temperature at 20 km vertical resolution below 150 km, and 5 km resolution above 150 km. In addition to simply filling the Thermospheric Gap, a primary focus of the OWLS mission is to understand how gravity waves propagate and dissipate in the thermosphere, addressing a Key Science Goal of the 2013 NAS Solar and Space Physics Decadal Survey. OWLS will achieve its science goals with two ultraviolet channels. One channel is a full-disk integrated far ultraviolet spectrograph for measuring density, temperature and abundance from 90-250 km at high absolute accuracy and 20 km vertical resolution, using methods proven in the early 1970s. The second channel is an extreme ultraviolet (EUV) imager with bands at 20 and 30 nm for measuring density, temperature and abundance from 150-400 km at <5 km vertical resolution, using technology proven on the

Solar Dynamics Observatory and methods proven recently for EUV photometers at both Earth and Mars. This talk will describe the OWLS science objectives, instrumentation, measurement principles, and anticipated observations.

C2.4-0011-18 THE LOW-LATITUDE IONOSPHERE/THERMOSPHERE ENHANCEMENTS IN DENSITY (LLITED) MISSION

Rebecca Bishop, rebecca.l.bishop@aero.org

The Aerospace Corporation, Los Angeles, California, United States
James Clemmons, james.clemmons@aero.org

The Aerospace Corporation, Los Angeles, California, United States
Aroh Barjatya, aroh.barjatya@erau.edu

Embry Riddle Aeronautical University, Daytona Beach, Florida, United States Richard Walterscheid, richard.walterscheid@aero.org

Aerospace Corporation, Los Angeles, California, United States

The Low-Latitude Ionosphere/Thermosphere Enhancements in Density (LLITED) CubeSat mission is a funded mission through NASA HTIDs program. It is a 3-year grant with CubeSat delivery at 20 months and a 1-year on-orbit mission life. The mission is to provide both ionosphere and thermosphere measurements related to the Equatorial Ionization Anomaly (EIA) and the Equatorial Temperature and Wind Anomaly (ETWA). The EIA and ETWA are two of the dominant ionosphere/thermosphere interactions on the low-latitude duskside. While the EIA has been extensively studied both observationally and with modeling, the ETWA is less well known since observations are infrequent due to a lack of suitably instrumented spacecraft at appropriate altitudes. LLITED will, for the first time, provide coincident high resolution measurements of the duskside ionosphere/thermosphere at lower altitudes that will characterize and improve our understanding of the ETWA, provide insight into the coupling physics between the ETWA and EIA, and increase our knowledge of the duskside dynamics that may influence space weather.

The LLITED mission will consist of two 1.5U Cubesats in a high-inclination circular orbit, with an orbit altitude between 350 and 450 km. The cubesats will maintain a 1/4 to 1/2 orbit separation to each other in order to observe any temporal changes as the ETWA evolves. The bus and subsystems are provided by The Aerospace Corporation. Both CubeSats will host three payloads: an ionization gauge (IG), planar ion probe (PIP), and GPS radio occultation sensor (GPSRO). The Aerospace Corporation is providing the IG and GPSRO sensors and EmbryRiddle is providing the PIP. The products provided are in-situ neutral pressure/density, in-situ plasma density, and slant TEC. The observations from LLITED will be combined with other available data, such as the remote sensing observations of ICON, to provide a comprehensive and compelling dataset of the ETWA.

C2.4-0012-18 THE MULTI-NEEDLE LANGMUIR PROBE SYSTEM FOR EXPLORATION OF THE GLOBAL IONOSPHERE

Joran Moen, jmoen@fys.uio.no University of Oslo, Oslo, Norway Huy Hoang, huy.hoang@fys.uio.no University of Oslo, Oslo, Norway

Lasse B.N. Clausen, lasse.clausen@fys.uio.no University of Oslo, Oslo, Norway

Espen Trondsen, espen.trondsen@fys.uio.no University of Oslo, Oslo, Norway

We present the University of Oslo (UiO) multi-Needle Langmuir probe (m-NLP) system developed for small satellites. The scientific driver for this measurement technique, originally invented for sounding rockets, is to investigate plasma structuring due to instability/turbulence processes. The system had acquired flight heritage on a number of sounding rocket missions before we developed a miniaturized version for cubesats. The m-NLP system is additionally capable of monitoring the spacecraft potential, and combined with an electron emitter, we may control the platform potential. Controlling the platform potential is indeed a demanding task for high quality measurements onboard small spacecraft. The m-NLP system was put on eleven of the European Union QB50 spacecraft. We developed a further enhanced version for NorSat-1, which was launched into a polar, Low-Earth Orbit on July 14th, 2017 from Baikonur, Kazakhstan. NorSat-1 carries the multi-needle Langmuir probe (m-NLP) instrument which is capable of sampling at a rate up to 1 kHz, thus offering unprecedented opportunity to continuously resolve ionospheric plasma density structures down to a few meters. The satellite crosses the equatorial and Polar Regions twice every 90 minutes, providing a wealth of data, that we will use to monitor turbulent regions disturbing Global Navigation Satellite System (GNSS) signals as input for ionosphere space weather forecast models. We are involved in several new projects under way. Our aim is to equip a fleet of LEO satellites to continuously monitor the GNSS disturbance regions around the Earth.

C2.4-0013-18 FIRST RESULTS FROM VELOX-CI GPS RADIO OCCULTATION MEASUREMENTS

Li Bingxuan, bxli@ntu.edu.sg

Nanyang Technological University, Singapore, SINGAPORE, Rep. Of Singapore Bo Han, bo.han@ntu.edu.sg

Nanyang Technological University, Singapore, SINGAPORE, Rep. Of Singapore Tzu-Wei Fang, tzu-wei.fang@noaa.gov

University of Colorado, Boulder, Colorado, United States Amal Chandran, achandran@ntu.edu.sg

Nanyang Technological University, Singapore, Singapore, Rep. Of Singapore

Global Positioning Systems (GPS) Radio Occultation (RO) is a robust atmospheric remote sensing technique that can derive vertical profiles of the Earth atmosphere. GPS receivers on Low Earth Orbiting (LEO) satellites are common platforms for hosting the RO experiment. Through the relative motion between the GPS satellite and the LEO satellites, the signals emitted from the GPS satellites pierce through the Earth's atmosphere and get refracted. The refracted GPS signal is then picked up by the receivers on LEO satellites. The atmosphere induces bending and attenuations to the GPS signal, which can be translated to useful atmospheric information such as the refractivity, temperature, pressure and humidity. These measurements can then be assimilated into current weather models to assist weather and climate studies.

Most GPS RO missions, such as CHAMP, SAC-C, TerraSAR-X, COSMIC, adopt the BlackJack series receivers developed by NASA's Jet Propulsion Laboratory (JPL), employ open-loop (OL) tracking when required. The OL tracking method can deal with the severe refractivity gradients that are commonly observed in the lower troposphere. Multiple RO payloads have been launched recently by many government with more commercial missions to be launched in the near future, however the data resources are still quite sparse for climate study. On the other hand, the commercial off-the-shelf (COTS) receivers have the advantage of low cost and short development time. And the COTS receivers are also commonly used to perform orbit determination and relative positioning in other missions.

VELOX-CI was launched on Dec. 16, 2015 into a near equatorial orbit. It is the second micro satellite of Satellite Research Center (SaRC) at Nanyang Technological University. VELOX-CI carried out a total of 136 RO measurements, and collected 448 hours of GPS data with the lowest penetration altitude of 6 km. In this study we present VELOX-CI RO results for troposphere refractivity analysis and ionosphere electron density analysis. We also evaluated the VELOXCI COTS receiver's precise orbit determination performance as a reference of possible error source. The RO results are compared against ground-based measurement, numerical weather model as well as other co-located satellite measurements from COSMIC

and TIMED-SABER. The troposphere refractivity profiles are compared with the integrated global radiosonde archive (IGRA) radiosonde data, ECMWF ERA5 product, and COSMIC and MERRA measurements. The ionosphere profiles are compared with ionosonde data from multiple locations, COSMIC and IRI. In this talk, we present several findings from the VELOX CI mission, which may help with the development and data processing of similar RO missions.

C2.4-0014-18 A NEW COMPACT AND LOW COST LANGMUIR PROBE AND ASSOCIATED ONBOARD DATA HANDLING SYSTEM FOR CUBESAT

Polinaya Muralikrishna, polinaya.muralikrishna@inpe.br

Instituto Nacional de Pesquisas Espaciais - INPE, São José Dos Campos, Brazil Langmuir Probe Team

S. Domingos, A.F.P. Horna and Walter A. dos Santos (INPE)

A new compact and low cost Langmuir Probe and associated onboard data handling system are being developed at Instituto Nacional de Pesquisas Espaciais for launching on board one of the future 2U CubeSat missions. The system is a simplified and compacted version of the Langmuir Probe payloads launched on board several Brazilian SONDA III rockets and also developed for the Brazilian scientific satellites SACI-1 and SACI-2. The onboard data handling system will have the dual functions of preprocessing the data collected by the Langmuir Probe and acting as the interface between the experiment and the on board computer. The Langmuir Probe sensor in the form of two rectangular stainless steel strips of total surface area of approximately 80cm^2 will be deployed soon after the injection of the CubeSat into orbit. A sweep voltage varying linearly from 0V to 3.0V in about 1.5 seconds and then remaining fixed at 3.0V for 1 second will be applied to the LP sensor to obtain both the electron density and electron temperature. A high sensitivity preamplifier will be used to convert the sensor current expected to be in the range of a few nano amperes to a few micro amperes into a varying potential. In order to cover the large dynamic range of the expected sensor current the preamplifier output will be further amplified by a logarithmic amplifier before being sampled and sent to the data handling system. The data handling system is projected to handle 8 analog channels and 4 digital words of 8 bits each. The incoming data will be stored in a RAM and later sent to the on board computer using a serial RS422 communication protocol. The interface unit will process the telecommands received from the on board computer. The interface is also projected to do FFT analysis of the LP sensor data and send the averaged FFT spectral amplitudes in place of the original unprocessed data. The system details are presented here.

C2.4-0015-18 DERIVATION OF IONOSPHERE IRREGULARITY FROM TOTAL ELECTRON CONTENT DATA MEASURED BY CUBESAT CONSTELLATION

Rahmi Rahmatillah, o350941r@mail.kyutech.jp Kyushu Institute of Technology, Kitakyushu, Japan Mengu Cho, cho@ele.kyutech.ac.jp

Kyushu Institute of Technology, Kitakyushu-shi, Japan Kateryna Aheieva, aheieva.kateryna486@mail.kyutech.jp Kyushu Institute of Technology, Kitakyushu, Japan

The study of ionosphere irregularities has been a scientific interest over the years. This irregularities shows the plasma density variation which can occur rapidly. Practically, this irregularities can affect the performance in the radio communication from satellite to the ground. Many complex factors can contribute to the irregularity in the ionosphere, such as geographic factor and space weather condition. Geographically, the variation of plasma density varies by latitude, longitude, height from the ground and the observation time. Apparently, the fluctuation of plasma density mostly occur in the low latitude 0 - 300 after sunset. Large depletion in the TEC number indicates the phenomenon of plasma bubble which located from the lower ionosphere to the top side of ionosphere. This article will discuss about the observation of ionosphere by SPATIUM, a 2U CubeSat project developed jointly by Kyushu Institute of Technology, Japan and Nanyang Institute of Technology, Singapore. SPATIUM suggests a mission to do scientific study of ionosphere using a satellite carrying a precise chip scale atomic clock (CSAC). This paper presents the basic algorithm to derive the ionosphere irregularity will be derived from the SPATIUM observation data.

C2.4-0016-18 PETITSAT - A 6U CUBESAT TO EXAMINE THE LINK BETWEEN MSTIDS AND IONOSPHERIC PLASMA DENSITY ENHANCEMENTS

Goddard Space Flight Center, Greenbelt, Maryland, United States Luis Santos, luis.h.santos@nasa.gov

Goddard Space Flight Center, Greenbelt, Maryland, United States

The midand low-latitude ionosphere is home to a variety of plasma density irregularities, including depletions (bubbles), enhancements (blobs), and small-scale scintillation, which result in the distortion of radio wave propagation. Recent observations from the C/NOFS satellite suggest that multiple mechanisms are responsible for forming plasma density enhancements, with wave action in the thermosphere as a significant driver of the enhanced densities. Indeed, statistical analysis of enhancements observed from satellites resembles the statistics of MediumScale Traveling Ionosphere Disturbances (MSTIDs) with respect to seasonal variability and solar activity. In order to investigate the link between these two phenomena, both in-situ data of the plasma enhancement and remote data of the MSTID at the magnetic footpoint are required. petitSat is a CubeSat mission designed to provide in situ measurements of the plasma density, 3D ion drift, as well as ion and neutral composition. The instrument suite includes a combined retarding potential analyzer and cross-track drift meter and a neutral mass spectrometer. This instrument suite will provide comprehensive information about the fluctuations in plasma, as well as changes in the neutral profile. petitSat will launch into a 51 deg inclination orbit at 400 km (consistent with an International Space Station deployment),

allowing for numerous conjunctions with the Boston University All-Sky Imager network and GPS receivers from the International Global Navigation Satellite Systems (GNSS) Service (IGS) network over the mission lifetime.

C2.4-0017-18 DORIS OBSERVATIONS FROM LEO FOR 3D SPACE WEATHER

David Rainwater, rain@arlut.utexas.edu

University of Texas at Austin, Austin, Texas, United States

Study of the upper and lower atmosphere has advanced to the point where a compelling need has emerged for global real-time specification of the most important observations as inputs to climate and other high-resolution assimilative models. For the ionosphere, plasmasphere and magnetosphere this is the local free electron density (ED); for the troposphere it is the local water vapor content (WVC). Currently, available data describes only the synoptic (few to tens of degrees) ionospheric features, but future needs require mesoscale (tens to hundreds of km) description. We describe a system concept for a DORIS receiver to be flown on a future constellation of weather satellites that would provide precise real-time global specifications of ionosphere 3D electron density profile (EDP) and troposphere WVC, as well as ionospheric scintillation maps at two length scales. We emphasize the ionospheric feature sizes that could be resolved - 100 km scale or less horizontally - and how the data sets obtained could help illuminate the transition from persistent to turbulent structures.

C2.4-0018-18 AN EQUATORIAL SATELLITE CONSTELLATION FOR SPACE WEATHER MONITORING AND NOW-CASTING OVER THE SINGAPORE REGION.

University of Colorado, Boulder, Colorado, United States Chi-Kuang Chao, ckchao@jupiter.ss.ncu.edu.tw

National Central University, Chung-Li, Taiwan, Taiwan, China

The Regional Ionosphere Mapping and Autonomous Uplink (RIMAU) mission is a constellation of six CubeSats in an equatorial orbit, making Radio Occultation (RO) measurements of the atmosphere and in-situ Ionospheric measurements to characterize the ionosphere over equatorial South-East Asia in near real time. RIMAU builds on the success of the VELOX-CI mission which carried a COTS NOVATEL GPS receiver and have been operating successfully since December 2015. The Satellite Research Centre at Nanyang Technological University in Singapore has designed, built, tested and operated 7 satellites so far ranging from 1U cubesat to 135 kg VELOX-CI microsatellite. RIMAU will carry GPS receivers for RO and an Ionospheric payload consisting of a planar Langmuir probe, retarding potential analyser and Ion trap/drift meter. RIMAU-1 is scheduled to be in operation by 2020 with the full constellation scheduled for flight by 2021. A secondary objective of RIMAU is to provide a Low Earth Orbiting nanosatellite platform for communication with remote sensors in the region. RIMAU-I will demonstrate communication with remote water sensors monitoring water pollutants and uplink from ground based GPS sensors to adjust the sampling rate for the Ionospheric probe during periods of high scintillation. Understanding the occurrence and impact of Ionospheric irregularities is critically needed for equatorial countries like Singapore. Forecasting Ionospheric plasma bubbles and their day-to-day variability is one of the long-standing frontier challenges in space physics. In this paper, we present a novel idea to combine ground based and space based Ionospheric observations to monitor in near-real time the Ionosphere over the Singapore region to characterize Ionospheric disturbances and their impact on communication and navigation systems. The main data products from these measurements will be vertical profiles of the Total

Electron Content (TEC) in the ionosphere, atmospheric temperature and humidity profiles in the troposphere. RIMAU TEC measurements will be combined with ground based TEC measurements from 60 GPS receivers in the SE Asia region, operated by the Earth Observatory of Singapore to produce 3D maps of the Ionosphere. The outcomes from the study will be a space weather 'now-cast' system for the region, which has applications to minimize impacts to a number of critical applications, such as point positioning and real-time kinematics (i.e., the location of moving vehicles), which are particularly relevant to the aviation and maritime industry and the emerging autonomous vehicle industry.

C2.4-0019-18 A COMPACT GAMMA SPECTROMETER FOR SPACE MISSIONS WITH MINIATURIZED SATELLITES

Adriano Di Giovanni, adriano.digiovanni@nyu.edu

New York University Abu Dhabi, Abu Dhabi, United Arab Emirates

New gamma detection technologies provide opportunities for revolutionary new science to be done from space. For example, Gamma-Ray Burst detections associated with gravitational waves are among the most important scientific goals to achieve over the next few years. To date, the number of space missions looking for gamma interactions along with calorimetric measurements is quite limited due to high costs and the wide energy ranges of the Physics involved. However, the widespread diffusion of space missions based on miniaturized satellites (i.e. CubeSats) makes a different approach possible. A constellation of compact and low weight gamma spectrometers can be a valid option for a new era of experiments in space. A direct application might be the detection of Terrestrial Gamma-Ray Flashes (TGF) triggered by lightning or thunderstorms originating in the Earth's atmosphere. The characteristic signatures (i.e. Energy range and time evolution) of such events have been measured by AGILE and FERMI: we think that a TGF dedicated mission will improve understanding of the physics behind lightning initiation along with a refined knowledge of the dynamics of particle acceleration in the atmosphere. In particular, the time resolution and dead time limitations of current detectors could be overcome.

In this work, we describe a possible array made of several independent gamma detectors: each unit is composed of a 1-inch Cerium Bromide scintillating crystal coupled to a compact photomultiplier tube (Hamamatsu R11265U-100). Due to limited power budget, a custom multichannel front end board is used to readout, operate and control the system. The proposed detector array has been designed to fit inside 1U of a CubeSat where two arrays could be deployed on a 3U-CubeSat. We will describe the characterization of the basic unit in terms of energy calibration, energy, and time resolution. The main characteristics of the photodetector in use, such as linearity and gain versus applied voltage and more in general, working parameters as a function of the temperature, as well as a complete characterization of the scintillating crystal, will be also a topic of this work.

C2.4-0020-18 SENSITIVITY OF THE OPAL INSTRUMENT FOR GRAVITY WAVE DETECTION

Kenneth Zia, kennethzia@gmail.com

Utah State University, Hyrum, Utah, United States Ludger Scherliess, ludger.scherliess@usu.edu

Utah State University, Logan, Utah, United States Michael Taylor, mike.taylor@usu.edu

Utah State University, Logan, Utah, United States

Understanding the Earth's lower thermosphere (altitude range 90km-140km) is of high interest to the space science community because of competing forcing due to solar heating above and episodic wave forcing from below. The NSF sponsored OPAL(Optical Profiling of the Atmospheric Limb) mission is designed to measure the temperature profile in this region by observing day-time integrated line of sight of the O2 A-band (760nm) emission on the limb. The OPAL instrument, on a 3U CubeSat (10 cm x 10 cm x 30 cm), has an altitude resolution of 1km from tangent altitudes of 80-160 km and is expected to be launched from the International Space Station (ISS) (400 km altitude). To investigate the instrument's ability to detect space weather signatures (i.e. solar storms and gravity waves) in the lower thermosphere, A-band emission data we have developed a suite of models that simulate the flight track of the satellite, the attitude of its optical systems, as well as the expected atmospheric O2 A-band observations that will be seen by the instrument. These models combine in a virtual CCD image that is used to develop and test different OPAL running modes for gravity wave detection. We will present development and integration of the models that resulted in thresholds for gravity wave observations by OPAL.

C3.1-0001-18 ATMOSPHERIC STUDIES BY SPACE MISSIONS IN THE SOLAR SYSTEM AND BEYOND

Athena Coustenis, athena.coustenis@obspm.fr Paris Observatory, Meudon, France

The solar system objects with atmospheres have been studied with dedicated space missions since the beginning of the space exploration age. Earth's close neighbours, Venus and Mars have in particular been privileged targets of space missions, most recently with ESA's Venus Express and Mars Express and with NASA's Mars Odyssey, MSL, MRO and MAVEN, among other. These spacecraft have given important insights on the origin and characteristics of the atmospheres of the terrestrial planets and in particular on their very different evolution from that of our own planet in terms of habitability (Coustenis and Encrenaz, 2013, "Life Beyond Earth", Cambridge Univ. Press). In the outer solar system, following in the footsteps of the Voyager missions, recent large space missions - usually involving international collaboration (like Galileo, Cassini-Huygens, or Juno) -, have determined with precision the properties of the dense and extended giant planets atmospheres, but also revealed among their satellites new possible habitats in icy moons with atmospheres harboring organic chemistry and water vapour, associated with internal liquid water oceans and available energy sources. Current investigations look at different physical processes, such as greenhouse effects and environmental conditions, to find answers for the differences we observe in the large variety of gaseous envelopes within the solar system and how this diversity can inform us on what we can expect in other planetary systems. Applying our findings in the solar system to exoplanets and exomoons with atmospheres may help us better interpret current and future observations of space missions and ground-based measurements. At the same time, our understanding of the solar system and our own origins may benefit from such new information.

C3.1-0002-18 SPECTRAL ALBEDO OF VENUS CLOUDS IN THE UV AS MEASURED ONBOARD THE VEX ORBITER

Space Research Institute of RAS (IKI), Moscow, Russia

Venus clouds possess high spherical albedo (70-80%) in the visible spectral range, and the planet disk looks very bright and homogeneous. On the other hand, the ultraviolet (UV) albedo is 2-3 times lower and the clouds appear to be very contrasted. The dark spots point out to presence of some cloud components that absorb solar radiation at wavelengths from 250 to 400 nm. One of molecules is sulfur dioxide (SO2), which varies from 0.1 to 1 ppm at the cloud top [1, 2]. Other candidates are also sulfur-bearing species, sulfur Sx with different valences [3], OSSO [4], and even FeCl3 [5]. So far, there was no published precise measurement of Venus albedo in spectral range 200-400 nm that would allow retrieval the unknown UV absorbers of Venus clouds.

In the present work we perform data processing from two spectrometers that measured UV albedo of Venus clouds onboard the Venus Express (VEX) orbiter in 2006-2014. The UV channel of SPICAV operated at 115-320 nm [6], while the UV-VIS channel of VIRTIS covered 300-1000 nm [7]. We have selected a few tens of simultaneous nadir observations with similar pointing that allows us combining the clouds reflectance spectra at 200-400 nm. At the moment, spectral and absolute radiance calibrations are being performed for correct merging of spectra between two spectrometers.

J.-L. Bertaux and the co-authors from IKI acknowledge support by the Ministry of Education and Science of Russian Federation grant #14.W03.31.0017.

In the atmosphere of Venus at 90-110 km altitudes in the transition region between the superrotation and the subsolar-antisolar circulation, tracking of the O2(a1g) 1.27μm nightglow is practically the only method of studying the dynamics. The nightglow images were obtained by VIRTIS-M on Venus Express from 2006 to 2008. The horizontal wind speed can be obtained by tracking the displacement of the bright morphological features at given pairs of images. The resulting global mean velocity vector field covers the nightside between latitudes 75°S - 0°N and local time 19 h - 5 h. The mean zonal and meridional components are asymmetrical between the morning and the evening side in terms of direction and magnitude. The zonal wind speed in the eastward direction from the morning side exceeds the westward (evening) by 20-30 m/s, and the streams "meet" at 22±1 h. The meridional component is predominantly poleward on the morning side, ranging from 0 to -50 m/s, and changes to equatorward at mid-latitudes. The influence of underlying topography was suggested in some cases: above mountainous regions flows behave as if they encounter an "obstacle" and "wrap around" highlands. Instances of circular motion were discovered, encompassing areas of 500-4000 km.

The main cloud deck within Venus' atmosphere, which covers the entire planet between approx. 50 and 70 km altitude, is believed to consist mostly of liquid sulfuric acid. Below the main clouds, the temperature is high enough to evaporate the H2SO4 droplets into gaseous sulfuric acid forming a haze layer which extends to altitudes as deep as 35 km. Gaseous sulfuric acid in the lower atmosphere is responsible for a strong absorption of radio waves as seen in Mariner, Pioneer Venus, Magellan and Venera radio occultation observations. These radio wave absorption measurements can be used to derive the amount of H2SO4 in Venus' atmosphere. The radio science experiment VeRa onboard Venus Express probed the atmosphere of Venus between 2006 and 2015 with radio signals at 13 cm (S-band) and 3.6 cm (X-band) wavelengths. The orbit of the Venus Express spacecraft allowed to sound the atmosphere over a wide range of latitudes and local times providing a global picture of the sulfuric acid vapor distribution. We present absorptivity and H2SO4 profiles derived from Xand S-band signal attenuation for the time of the entire Venus Express mission. More than 600 H2SO4 profiles show the global sulfuric acid vapor distribution covering the northern and southern hemisphere on the dayand night side of the planet. A distinct latitudinal H2SO4 gradient and a southern northern symmetry are clearly visible. Observations over 8 years allow to study also long-term variations. Indications for temporal H2SO4 variations are found, at least at northern polar latitudes. The results are compared with observations retrieved by other experiments (VIRTIS, SPICAV) onboard Venus Express as well as with previous observations like Mariner, Pioneer Venus and the Magellan spacecraft.

C3.1-0005-18 SIMULATIONS OF VERTICAL PROFILES OF SULFUR MONOXIDE AND SULFUR DIOXIDE IN VENUS' MESOSPHERE

Franklin Mills, frank.mills@anu.edu.au

Australian National University, Canberra ACT, Australia Joshua Petrass, fmills@spacescience.org

California Institute of Technology, Pasadena, California, United States

Sulfur dioxide (SO2) plays many important roles in Venus' atmosphere. It is a precursor for the sulfuric acid that condenses to form Venus' global cloud layers and is likely a precursor for the unidentified UV absorber, which, along with CO2 near the tops of the clouds, appears to be responsible for absorbing about half of the energy deposited in Venus' atmosphere [1]. Published simulations using standard photochemistry [2,3] indicate the mixing ratio of SO2 should decrease roughly monotonically with increasing altitude as the source for SO2 is the troposphere. Observations, however, have consistently found an inversion layer in the upper mesosphere (above about 85 km altitude) where the mixing ratio of SO2 increases with increasing altitude [4,5,6]. Simulations using condensed H2SO4 as the medium for transporting sulfur from the lower mesosphere to the upper mesosphere have succeeded in replicating the upper mesosphere SO2 inversion layer [2,7], but these simulations either have required assumptions that stretch significantly the boundaries of known laboratory data or their calculated gaseous H2SO4 abundance has significantly exceeded the observational upper limit on gaseous H2SO4 [8]. S8 remains as a viable alternative medium by which sulfur can be transported from the lower mesosphere to the upper mesosphere but there are significant uncertainties in the proposed mechanism due to lack of laboratory data [7]. Two new approaches show promise as alternative explanations for the upper mesosphere SO2 inversion layer.

The Caltech/JPL photochemical model [9] was used for the numerical simulations. For these simulations, the 1-d continuity equation was solved simultaneously for all species over 58-110 km altitude. Vertical transport via eddy diffusion was set based on observations, as were the lower boundary conditions for HCl, CO, and OCS. Solar fluxes were based on measurements obtained by SORCE SOLSTICE and SORCE SIM [10,11]. For solar zenith angle (SZA)dependent simulations, calculations were run to steady-state using the solar flux expected for a specified local time on Venus' equator.

Calculated SZA-dependent SO2 profiles illustrate the upward shift with increasing SZA of the altitude at which optical depth unity is reached for the wavelengths where SO2 absorbs strongly [12]. These calculations represent the chemistry that would be expected if horizontal transport is neglected and the chemistry is allowed to equilibrate between vertical transport of mass and photons.

Comparing the calculated photochemical and transport lifetimes [12], photo-dissociation effectively stops at smaller SZAs at lower altitudes and the SO2 mixing ratio is approximately frozen at the mixing ratio where the photo-dissociation and transport lifetimes are equal. This "quenching," analogous to that occurring in temperature-dependent processes, results in a profile where the SO2 mixing ratio increases by a factor of two from 70 to 80 km altitude near the terminator. This agrees qualitatively, but not quantitatively, with observations.

Another possibility that has received only preliminary study is that compounds of S-Cl-O [13] may be sufficiently long-lived in the mesosphere to transport sulfur from the lower mesosphere to the upper mesosphere.

C3.1-0006-18 SULFUR CHEMISTRY AND CLOUDS ON VENUS

Vladimir Krasnopolsky, vlad.krasn@verizon.net

Moscow Institute of Physics and Technology, Moscow, Russia

Sulfur dioxide SO_2 is the most abundant minor species in the lower atmosphere of Venus with mixing ratio of 130 ppm. Chemistry is initiated in the lower atmosphere by production of free sulfur in $SO_2 + CO \rightarrow CO_2 + SO$ followed by $SO + SO \rightarrow SO_2 + S$. S recycles between free sulfur S_X (x = 1 to 8) and OCS with no net loss, so that mixing ratio of OCS + xS_X is constant and equal to 20 ppm. Photolyses of S_3 and S_4 stimulate this exchange as well. OCS + CO is also constant at 35 ppm below 35 km. Downward flow of H_2SO_4 + CO from the middle atmosphere is another source of chemistry in the lower atmosphere. Krasnopolsky and Pollack (1994) proposed two processes with a net reaction $SO_3 + 2\ OCS \rightarrow CO_2 + CO + SO_2 + S_2$ that is probably a substitute of a more complicated reaction system. The chemical kinetic model by Krasnopolsky (2013) that involves the above chemistry and this reaction, predicts vertical profiles of OCS, CO, H_2SO_4, S_3, and S_4 that agree with the spacecraft and ground-based observations. A very slow reaction $S + HCl \rightarrow SH + Cl$ originates hydrogen and chlorine chemistries in the lower atmosphere. They result in formation of hydrogen sulfide H_2S decreasing from 150 ppb near the surface to 30 ppb at 47 km. The predicted H_2 abundances are 3.5 and 8.5 ppb, respectively. The most abundant chlorine product is SO_2Cl_2 with mixing ratio of 3.5 ppb at 28-47 km. Formation of sulfuric acid in a narrow layer near the cloud tops is a key feature of Venus' photochemistry that greatly reduces abundances of SO_2 and H_2O above the clouds. Delivery of SO_2 and H_2O through this bottleneck determines the chemistry and its variations above the clouds. Small variations of eddy diffusion near 60 km result in variations of SO_2, SO, and OCS at and above 70 km within a factor of 30 and do not require volcanism. Variations of the SO_2/H_2O ratio at the lower boundary have the similar effect. The photochemistry does not predict significant sources and sinks of sulfur and chlorine species above 75 km, and the increase in the mixing ratios of SO_2 + SO, HCl, and HF to 100 km in some observations does not conform the element conservation. Along with the ClCO cycle, S

$+ O_2 \rightarrow SO + O$ is the basic process of O_2 removal.

H_2O-H_2SO_4 system was modelled in the Venus clouds by Krasnopolsky (2015). Gao et al. (2014) and Parkinson et al. (2015) calculated microphysics and particle size distributions at various levels in the clouds and haze. Krasnopolsky (2016) predicted aerosol sulfur at 10% of mass loading in the lower cloud layer, in accord with the Vega gas chromatograph and mass spectrometer measurements. Data on $FeCl_3$ as the mode 1 particles in the lower and middle cloud layers and the solution of 1% $FeCl_3$ in sulfuric acid in the mode 2 particles in the upper cloud layer as the NUV absorber have been updated as well. The controversial detections of chlorine in the middle cloud layer and phosphorus in the lower cloud layer by the Vega X-ray radiometer (Andreichikov et al. 1987) may be explained by condensation of $AlCl_3$ and H_3PO_4, respectively, but require independent confirmation.

C3.1-0007-18 INTERACTION OF SOLAR-RELATED EFFECTS AND STATIONARY GRAVITY WAVE ABOVE APHRODITE TERRA ACCORDING TO VMC/ VENUS EXPRESS WIND FIELDS

A set of UV (365 nm) images obtained by the Venus Monitoring Camera onboard Venus Express spacecraft was used to study the circulation of the atmosphere at upper boundary of clouds (70±2 km). 172000 displacement vectors (257 orbits) were obtained by digital wind tracking technique for observation period from 2006 to 2014. This data set allows studying both variation of the wind speed vs. latitude and longitude (correlation with surface topography) and dependence on local time. The zonal speed decrease was found above Aphrodite Terra. It has a solar-related character and strongly connected to the local noon. We studied the shape of the minimum wind speed structure (dependence of wind speed vs. longitude and latitude). It has an elongated shape in latitude. It was found that it repeats a contour of Aphrodite Terra at noon. The shape is conserved at least up to 30°S. In the same time, the wind speed increases by approximately 5 m/s to 30°S, and the area of minimum zonal speed shifts in direction of superrotation. The Sun influence manifests itself in the region of the stationary gravity wave existence above Aphrodite Terra as the mean zonal flow deceleration in near equatorial latitudes (0-30°S). The zonal speed minimum is observed at noon above highest region of Ovda Regio (western part of Aphrodite Terra). Outside the Aphrodite Terra, the Sun influence does not manifest itself. The structure above highlands of Aphrodite Terra observed at noon may be a result of the stationary wave which generated by Aphrodite Terra and possible higher stability of the atmosphere, as a result of Solar heating, allow gravity waves to reach the upper clouds where they break and decelerate the mean zonal wind. J.-L. Bertaux, I.V. Khatuntsev and

M.V. Patsaeva were supported by the Ministry of Education and Science of Russian Federation grant 14.W03.31.0017.

C3.1-0008-18 CONTRIBUTIONS OF THE CURIOSITY ROVER TO THE UNDERSTANDING OF THE MARTIAN ATMOSPHERE

Ashwin Vasavada, ashwin.r.vasavada@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Mars Science Laboratory Science Team

Ashwin R. Vasavada, Joy Crisp, Michael Meyer, and 500 others.

NASA's Curiosity Mars rover landed within Gale crater in August 2012 to assess the habitability of Mars in the past and present through investigations of the geology, geochemistry, and environment. A number of instruments on the rover study the atmosphere, including the grayscale Navigation Cameras (Navcam), the color Mast Cameras (Mastcam), the ChemCam spectrometer in passive mode, the Rover Environmental Monitoring Station (REMS), and the Sample Analysis at Mars (SAM) quadrupole mass spectrometer (QMS) and tunable laser spectrometer (TLS). Measurements span three Mars years. In addition, records of pressure, air and ground temperature, UV flux, wind, and relative humidity have hourly or better resolution over the full martian day. The results have improved our understanding of the evolution of the atmosphere as well as processes at scales from local to planetary.

Volume mixing ratios and isotopic ratios are determined with unprecedented precision. Some isotopes of Kr and Xe may be products of spallation or neutron capture in the regolith. Isotopic fractionation in H, C, O, N, and noble gases provides evidence of substantial atmospheric loss to space. D/H in water evolved from Hesperian clay minerals is intermediate between the present value and that of very early Mars, suggesting that a larger exchangeable water inventory existed at the time that the clay minerals formed in an ancient lake and groundwater system within the crater. Systematic measurements of methane show a repeating annual cycle that requires an active and seasonally variable source of methane, as well as transient spikes that remain unexplained. Column water vapor exhibits a seasonal behavior similar to that of orbiter measurements, but mixing ratios measured at the surface are depressed at night, consistent with temperature-dependent adsorption by surface materials. Curiosity's instruments do not have the sensitivity to directly measure this adsorption. The surface reaches the frost point for a few nights each winter, but frost has not been detected.

The pressure record reflects annual exchange with the polar caps; tidal modes as modulated by atmospheric dust heating; Northern Hemisphere equator-crossing baroclinic eddies; small dips due to dust-free vortices and dust devils; and, fluctuations from wind-induced dynamic pressure. Slope-driven circulations from the crater rim and central mound dominate the wind measurements, but local topography is observed to modify wind speed and direction. Winds also are inferred from observations of grain

and bedform motion in sand deposits, and from ventifacts. Dust optical depth peaks in both middle and late southern summer and is mini- mal through southern winter. Atmospheric dust within the crater varies similarly, but more smoothly, moderated by the rate of mixing vertically in the crater and horizontally with outside air. Local dust lifting results from gusts and vortices. Dust aerosol particle size is positively correlated with optical depth. The Aphelion Cloud Belt brings elevated water ice cloud opacity and increased cloud activity in southern winter, with inter-annual variability. Cloud detections are greatest in the morning with a secondary peak in mid-afternoon. Water ice crystal shapes are constrained from photometric analyses of all-sky imaging.

Mars Express remains one of ESA's most scientifically productive missions whose publication record now exceeds 1000 papers. Characterization of the geological processes on a local-toregional scale by HRSC, OMEGA and partner experiments on NASA spacecraft has allowed constraining land-forming processes in space and time. Recent results suggest episodic geological activity as well as the presence of large bodies of liquid water in several provinces (e.g. Eridania Planum, Terra Chimeria) in the early and middle Amazonian epoch and formation of vast sedimentary plains north of the Hellas basin. Mars Express observations and experimental teams provided essential contribution to the selection of the Mars-2020 landing sites. More than a decade-long record of the atmospheric parameters such as temperature, dust loading, water vapor and ozone abundance, water ice and CO2 clouds distribution, collected by SPICAM, PFS and OMEGA spectrometers as well as subsequent modeling have provided key contributions to our understanding of the martian climate. ASPERA-3 observations of the ion escape covering complete solar cycle have revealed important dependencies of the atmospheric erosion rate on parameters of the solar wind and EUV flux. The structure of the ionosphere sounded by the MARSIS radar and the MaRS radio science experiment was found to be significantly affected by the solar activity, the crustal magnetic field, as well as by the influx of meteorite and cometary dust. MARSIS and ASPERA-3 observations suggest that the sunlit ionosphere over the regions with strong crustal fields is denser and extends to higher altitudes as compared to the regions with no crustal anomalies. The ionospheric plasma expands to higher altitudes where it contacts with the solar wind plasma. Reconnection of solar magnetic field lines carried by the solar wind with field lines of crustal origin opens channels through which the ionospheric plasma escapes to space, producing strong and narrow cavities in the density. The situation is very different on the night side where the ionosphere has patchy structure. Such patchy ionizations are observed in the regions where field lines have a dominant vertical component. Through these patches the ionospheric plasma from the dayside penetrates and supplies the nightside ionosphere. Mars Express provides unique observation capabilities amongst the flotilla of spacecraft investigating Mars. The mission has been extended till the end of 2020. The observation program proposed for 2019-2020 includes both augmenting the coverage and extending long-time series, as well as new elements and potentially new opportunities for discoveries. It will be boosted by collaboration and synergies with NASA's MAVEN, ESA-Roscosmos Trace Gas Orbiter and other missions. The talk will give the mission status, review the recent science highlights, and outline future plans.

Mars Express team

Mars Express has continuously monitored the Martian environment from orbit since January 2004 (a total of more than seven Martian years) and is planned to continue for several more years. Among the numerous and important outcomes of the mission is thus a unique ensemble of climatology datasets. The datasets are unique because of 1) the very diverse payloads and 2) the non sun-synchronous polar orbit which has allowed, year after year, to observed atmospheric phenomena at various local times and seasons. The Martian environment have been remotely observed at many wavelengths: radar (ionosphere), radio (temperature and ionosphere), thermal infrared (temperatures, aerosols, clouds, water vapor), near infrared (frost, aerosols, water vapor,fluorescence), visible, and UV (ozone, temperatures, aerosols, airglow). The Mars Express team is now working to make the Mars Express "legacy" high level dataset available to the science community in the most convenient way on the ESA Planetary Science Archive.

C3.1-0011-18 INTERANNUAL VARIABILITY IN THE 'SOLSITICIAL PAUSE' IN MARTIAN PLANETARY WAVE ACTIVITY

Stephen Lewis, stephen.lewis@open.ac.uk

The Open University, Milton Keynes, United Kingdom James Holmes, james.holmes@open.ac.uk

The Open University, Milton Keynes, United Kingdom

Planetary waves have long been observed in the winter hemisphere of Mars, for example in the Viking Lander 2 surface pressure record, and are simulated in Mars global circulation models (MGCMs). Some of these waves are trapped near to the surface and give rise to the day-to-day variability, or weather, seen in the lower atmosphere. Large amplitude wave activity lasts from autumn to spring, but recent assimilations of spacecraft observations have led to the suggestion that wave activity near the surface falls to a subsidiary minimum directly around the winter solstice, a phenomenon called the 'solsticial pause' (Lewis et al. 2016). This behaviour is in contrast to waves higher in the atmosphere, above about 20 km, where activity can peak close to winter solstice.

We have conducted a nine-Mars Year (MY) consistent reanalysis of the martian atmosphere covering the period MY 24-32 and making use of data from three different spacecraft. Remotelysensed measurements of temperature, dust opacity, water and ozone from NASA's Mars Global Surveyor (MGS) and Mars Reconnaissance Orbiter (MRO) and ESA's Mars Express (MEx) were assimilated into a continuous model simulation. One of the most striking features of the reanalysis is the year-to-year variation in the martian dust loading, in particular during Northern Hemisphere winter. We establish that the solsticial pause is a robust, repeatable feature in both hemispheres and discuss its interannual variability.

Lewis, S.R., Mulholland, D.P., Read, P.L., Montabone, L., Wilson, R.J., Smith, M.D., 2016. The solsticial pause on Mars: 1. A planetary wave reanalysis. Icarus 264, 456–464.

C3.1-0012-18 LARGE-SCALE TRAVELING WEATHER SYSTEMS IN MARS' SOUTHERN EXTRATROPICS

Jeffery Hollingsworth, jeffery.l.hollingsworth@nasa.gov

NASA Ames Research Center, Moffett Field, California, United States Melinda Kahre, melinda.a.kahre@nasa.gov

NASA Ames Research Center, Moffett Field, California, United States Richard Urata, richard.a.urata@nasa.gov

NASA Ames Research Center, Moffett Field, New Jersey, United States

Between late autumn and early spring, the middleand high-latitudes within Mars' atmosphere support strong mean equator-to-pole temperature contrasts and an accompanying mean westerly polar vortex. Observations from both the MGS Thermal Emission Spectrometer (TES) and the MRO Mars Climate Sounder (MCS) indicate that such strong mean baroclinicitybarotropicity supports intense, large-scale eastward traveling weather systems (i.e., transient synoptic-period waves). Such extratropical weather disturbances are critical components of the global circulation as they serve as agents in the transport of heat and momentum, and generalized scalar/tracer quantities (e.g., atmospheric dust, water-vapor and ice clouds). These weather systems also interact with other large-scale atmospheric circulation components such as the quasi-stationary (i.e., forced Rossby) modes and the global thermal tidal modes. The character of such traveling extratropical synoptic disturbances in Mars' southern hemisphere during late winter through early spring is investigated using a high-resolution Mars global climate model (Mars GCM). The climate model includes a complex water-ice cloud microphysics package, one that produces simulation results that compare relatively well with the planet's current water cycle. The Mars GCM imposes interactively-lifted and radiatively-active dust based on a threshold value of the surface stress. The model exhibits a reasonable "dust cycle" (i.e., globally averaged, a dustier atmosphere during southern spring and summer occurs). Compared to the northern-hemisphere counterparts, the southern synoptic-period weather disturbances and accompanying frontal waves have smaller meridional and zonal scales, and are far less intense. Influences of the zonally asymmetric (i.e., east-west varying) topography on southern large-scale weather are investigated, in addition to large-scale up-slope/down-slope flows and the diurnal cycle. A southern storm zone in late winter and early spring presents in the western hemisphere via orographic influences from the Tharsis highlands, and the Argyre and Hellas impact basins. Geographically localized transient-wave activity diagnostics are constructed that illuminate dynamical differences amongst the simulations and these are presented.

C3.1-0013-18 A COUPLED ATMOSPHERE-HYDROSPHERE GLOBAL CLIMATE MODEL OF EARLY MARS: REPRODUCTION OF A 'COOL AND WET' SCENARIO FOR THE FORMATION OF WATER CHANNELS

Hiromu Nakagawa, rom@pat.gp.tohoku.ac.jp Tohoku University, Sendai, Japan

Martian water channels are considered evidence of a climate warm enough to allow the existence of long-term fluvial systems on early Mars during the Noachian and Hesperian boundary (3.853.6 Ga). Quantitative inferences of water channel formation from climate models are crucial to develop an accurate understanding of the early Martian environment. We present the results of a 3-dimensional Paleo Martian Global Climate Model (PMGCM) assuming the CO2/H2O atmosphere under the 'Faint Young Sun' (solar luminosity of 75% of the current value), with surface pressures between 0.5 and 2 bars. The PMGCM also has a hydrologic cycle module, which includes ocean thermodynamics, water vapor advection/convection/condensation/precipitation processes, and surface fluvial activities (e.g. fluvial and sediment transport).

The simulation with a surface pressure exceeding 1.5 bars indicated that as per the PMGCM, the early Martian surface environment would have been 'cool' (between 'warm' and 'cold'); namely, the mean surface temperatures were high enough (> 273 K) during spring to autumn, to allow seasonal melting of snow-ice deposits, and low enough (< 273 K) during winter to produce considerable snow precipitation and accumulation. The PMGCM also indicated a 'wet' surface environment characterized by precipitation and seasonal melting of snow/ice (neither 'dry' nor 'permanent frozen' states), and enough fluvial sediment transport in the southern low-mid latitudes to reproduce Martian valley networks within a relatively short time (less than 10 million years). We suggest that a moderate climate, that is, 'cool and wet' conditions lying between 'warm and wet' and 'cold and frozen,' is preferable to explain the fluvial activity on early Mars, which does not need to consider non-climatic mechanisms such as warming by meteorite impacts.

C3.1-0014-18 EXOMARS 2016 TRACE GAS ORBITER STATUS REPORT

Jorge Vago, jorge.vago@esa.int

European Space Agency, Noordwijk, Netherlands ExoMars Team

The ExoMars programme is a joint activity by the European Space Agency(ESA) and ROSCOSMOS, Russia. It consists of the ExoMars 2016 mission, launched 14 March 2016, with the Trace Gas Orbiter, TGO, and the Entry Descent and Landing Demonstrator, EDM, named Schiaparelli, and the ExoMars 2020 mission, to be launched in July 2020, carrying a Rover and a surface science platform. TGO arrived at Mars on 19 October 2016 and was inserted into a near equatorial, highly elliptical 4 sol period capture orbit. Two orbits in late November were dedicated to instrument calibration and initial science observations, where an excellent performance of all instruments could be confirmed. In January 2017 the orbital plane was changed to its final inclination of 74 degrees and the period was reduced to one Sol. Early March 2017 an additional two orbits were scheduled for instrument tests and observations, after which a long period of aerobraking commenced. The final near circular 400km altitude orbit, with a 2 hour period, is expected to be reached in April 2018 when instrument commissioning and initial scientific observations will start. The TGO scientific payload consists of four instruments. These are: ACS and NOMAD, both being spectrometers for atmospheric measurements in solar occultation mode and in nadir mode, CASSIS, a multichannel camera with stereo imaging capability, and FREND, an epithermal neutron detector for search of subsurface hydrogen. The mass of the TGO is 3700 kg, including fuel and the mass of EDM was 600 kg. The EDM was carried to Mars by the TGO and was separated three days before arrival at Mars but unfortunately failed during the last stage of the descent. This presentation will cover a brief description of the Trace Gas Orbiter mission, the present status and the planned future activities.

The NOMAD ("Nadir and Occultation for MArs Discovery") spectrometer suite [1] on board the ExoMars Trace Gas Orbiter (TGO) has been designed to investigate the composition of Mars' atmosphere, with a particular focus on trace gases, clouds and dust. The detection sensitivity for trace gases is considerably improved compared to previous Mars missions, compliant with the science objectives of the TGO mission. This will allow for a major leap in our knowledge and understanding of the Martian atmospheric composition and the related physical and chemical processes.

The instrument will conduct a spectroscopic survey of Mars' atmosphere in ultraviolet (UV), visible and infrared (IR) wavelengths covering large parts of the 0.2-4.3 μm spectral range. NOMAD is composed of 3 channels: a solar occultation only channel (SO - Solar Occultation) operating in the infrared (2.3-4.3 μm), a second infrared channel (2.3-3.8 μm) capable of doing nadir, but also solar occultation and limb observations (LNO - Limb Nadir and solar Occultation), and an ultraviolet/visible channel (UVIS - UV visible, 200-650 nm) that can work in the three observation modes. NOMAD offers an integrated instrument combining a flight-proven concept and innovations based on existing and proven instrumentation: SO is a copy of the Solar Occultation in the IR (SOIR) instrument [2] on Venus Express (VEx), LNO is a modified version of SOIR, and UVIS has heritage from the development in the context of the Humboldt lander.

NOMAD will provide vertical profiling information for atmospheric constituents at unprecedented spatial and temporal resolution. Indeed, in solar occultation, the vertical resolution is less than 1 km for SO and UVIS, with a sampling rate of 1 s (one measurement every 1 km), and occultations will range from the surface to 200 km altitude. NOMAD will also provide mapping of several constituents with an instantaneous footprint of 0.5 x 17 km^2 (LNO channel) and 5 km^2 (UVIS channel) respectively, with a repetition rate of 30 Martian days.

Preliminary results will be presented and discussed, covering observations recorded during cruise, Mars orbit insertion, the Commissioning Phase and first few weeks of the Science Phase.

C3.1-0016-18 SATURN AT 1-10 KM RESOLUTION: CASSINI IMAGING DURING THE FINAL YEAR

Andrew Ingersoll, api@gps.caltech.edu

California Institute of Technology, Pasadena, California, United States Shawn Ewald, spe@gps.caltech.edu

California Institute of Technology, Pasadena, United States

During Cassini's last year of existence, the spacecraft took numerous images of Saturn's northern hemisphere at 1-10 km resolution. The spacecraft was in a high-inclination orbit, so the image sequences were usually scans from the north pole to the equator. In the southern hemisphere, ring shadows interfered with the illumination of the planet. The spacecraft made its first dive between the rings and the planet on April 26, 2017 and took its final plunge into Saturn's atmosphere on September 15, 2017. Between those two dates, the Imaging Science Subsystem (ISS) imaged Saturn on two separate polar passes, with about 80 wide-angle images per pass. At closest approach, which was near the equator, the resolution was about 1 km per pixel. Such resolution was available before April using the narrow-angle camera. Here we present a sample of those images and their possible scientific significance.

Optically thin filamentary clouds are a common feature. The individual filaments are traceable for thousands of km. Given the clouds' low relative motion and their fine scale structure, we conclude that the horizontal diffusion coefficient is extremely small. We compare these clouds with similar clouds on Earth.

Scarp-like clouds, which represent an abrupt change in cloud altitude, are also common. They are optically thick and cast prominent shadows, enabling one to estimate the height of the scarp. The scarps usually follow lines of constant latitude and often are coherent for thousands of km and persist for years.

Ensembles of cyclones and anticyclones 2000-3000 km in diameter can travel together, despite their being at slightly different latitudes and therefore subject to slightly different ambient zonal velocities. We find that at high northern latitudes the cyclones and anticyclones persist for years, in agreement with del Rio-Gaztelurrutia et al. [Icarus 302, 499-513, 2018].

Based on methane-band imaging, the cloud tops of the anticyclones are high and those of the cyclones are low. Shading from oblique illumination indicates that the cloud tops of the anticyclones are dome-shaped.

C3.1-0017-18 OBSERVATIONS OF TITAN'S DETACHED HAZE 2005 - 2017

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, United States

Spacecraft images and stellar occultation measurements of Titan throughout the UV-Visible range reveal a local maximum in brightness or extinction optical depth at altitudes from about 250 - 500 Km above Titan's surface. The appearance in images is of a distinct haze layer, 'detached' from and above the main haze that extends to the surface. We now know that the optical appearance can be attributed to a deficit in the haze density just below the apparent altitude of the detached haze. The detached haze was first seen in Voyager images in 1981 (K. Rages and J. Pollack, Icarus, 55, 50-62, 1983, doi: 10.1016/0019-1035(83)90049-0). With hundreds of images of Titan and several UV occultations observed by Cassini ISS and UVIS instruments we now have a time history of the haze over a significant fraction of a Titan year. These show seasonal behavior of the altitude and amplitude of the detached haze that has only been recognized in retrospect as likely due to the breakup of the meridional circulation near equinox in the stratosphere and mesosphere. Some details of the observations are still not adequately explained by models. The detached haze disappeared after mid-2012 and began to reappear weakly and intermittently in 2016. These observations drive new models for Titan's circulation and haze microphysics. Future observational work will focus on the latitude distribution of the haze morphology, probes to deeper layers via longer-wavelength observations, and details revealed at higher spatial resolution.

C3.1-0018-18 PROFILES OF TITAN'S HIGH-ALTITUDE HAZE FROM MULTIPLE OCCULTATIONS

Jet Propulsion Laboratory, Pasadena, California, United States Yuk Yung, yly@gps.caltech.edu

California Institute of Technology, Pasadena, California, United States

Haze in Titan's upper atmosphere were observed in Cassini UVIS stellar occultations. Pointing motion, however, impaired the analysis process and only three occultations have been published to date. Most of the occultations are usable, but require special treatment. To address the problem, an innovative analytic method for correcting the effect of pointing motion has been developed using forward modeling of the Cassini/UVIS instrument spectral response function. The Markov Chain Monte-Carlo (MCMC) method has been applied to the analysis by including pointing in the state vector as parameters in the spectral fitting process. In addition to haze, LOS (line-of-sight) abundances of twelve other hydrocarbon and nitrile species are obtained in the analysis. Reduction of high-altitude haze profiles for thirteen occultations has been obtained, most of which have never been analyzed because of pointing motion. The new results provide a 2-D (highly interpolated) regional map of the haze abundance in Titan's upper atmosphere.

C3.1-0019-18 HELIUM 584Å AND H LYMAN-ALPHA AIRGLOW IN GIANT PLANETARY ATMOSPHERES: MODELING, OBSERVATIONS, AND IMPLICATIONS

Christopher Parkinson, theshire@umich.edu

University of Michigan, Ann Arbor, Michigan, United States Larry W. Esposito, larry.esposito@lasp.colorado.edu University of Colorado, Boulder, Colorado, United States

The atmosphere of the outer planets is mainly composed of H2 and neutral atomic helium. The study of He 584 A and H Lyman-alpha brightnesses is interesting as the EUV and FUV (Extreme and Far Ultraviolet) planetary airglow have the potential to yield useful information about mixing and other important parameters in their thermospheres. Time variation, asymmetries, and polar enhancement of the airglow are also possible and analysis of the public archived NASA mission data sets (i.e. Voyager and Cassini) can help solve some of the outstanding problems associated with these phenomena. The comparison of observations with results from sophisticated photochemical and radiative transfer models can also help ameliorate unexplained differences in the dynamical processes operating within planetary upper atmospheres. Powerful analysis techniques allow us to extract information on atmospheric mixing, temperatures, and temporal changes due to the solar and seasonal cycles from the variations in distribution and intensity of airglow emissions that result. The presentation will discuss the implications of interpretations from a comparison of modeling and observations in giant planetary atmospheres.

C3.1-0020-18 ANALYTICAL AND NUMERICAL STUDIES IN RADIO OCCULTATION EXPERIMENTS

Adrien Bourgoin, adrien.bourgoin@unibo.it University of Bologna, Forlì, Italy

Paolo Tortora, paolo.tortora@unibo.it Università di Bologna, Forli, Italy

Luis Gomez Casajus, luis.gomezcasajus@unibo.it Università di Bologna, Forlì, Italy

Marco Zannoni, m.zannoni@unibo.it Università di Bologna, Forlì, Italy

Since the 60's, radio occultation geometry has proven to be a powerful opportunity for sounding remotely planetary atmospheres. The basic idea behind this methodology is to analyze the changes in the Doppler frequency of a radio link between a transmitter and a receiver, when they are mutually occulted by a media of non-unity index of refraction. In the literature, there are different approaches devoted to the retrieval of the refractive profile from the Doppler variations. Let's mention, i) the analytic formulation of the Abel inversion which is only employed for spherically symmetric atmospheres, and ii) the ray tracing method which is a numerical integration of the fundamental equations of optics and which is well suited for atmospheres with more complicated shapes. In this context, we discuss the benefits of a new formalism based on a full reformulation of the fundamental equations of optics. This new approach provides a very comprehensive description of the light trajectory inside a media which is mainly shaped by a gravitational potential. We show how the first order effects on the light ray trajectory due to various perturbations can be obtained from this formalism. We derive the effects due to an oblate atmosphere and apply the solution to real radio occultation experiments carried out by the Cassini mission at Saturn. The validity of the proposed approach is assessed comparing the results with other studies available in the literature.

C3.1-0021-18 THE STUDY OF ATMOSPHERES OF EXOPLANETS: STATUS AND PERSPECTIVES

Pierre Drossart, pierre.drossart@obspm.fr Paris Observatory, Meudon, France

The study of the atmospheres of exoplanets is at the verge of a new revolution. After the detection of thousands of planetary systems, most of the physical parameters obtained so far are still restricted to orbital parameters, mass and size of these objects, which is notoriously insufficient to characterize the systems due to multivalue retrievals from inverse models. Constraining the atmospheric structure and composition has been possible only for a dozen of planets, from IRAC, Spitzer, HST or ground based telescopes. The James Webb Space Telescope, to be launched in 2019, is expected to observe many more exoplanets transits and eclipses, as well as direct observations when possible, with exquisite signal to noise [1]. Today, the current knowledge of the exoplanets corpus has unveiled a large variety of systems, not known in our Solar System, which would even have been thought impossible 15 years ago: hot Jupiters, warm Neptunes, Superearths, etc. Our Solar System is definitely not the common standard for planets in the Universe, and anthropocentrism has once again be defeated, urging for more open mind approaches to understand exoplanetary systems. New missions will be needed to address this scientific goal [2]. Nevertheless the great details available from our Solar System planets is still of great use as a template to validate models before extrapolation, or as a "ground truth" model to test observation retrieval. The possibility to infer the history of Solar System atmospheres on Venus, Mars or Earth has also profound implications on the research of exoplanets. The new era of interpretation of planetary atmospheres will have to combine expertise from:

Stellar physics, to know as accurately as possible the stellar environment, activity and history of the exoplanets.

Planetology: spectroscopy of planetary atmospheres has developed a corpus of expertise by 50 years of space observations on planets, including Earth, which can be deployed to study the new worlds

Spectroscopy: as traditional spectroscopic databases for hot temperature molecules are challenged by the needs of exoplanet modelling, the breakthrough in spectroscopic analysis came with ab initio models accurate enough to provide complete molecular spectroscopic data for hot bands observed in the near infrared and for various molecules [3]

Big data analysis: new methods of calculations including Artificial Intelligence algorithms are emerging to deal with the huge database and the complexity of models [4]

The era of exoplanetology is only starting to emerge and we can expect in the next decades new revolutions in the science of planets, with new missions and instruments like the future ESA/M4 ARIEL mission [5].

C3.1-0022-18 CLIMATES OF HIGH OBLIQUITY TERRESTRIAL PLANETS

Ana Lobo, lobo@caltech.edu

California Institute of Technology, Pasadena, California, United States Simona Bordoni, bordoni@gps.caltech.edu

California Institute of Technology, Pasadena, California, United States

Ongoing discoveries of terrestrial exoplanets suggest that these planets might span a wide range of climatic regimes and atmospheric circulations, which will strongly impact their habitability. Here, we use an idealized moist general circulation model in aquaplanet configuration to characterize the atmospheric circulations of terrestrial planets with high obliquities. We increase the obliquity from earth-like values of 23.5° up to 90°. This not only provides for a systematic exploration of the impact of obliquity on a planet's climate, but also includes the range of obliquities experienced by Mars' orbit in the past.

Because obliquity impacts the seasonal distribution of insolation, our simulations have a seasonally varying insolation forcing. High obliquity climates show interesting features, which are not necessarily predictable a priori. For instance, while for obliquities larger than 54° more energy is delivered at the poles than at the equator, the annual mean surface temperatures produce equator-to-pole temperature gradients that are much flatter than the insolation. This points to the importance of atmospheric energy transport, which is primarily accomplished during the warm seasons by strong and broad cross-equatorial Hadley circulations that transport energy from the summer to the winter hemisphere.

Seasonal precipitation patterns also feature interesting peculiarities. In Earth-like low obliquity cases net precipitation (the difference between precipitation and evaporation) is primarily balanced by mean moisture flux convergence in the tropics and eddy moisture flux convergence in the extratropics. In high obliquity cases, however, storage effects become increasingly important in the polar regions because of rapid temperature changes. More specifically, as polar temperatures drop quickly from their maximum values around the summer solstice, the water vapor in the atmospheric column rapidly condenses out, producing large amount of precipitation there. At lower latitudes, precipitation is primarily associated with seasonally migrating convergence zones within the Hadley circulation. As the solstice-season cross-equatorial Hadley cells become broader with increasing obliquity, peak precipitation becomes progressively more separated from their poleward boundary and from widely used diagnostics, such as the lowerlevel moist static energy maximum and the energy flux equator. This emphasizes the need for more robust theories that are broadly applicable to climates more exotic than Earth's.

C3.1-0023-18 PROBING PLANETARY ATMOSPHERES USING POLARIMETRY

Padma Yanamandra-Fisher, padmayf@gmail.com

Space Science Institute, Rancho Cucamonga, California, United States

Our solar system shows a large variety of atmospheric polarization properties of its components, ranging from the inner to outer planets, planetary rings, and moons, comets, asteroids, dust; even the sun, Earth and Moon. The unique signatures arise from the particular scattering media of the various solar system objects, from clouds in the equatorial region of Jupiter or on Venus, to the thick, highly polarizing haze on Titan and the poles of Jupiter, and Rayleigh scattering by molecules on Uranus and Neptune. Planetary atmospheres have unique polarimetric signatures that vary with the state of the atmosphere. Changes in the clouds/thermal filed can be brought about by endogenic dynamical processes such merger of vortices; global, planetary scale upheavals, and external factors such as celestial collisions (such as D/Shoemaker-Levy 9 impact with Jupiter in 1994, etc.); or from the outbreak of planetary disturbances (such as the storms and cloud outbreaks on Jupiter and Saturn) and also measured via limb polarization in methane bands, thereby probing the atmosphere. Although the range of phase angles available from Earth for outer planets is restricted to a narrow range, limb polarization measurements provide constraints on the polarimetric properties. For example, at the equator, much of the observed reflected radiation is due to the presence of clouds and therefore, low polarization. Polar asymmetry exists between the two poles, while the planetary disk is unpolarized on both Jupiter and Saturn. Jupiter is known to exhibit a strong polar limb polarization and a low equatorial limb polarization due to the presence of haze particles and Rayleigh scattering at the poles. In contrast, at the equator, the concentration of particulates in the high atmosphere might change, changing the polarimetric signature and aurorae at both poles. The polarimetric maps, in conjunction with thermal maps and albedo maps, can provide constraints on modeling efforts to understand the nature of the aerosols/hazes in Jovian atmosphere. Saturn exhibits limb polarization, like Jupiter, and its ring system too. Multiple scattering in planetary atmospheres manifest in circular polarization; Venus and Mars allow the probing their clouds and dust respectively. I will discuss the probing of planetary atmospheres via polarimetry and use it as a reference for other planetary systems. Some of our observations are acquired by a global network of amateur planetary imagers astronomers. Details/results of these studies will be presented to optimize the observing strategy of planetary atmospheres, to understand the diversity in our solar system, and other planetary systems.

C3.1-0024-18 ANALYSES OF WAVE VARIATIONS IN VENUS' CLOUD-LEVEL ATMOSPHERE SIMULATED WITH A MIDDLE ATMOSPHERE GCM

Helen Parish, hparish@g.ucla.edu

University of California, Los Angeles, Los Angeles, California, United States Jonathan Mitchell, jonmitch@ucla.edu

UCLA, Los Angeles, United States

We use a Venus middle atmosphere general circulation model (GCM) to assess the role that propagating waves play in generating the cloud-level winds and temperature structure. Measurements at cloud altitudes are characterized by waves with a wide variety of periods and wavelengths, including gravity waves, thermal tides, Rossby waves, and Kelvin waves. However, the origin and importance of different waves, their interactions, and their variability over time are not well understood. We have developed a middle atmosphere model, based on the FMS code, with a lower boundary raised relative to the surface to just below cloud altitudes (40 km altitude or 4 x 105 Pa), to focus on the dynamics of the cloud-level atmosphere. The model upper boundary altitude is around 95 km (3 Pa). In these simulations, we use a Newtonian cooling radiation scheme, based on the Held-Suarez formulation for relaxation of temperature to a specified radiative equilibrium. Since the lower atmosphere is not simulated directly in this model we have introduced a simple linear friction within the first 2 km from the lower boundary to maintain zonal and meridional winds within observed values. We simulate waves which are assumed to be propagating upwards from the lower atmosphere by introducing wave forcing near the lower boundary of the model. In this study, we investigate the effects of propagating Kelvin and Rossby waves. We perform sensitivity tests in which we modify wave forcing parameters, to determine the influence of the different waves on the cloud-level atmosphere. We validate our results by comparison with available observations, including probe measurements and observations from the Venus Express and Akatsuki missions.

C3.1-0026-18 THE ESCAPE OF O AND C FROM THE EARLY MARTIAN ATMOSPHERE DUE TO ION PICK UP

Herbert Lichtenegger, herbert.lichtenegger@oeaw.ac.at

University of Arizona, Tucson, United States Esa Kallio, esa.kallio@aalto.fi

Aalto University, Espoo, Finland

We present loss rates of O and C from the early Martian atmosphere due to ion pick up for four points in time in its history corresponding to 1, 3, 10, and 20 times the present solar EUV flux. Based on density profiles of the background atmosphere of O and C and on the profiles of suprathermal O and C produced by dissociative recombination, ionization rates are estimated and the trajectories of these newly created ions are calculated by means of a hybrid code, taking into account the interaction with the magnetized solar wind. The impact rate of ions entering the atmosphere as well as the ion escape rates are determined.

Moreover, we compare these ion loss rates to the corresponding rates of suprathermal O and

C. We found that ion pick up loss becomes comparable with neutral escape rates and that the former dominates the escape for 20 EUV. This suggests that up to about 1 Gyr after Mars' origin, the main loss mechanism is ion pick up process, whereas loss due to suprathermal atoms was more efficient during later times.

C3.1-0027-18 VOLATILE ORGANIC COMPOUNDS STABILITY AT EXOPLANETARY ATMOSPHERES

Thiago Monfredini Da Silva, tmonfreds@gmail.com Brazilian Synchrotron Light Laboratory, Campinas, Brazil Md Golam Mostafa, st009238@stud.fit.ac.cy

Frederick University, Cyprus, Nicosia, Cyprus

The last decades of exoplanet research have revealed that exoplanets are very common and diverse in their orbital and bulk properties. With the possibility of obtaining spectra of the atmosphere of exoplanets now on the technological horizon, characterizing the atmospheres of extrasolar planets is a new frontier in exoplanetary science. There has been a growing interest on determining what properties of atmospheric chemistry are indicative of the presence of a biosphere. Some molecules, like molecular oxigen and ozone have been proposed as possible determining evidence of the presence of life; however, their detectability fluctuates, and they are capable of being produce abiotically, leading to the possibility of false positives. Species such as toluene, isoprene and other terpenoids are reactive volatile organic compounds (VOCs). They are emitted in significant amount by trees and other vegetations. Also, it can be quite reactive under atmospheric conditions, with short chemical lifetimes (minutes-hours). So, the emission of biogenic VOCs can play an important role in the photophysics and photochemistry of the atmosphere, affecting the oxidative capacity of the atmosphere. To understand the molecular stability of VOCs in the atmosphere, we have measured the absolute photoionizing cross-section of these molecules, using an ionizing chamber and ion-trap spectrometer, with UV, EUV and soft X-ray radiation (3-300 eV) from the Toroidal Grating Monochromator (TGM) beamline of the Brazilian Synchrotron Light Laboratory (LNLS), to simulate the radiation field of different types of stars and astrophysical situations. The ionizing chamber has four ion-collectors, two guard-electrodes, a repeller and a pair of secondary electron deflectors in a cylindrical symmetry. We used a Logarithmic Ammeter to measure ion current. It was determined the optimized voltage of the ion collector as 20 V from the plateau of ion current versus applied potential curve, through the ionization of argon, nitrogen and xenon with pressures between 10−8 and 10−6

torr. In our preliminary results, we have determined photoionizing cross-section of toluene at energies of 100 eV and 280 eV produces. Also, these results sugest that the photofragmentation of toluene at these energies produces high rates of double ionizied fragments.

C3.1-0028-18 PHOTOCHEMISTRY IN SATURN'S RING-SHADOWED ATMOSPHERE: PHOTOCHEMICAL AND HAZE PRODUCTION

After 13 years of observing Saturn, Cassini explored for nearly a half Saturnian year. During this epoch, in addition to seasonal solar inclination changes, the ring shadow has moved from covering much of the northern hemisphere to covering a large swath of the southern hemisphere. The intensity of both ultraviolet and visible sunlight penetrating through the rings varied depending on Saturn's axial tilt relative to the Sun and the optical thickness of each ring system, i.e. the rings act like semi-transparent venetian blinds. This effect magnifies the effect of axial tilt alone and acts to turn off photochemistry and haze generation, an effect seen with the presence of a bluish northern atmosphere in 2004 and color change to blue in the southern hemisphere after equinox. We report on the impact of the oscillating ring shadow, seasonal axial tilt, and solar flux, on photochemistry of hydrocarbons and phosphine in Saturn's stratosphere and upper troposphere. The impact on the abundance of long-lived photochemical products leading to haze formation and on disequilibrium species is explored. We will also present analysis of Cassini's CIRS, UVIS, and VIMS datasets that provide an estimate of the evolving haze content. Specifically, we will examine how the region inside Saturn's famous hexagonal jet stream evolves over time from a relatively clear atmosphere to hazy atmosphere and how the jet stream acts like a barrier to transport, thus isolating Saturn's north polar region from outside influences. Lastly, an estimate of the impact of ultraviolet ring-shine on photochemistry is provided.

The research described in this paper was carried out in part at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration.

C3.1-0029-18 SULFURIC ACID VAPOR ABSORPTION AT MILLIMETER WAVELENGTHS: IMPLICATIONS FOR VENUS OBSERVATIONS

Alex Akins, aakins6@gatech.edu

Georgia Institute of Technology, Atlanta, Georgia, United States
Paul Steffes, paul.steffes@ece.gatech.edu

Georgia Institute of Technology, Atlanta, Georgia, United States

Powerful radio telescope arrays such as the Atacama Large Millimeter/Submillimeter Array (ALMA) can be valuable tools for measuring the millimeter-wavelength emission of Venus. Past observations from such arrays have indicated significant diurnal variations in observed brightness temperature. Proper interpretation of this variation in brightness requires the development of radiative transfer models informed by laboratory measurements of gas absorption under Venus conditions. To this end, a laboratory campaign has been undertaken to characterize the opacity of sulfuric acid vapor at millimeter wavelengths. The highest abundance of sulfuric acid vapor at Venus is found in the sub-cloud region, so the laboratory measurements have been carried out at conditions close to those found in this region. Absorption measurements are made using a stainless steel, gold-plated semi-confocal open resonator which is housed in a pressure vessel. This configuration is itself housed in a temperature chamber capable of reaching temperatures relevant to the sub-cloud region of Venus. Measurements of sulfuric acid vapor absorption pressure-broadened by up to 3 bars of carbon dioxide between 2 mm and 4 mm wavelengths have been made at 533 and 550 Kelvins. Multiple sources of error in thes measurement have been taken into account to determine the effective sensitivity of the system. Initial results suggest that sulfuric acid vapor absorption at millimeter wavelengths follows a collisionally-broadened Van Vleck-Weisskopf lineshape model. This lineshape model relies on measured and calculated rotational lines tabulated in the JPL Spectral Line Catalog. In contrast, the centimeter-wavelength absorption of sulfuric acid vapor as measured by Kolodner and Steffes (1998) is higher than that predicted by lineshape theory, and a best-fit expression had to be developed to accurately model it. This suggests the possibility that the microwave absorption of sulfuric acid is similar to that of water, consisting of contributions from the spectral lines of the molecule and a continuum absorption feature. Future measurements in this laboratory campaign will determine the absorption of sulfuric acid vapor between 7.5 mm and 1 cm to form a more accurate opacity model. This data can be combined with previous data on the millimeter wavelength opacity of sulfur dioxide (Bellotti and Steffes 2015) to develop accurate radiative transfer models for interpretation of results from radio telescopes and provide further insight into the aforementioned variability of millimeter-wavelength emission from Venus.

C3.1-0030-18 PROPOSAL ON THE DEVELOPMENT OF A LASER RADAR UTILIZED TO DETECT MAR'S DUST AEROSOL

Sandstorms on Mars are an important kind of atmospheric phenomenon. In the growing boom of Mars exploration, the monitoring and scientific research of the sandstorm climate is of great significance. In this paper, the development plan of micro laser radar for detection of dust aerosols from a Mars orbiter has been outlined. Compared with the telemetry of visible light camera, it can not only collect information for the origin of sandstorm and its spreading, but also obtain the detailed data for dust aerosols including column concentration, particle size distribution, total amount of dust, and so on. In the schematic design of the radar, under relatively low power consumption(12W), its detection sensitivity of aerosol size, spatial resolution and vertical resolution of aerosol reach 53nm, 1km, 30m, respectively.

C3.1-0031-18 SPECTRO-POLARIMETRY OF PLANETARY ATMOSPHERES: RADIATIVE TRANSFER SIMULATIONS AND INSTRUMENT CONCEPT

Bhavesh Jaiswal, bhaveshisrojaiswal@gmail.com Indian Space Research Organization, Bangalore, India Anuj Nandi, anuj@isac.gov.in

Physical Research Laboratory, Ahmedabad, Ahmedabad, India

Planetary atmospheres are characterized based on their gaseous composition as well as the aerosols or clouds in the atmosphere. Spectroscopy generally gives information about the gaseous composition of the planets whereas polarimetry is known to be sensitive to the scatterer present in the atmosphere (like aerosols and clouds). Combined together, the spectropolarimetry gives complete information about the atmosphere of a planet. We are developing an Acousto-Optic Tunable Filter (AOTF) based near - infrared (1 - 1.7 µm) spectro-polarimeter for ISRO's upcoming Mars and Venus missions. We also aim to observe Earth's spectropolarimetric signatures from a Geo-stationary platform.

The atmosphere of Mars contains tiny amounts of water vapour which combined with ubiquitous Martian dust, forms clouds at high altitudes (30-50 km). We show with the help of a radiative transfer model as to how a limb viewing spectro-polarimeter can reveal the process of condensation in Martian atmosphere. We show the polarization signatures of dust and clouds and expected level of water vapour absorption in Martian limb. Since Mars atmosphere is largely un-explored as far as polarization studies are concerned so we expect a good scientific gain from such an experiment. In the similar context, we intend to study the scattered polarization from Venus' sulphuric acid clouds. We aim to study the polarization within a strong CO2 absorption band which would possibly provide information about the vertical structure of the clouds in Venusian atmosphere. We also plan to study the spectro-polarimetric signatures of Earth from a Geo-stationary platform. This study would provide us with a global view of scattered polarization from Earth. Since Earth is a known habitable planet with an active - weather system, it would be possible to study the bio-signatures such as O2 and H2O and also characterize the changing cloud cover with the help of scattered polarization. This study would prove to be a benchmark for the future characterization of habitable zone extra-solar planets.

In this paper, we present the spectro-polarimetric (simulated) signatures from Mars, Venus and Earth atmosphere along with unique concept design of the instrument, which is under development at ISRO.

C3.1-0032-18 INFLUENCE OF THE STRUCTURE AND COMPOSITION OF MARTIAN SURFACE ON VISIBILITY THE FEATURES OF ATMOSPHERIC TRACE GASES IN MID-INFRARED SPECTRA - THE RESULTS OF NUMERICAL SIMULATION AND ANALYSIS OF SOME AVAILABLE PICTURES OF MARS

Maria I. Blecka, mib@cbk.waw.pl

Space Research Centre of the Polish Academy of Sciences, Warsaw, Poland

The presented work is directly connected with the measurements of the stereoscopic camera CASSiS (The Colour and Stereo Surface Imaging System) a part of payload of ExoMars Trace Gas Orbiter (TGO) of the ESA mission in which researchers and engineers from SRC - PAS are engaged. The CASSiS camera will give us the opportunity of analysis the structure and locations on the surface of Mars of the possible sources of trace gases e.g. methane. Identification and monitoring of minor species in the atmosphere are performed from orbiter by spectrometric instruments (e.g. NOMAD, ACS). The existence of trace gases, in particular methane on Mars is a topic of special interest because of their influence on climate and as a potential signature of past or present life development on Mars. There are various types of features on Martian surface that could be connected with methane release e.g. mud-volcanos in Utopia and Acidalia, Gusev Crater, Arabia Terra, Valles Marineris and rims of big craters. The processes making possible emission of methane occur in diverse places on Mars in sedimentary and igneous rocks and probably are originated in different ways. Maybe in high temperature geothermal reactions or connected with ancient activity of micro-organism, during degassing of volcanic magma or in low-temperature processes in serpentinized rocks. The way of generation the trace gases depends on the structure and composition of the soil and on physical state of the atmosphere. The recorded spectra appear as a result of a combination of different light-matter interactions, such as scattering, reflection, absorption and emission. These processes may act several times, each in a way that depends on the composition, temperature and pressure of the atmospheric gases and on the physical and chemical parameters of the material of the surface, and dust in the atmosphere. The main issue in the interpretation of the measured Martian spectra is how to discriminate between surface and atmospheric contribution to the spectral features. The character of these features can change drastically according to specific conditions, for example because of variations in mineralogical composition and in dimensions of the grains. The elaborated model provides estimates of the spectral reflectance/emittance and total radiance from Martian surface and atmosphere in the Mid-infrared spectral range. We perform analysis of common effects of the surface and atmosphere contains trace gases on radiance spectra. We take into account the spectral signatures of the surface and the atmospheric trace gases (first of all methane) in various physical conditions. From the pictures done by HIRISE instrument we select the examples of diverse shapes of the surface with various subtle structures of the soils. These various kinds of surfaces are spectrally described by an appropriate reflectance or emissivity of minerals and rocks (e.g. the serpentinized rocks) for selected locations. Spectral reflectance and emissivity of the modelled regions we calculate from n,k with Mie and Hapke theories or we use the values measured in the laboratory. The physical properties of the atmosphere is characterized by its thermodynamical parameters and absorbing and scattering properties.We discuss the possible visibility of spectral features of methane in radiance spectra. We hope that interpretation of data from TGO will benefit from our simulation of the spectra we expect will be acquired by NOMAD and ACS.

C3.1-0033-18 ENVISION: UNDERSTANDING WHY OUR MOST EARTH-LIKE NEIGHBOUR IS SO DIFFERENT

Thomas Widemann, thomas.widemann@obspm.fr Observatoire de Paris, Meudon, France

Richard Ghail, r.ghail@imperial.ac.uk

Imperial College University of London, London, United Kingdom
Colin Wilson, wilson@atm.ox.ac.uk

University of Oxford, OXFORD, United Kingdom

Why are the terrestrial planets so different? Venus should be the most Earth-like of all our planetary neighbours: its size, bulk composition and distance from the Sun are very similar to those of Earth. Its original atmosphere was probably similar to that of early Earth, with abundant water that would have been liquid under the young sun's fainter output. Even today, with its global cloud cover, the surface of Venus receives less solar energy than does Earth, so why did a moderate climate ensue here but a catastrophic runaway greenhouse on Venus? How and why did it all go wrong for Venus? What lessons can be learned about the life story of terrestrial planets in general, in this era of discovery of Earth-like exoplanets? Were the radically different evolutionary paths of Earth and Venus driven solely by distance from the Sun, or do internal dynamics, geological activity, volcanic outgassing and weathering also play an important part?

Following the primarily atmospheric focus of Venus Express, we propose a new Venus orbiter named EnVision, submitted in October 2016 in response to ESA's M5 call for Medium-size missions for its Science Programme, for launch in 2029. EnVision will focus on Venus' geology and geochemical cycles, seeking evidence for present and past activity. The payload comprises a state-of-the-art S-band radar which will be able to return imagery at spatial resolutions of 1 - 30 m, and capable of measuring cm-scale deformation; this is complemented by subsurface radar, IR and UV spectrometers to map volcanic gases, and by geodetic investigations.

C3.1-0034-18 PROPAGATION OF TRANSIENT PERTURBATIONS INTO A PLANET'S EXOSPHERE: MOLECULAR KINETIC SIMULATIONS

Ludivine Leclercq, ll2ad@virginia.edu

University of Virginia, Charlottesville, Virginia, United States Robert Johnson, rej@virginia.edu

University of Virginia, Charlottesville, Virginia, United States Francois Leblanc, francois.leblanc@latmos.ipsl.fr

Laboratoire Atmosphères, Milieux, Observations Spatiales, France

Atmospheric perturbations such as gravity waves, or perturbations due to the atmospheric interaction with an incident plasma, can affect the composition and the structure of planets' upper atmosphere. Our goal is to study how these perturbations dissipate and propagate into an atmosphere, in particular in the exobase region, which is the transition region between the collisional and collisionless regions. We present results of molecular kinetic simulations describing the evolution of density and temperature in a multi-component atmosphere, in the case of Mars in particular. Results show that atmospheric perturbations' propagation is dependent on the collision rate, and therefore propagates differently depending on the species.

SPACE STUDIES OF THE UPPER ATMOSPHERES OF THE EARTH AND PLANETS INCLUDING REFERENCE ATMOSPHERES (C)

PLANETARY UPPER ATMOSPHERES, IONOSPHERES, AND MAGNETOSPHERES (C3.2)

C3.2-0001-18 MAGNETOSPHERE OF MERCURY: THE VIEW FROM MESSENGER

James Slavin, jaslavin@umich.edu

University of Michigan, Ann Arbor, Michigan, United States

MESSENGER's three close fly-bys and 4 years of observations from orbit have revealed that Mercury possesses a highly dynamic and complex magnetosphere. Despite the low altitude of its magnetopause, induction currents in Mercury's highly conducting iron core resist compression of the dayside magnetosphere by the solar wind, even during coronal mass ejection impacts. However, the dayside magnetosphere sometimes disappears during periods of strong southward interplanetary magnetic fields. Mercury's surface-bounded exosphere is maintained by sputtering and other surface interactions that eject neutrals from the regolith. Prospects for understanding Mercury's coupled magnetosphere - exosphere - solid planet as a system with the measurements to be returned by ESA's BepiColombo mission in 2025 will be discussed.

C3.2-0002-18 THE SOLAR WIND INTERACTION WITH MERCURY

Mats Holmstroem, matsh@irf.se

Swedish Institute for Space Physics, Kiruna, Sweden Shahab Fatemi, shahab@irf.se

Swedish Institute for Space Physics, Sweden

The magnetosphere of Mercury has many interesting features. It is small compared to Earth's, making it respond to solar wind changes on short time scales. The planet also has a tenuous atmosphere, where the exosphere reaches all the way down to the surface. Another factor that will affect the solar wind interaction is the large core of the planet. Here we model the magnetosphere of Mercury using a hybrid plasma solver (ions as particles, electrons as a fluid). The solar wind interaction with Mercury is studied and we present the general morphology of the plasma interactions, both close to the planet and on a larger scale, for different solar wind conditions. In particular we also examine particle precipitation and the turbulent foreshock region. We compare with earlier modeling work, with observations by MESSENGER and discuss implications for BepiColombo.

C3.2-0003-18 WAVE IMPACTS ON THE VENUS UPPER ATMOSPHERE (ABOVE THE CLOUD TOPS): DATASETS AND RECENT GCM MODEL SIMULATIONS

Amanda Brecht, amanda.s.brecht@nasa.gov

NASA Ames Research Center, Moffett Field, California, United States Stephen Bougher, bougher@umich.edu

University of Michigan, Ann Arbor, MI, Michigan, United States Erdal Yiğit, eyigit@gmu.edu

George Mason University, Space Weather Lab, Fairfax, VA, Virginia, United States Gabriella Gilli, ggilli@oal.ul.pt

Portugal

The upper atmosphere of Venus has been observed for many decades by multiple means of observations (e.g. ground-based, orbiters, probes, fly-by missions). The European Space Agency Venus Express (VEX) orbiter and more recently the Japanese mission, Akatsuki, have been providing illuminating observations of the Venusian atmosphere. From past and present observations there is evidence of wave activity contributing to Venus' atmospheric dynamics and variability. Systematic studies with theoretical models can help better understand the underlying physical processes. The presented work will discuss parameter space guided by observations for characterizing planetary-scale waves (Rossby and Kelvin) and small-scale gravity waves, and their implementation within numerical models. For the first time, a whole atmosphere nonlinear gravity wave parameterization of Yiğit et al. [2008, JGR] is implemented into the Venus Thermospheric General Circulation Model (VTGCM) [Bougher et al. 1988, Icarus; Brecht et al. 2011, JGR]. In conjunction, model simulations utilizing the parameter space will be conducted, thereby demonstrating the impact of planetary waves and gravity waves upon Venus' upper atmosphere.

Atmospheric waves play a crucial role in all stably stratified planetary atmospheres. They contribute significantly to the redistribution of momentum, energy and dust between the different atmospheric regions.

In the Martian thermosphere, thermal tides have been observed e.g. by radio occultation or accelerometer measurements on MGS. Recently, the NGIMS instrument on MAVEN reported gravity waves in the thermosphere of Mars. On Venus, thermospheric waves have been observed by in situ measurements in the polar region, and by the VIRTIS instrument on Venus Express.

The radio science experiment VeRa on Venus Express used the radio subsystem of the spacecraft to retrieve refractivity profiles in the atmosphere and ionosphere of Venus. Venus Express was equipped with a dedicated onboard ultrastable oscillator, which allowed to conduct the measurements in a oneway radio link mode. The refractivity profiles are used to retrieve profiles of temperature, pressure and neutral number density in the troposphere and mesosphere of Venus (40 - 90 km) and electron density profiles in the ionosphere. More than 900 profiles with a high vertical resolution could be retrieved between 2006 and 2014.

The Mars Express Radio Science Experiment (MaRS) uses the same radio occultation technique to retrieve atmospheric profiles in the lower atmosphere of Mars (a few hundred metres above the surface to 40 km) and electron density profiles in the ionosphere. MaRS uses a twoway radio link mode, stabilized by a hydrogen maser on Earth. So far, the MaRS data set comprises more than 800 profiles and the mission is still ongoing.

Both experiments use two coherent frequencies (XS-band) for their investigations. These two frequencies are required to discriminate between plasma density fluctuations in the ionosphere and Doppler related frequency shifts caused by spacecraft movement.

Planetary scale waves have been detected in the Martian ionosphere. These large scale waves propagate from the lower atmosphere upwards and lead to altitude changes of the main ionospheric peaks as a function of planetary longitude. These waves can be identified as thermal tides influenced by the Martian topography.

Small scale wavelike structures have also been detected in the ionosphere of Mars and Venus below the main ionospheric layers and in the topside of the ionosphere. The observed features can be classified by a careful analysis of the observed electron density fluctuations in combination with simulations based on ray tracing methods and comparisons with atmospheric model predictions. An ionospheric time stepping model (Ion-A2) is used to study the observed electron density fluctuations.

Acknowledgments

The MaRS Experiment is funded by the German Space Agency (DLR) under grant 50QM1401.

C3.2-0005-18 MODELING OF OBSERVATIONS OF THE OH NIGHTGLOW IN THE VENUSIAN MESOSPHERE

Christopher Parkinson, theshire@umich.edu

University of Michigan, Ann Arbor, Michigan, United States Amanda Brecht, amanda.s.brecht@nasa.gov

NASA Ames Research Center, Moffett Field, California, United States Stephen Bougher, bougher@umich.edu

University of Michigan, Ann Arbor, MI, Michigan, United States

Airglow emissions, such as NO and O2, have been observed previously on Venus. Airglow emissions provide insight into chemical and dynamical processes that control the composition and energy balance in the upper atmosphere. The OH airglow emission has been observed previously only in the Earth's atmosphere which was discovered (Meinel 1950) in high-resolution spectra of the Earth's atmosphere and were successfully modeled by Pickett et al. (2006). Similarly, Venus airglow emissions have been unambiguously detected in the wavelength ranges of 1.401.49 and 2.63.14 m in limb observations by the Visible and Infrared Thermal Imaging Spectrometer (VIRTIS) on the Venus Express (VEX) spacecraft. These emissions are attributed to the OH (20) and (10) Meinel band transitions as well (Piccioni et al., 2008).

We have used a 1-D photochemical model derived from the Caltech/JPL KINETICS model (Parkinson et al., 2010; Pickett et al., 2006; Allen et al., 1981) and the Venus Thermospheric General Circulation Model (VTGCM) 3-D finite difference hydrodynamic model of Venus' upper atmosphere (Bougher et al., 1988) to model the OH nightglow in the Venusian mesosphere. This is done by treating the vibrationally excited states of OH for v = 1- 9 as separate chemical species, analogous to Pickett et al. (2006) for the Earth. Two chemical pathways for production are considered and vibrationally OH is produced via both these reactions. Subsequently, collisional quenching of OH proceeds via a single quantum collisional cascade, where CO2 is the dominant (only) quenching agent considered.

Our model calculations predict a layer that is very consistent with the analysis of VEx VIRTIS observations. We discuss the results of modeling the OH nightglow and compare with observations, also making connections with the O2 nightglow (cf. Soret et al. 2011, 2012; Brecht et al., 2011)

The existence of lightning on Venus has been studied by numerous space missions for over 50 years. The Soviet Venera landers detected radio waves due to lightning during the descent of the landers and while on the surface. Venera 9 even detected an optical signature with its visible spectrometer. The Pioneer Venus (PVO) orbiter also detected radio waves determined to be from lightning, but only while on the nightside because of excessive noise in the electric antenna caused by the sun. These signals exhibited a decrease in amplitude at higher altitudes, implying a source from below, i.e. lightning in the clouds. Most recently, Venus Express (VEX) detected whistler-mode waves in the Venus ionosphere with its dual fluxgate magnetometer. The entire 8.5+ year dataset has been analyzed with over 2200 signals identified. Signal lengths range from one second to more than one minute. These longer signals are likely due to multiple bursts as the spacecraft passed over a storm. The majority of the signals were detected when VEX was around 250 km, approximately 3% of the time it was near this altitude. In order to demonstrate that the whistlers detected by VEX originate below the ionosphere, we first need to calculate the Poynting vector, which is difficult for two reasons: VEX had no electric field sensor and it did not take measurements of the electron density in the lower ionosphere where these signals were observed. Thus, we have employed the VIRA electron density model, which allows us to estimate the Poynting flux of the waves. Since the model was developed during the PVO era, when the solar EUV was more intense, we have scaled it to match the solar cycle conditions during the VEX campaign. With the three components of the magnetic field and an estimate of the electron density, we can statistically show that the whistler-mode waves observed by Venus express do indeed originate from the atmosphere below. Next, we estimate the energy of the bursts and compare Venus lightning rates to terrestrial lightning and rates.

C3.2-0007-18 OVERVIEW OF THE OBSERVED VENUS SOLAR WIND INTERACTION

The Venus-solar wind interaction was initially probed in detail by the Pioneer Venus Orbiter, but the combination of the PVO orbit and the time period of the mission left us with a somewhat ideal but biased view favoring a robust ionospheric obstacle picture. The more recent Venus Express mission provided an opportunity to probe both unexplored regions of the interaction as well as conditions when the ionosphere was weakened by low solar activity. This provided in effect a natural 'experiment' departing from the nearly classical unmagnetized planet interaction. We describe some of the contrasts and similarities revealed by the different timings and circumstances of these two missions.

C3.2-0008-18 ASYMMETRIES IN THE MAGNETOSHEATH FIELD DRAPING ON VENUS' NIGHT SIDE

Magda Delva, magda.delva@oeaw.ac.at

Space Research Institute, Austrian Academy of Sciences, Graz, Austria Martin Volwerk, martin.volwerk@oeaw.ac.at

Austrian Academy of Sciences, Graz, Austria Riku Jarvinen, riku.jarvinen@aalto.fi

Aalto University, Espoo, Finland Cesar Bertucci, cbertucci@iafe.uba.ar IAFE, Buenos Aires, Argentina

Draping features of the interplanetary magnetic field around non-magnetic bodies, especially Venus, have been studied in detail in numerical simulations and also from observations. Existing analytical and numerical work for non-perpendicular IMF and solar wind velocity direction show a kink in the draped fieldlines in the near magnetosheath on the quasi-parallel side of the bow shock. Here, long-term magnetic field data from the Venus Express mission (2006-2014) are analyzed in the near night-side region of the magnetosheath, searching for differences in the draping pattern between the quasi-paralleland quasi-perpendicular side of the shock. From these MAG data, the kink in the fieldlines occurring only on the quasi-parallel side is clearly identified from the change of sign in the field component parallel to the solar wind velocity. Furthermore, an asymmetry in the deflection of the out-of-plane field component due to the slipping of the fieldlines over the planetary obstacle is also found, which confirms predictions from numeral studies and from earlier work.

The Mars Atmosphere and Volatile EvolutioN (MAVEN) mission's Imaging Ultraviolet Spectrograph (IUVS) observes Mars in the far and mid ultraviolet (110-340 nm), investigating lower and upper atmospheric structure and indirectly probing neutral atmospheric escape. The instrument is among the most powerful spectrographs sent to another planet, with several key capabilities: separate Far-UV Mid-UV channels for stray light control; a high-resolution echelle mode to resolve deuterium and hydrogen emission; internal instrument pointing and scanning capabilities to allow complete mapping and nearly continuous operation; and optimization for airglow studies. After two Earth years in orbit (one Mars year), IUVS has assembled a large quantity of data and provided insights on present-day processes at Mars including dayglow, nightglow, aurora, meteor showers, clouds, and solar-planetary interactions. In this presentation, we will highlight key results obtained by IUVS, including: (1) mapping of thermospheric composition, structure, and variability; (2) long-term tracking of H escape, O escape, and D/H ratios, and (3) detection and mapping of diffuse auroral emission. We will present an overview of these results and a discussion of their implications for understanding Mars atmospheric dynamics and evolution.

C3.2-0010-18 MARS NITRIC OXIDE NIGHTGLOW AND ITS IMPLICATIONS FOR THE VARIABLE UPPER ATMOSPHERE CIRCULATION

Arnaud Stiepen, arnaud.stiepen@uliege.be University of Liège, Liège, Belgium

Mars Nitric Oxide Nightglow MAVEN/IUVS and LMD-MGCM team

Arnaud Stiepen, Sonal K. Jain, Nicholas M Schneider, Justin Deighan, Francesco GonzálezGalindo, Zachariah Milby, Emilie Royer, J-C Gérard, S. Bougher, M.H. Stevens, J.S. Evans,

A.I.F. Stewart, M.S. Chaffin, W.E. McClintock, J.T. Clarke, G.M. Holsclaw, F. Montmessin,

F. Lefèvre, F. Forget, M. Crismani, D.Y. Lo, B. Hubert, B.M. Jakosky

On the dayside thermosphere of Mars, solar extreme ultraviolet radiation dissociates CO2 and N2 molecules. O(3P) and N(4S) atoms are carried by the day-to-night hemispheric transport. They descend in the nightside mesosphere, where they can radiatively recombine to form NO(C2). The excited molecules rapidly relax by emitting UV photons in the and bands. These emissions are thus indicators of the N and O atom fluxes transported from the dayside to Mars' nightside and the descending circulation pattern from the nightside thermosphere to the mesosphere, as well as impact of waves and/or tides in this region (e.g., Stiepen et al., 2017).

These emission have been discovered at Mars by the Mars Express SPICAM instrument (Bertaux et al., 2005 ; Cox et al., 2008 ; Gagné et al., 2013 ; Gérard et al., 2008 ; Stiepen et al., 2015) and modeled by the MGTCM (Bougher et al., 1990) and the LMD-MGCM (González-Galindo et al., 2009). Recently, the IUVS instrument on board MAVEN spacecraft accumulated a large dataset of nightside disk images and vertical limb scans (Stiepen et al., 2017) during two consecutive martian years covering several seasonal conditions. For the first time, observations cover a full night disk, extending previous studies in both time and space coverage.

We will present results concerning the variability of the brightness and altitude of the emission with season (solar longitude and latitude) and geographical position (longitude, local time). We will present results on local time behavior in polar regions, especially a dawn-dusk asymetry in the emission. We show the possible impact of atmospheric waves structuring the emission longitudinally and indicating a wave-3 structure in Mars' nightside mesosphere close to the equator. We will also show the results of a search for local time control of the wave-3 pattern in equatorial emissions. We provide possible interpretation for local and global changes in the mesosphere dynamics. In particular, quantitative comparison with calculations of the LMDMGCM show that the model globally reproduces the trends of the NO nightglow emission and its seasonal variation but also shows large discrepancies that can be interpreted as a computed transport too efficient toward the night winter pole.

C3.2-0011-18 DATA AND MODEL COMPARISONS OF THERMOSPHERIC DENSITY STRUCTURES NEAR THE DAWN AND DUSK TERMINATORS AT MARS

Marcin Pilinski, marcin.pilinski@lasp.colorado.edu

LASP / University of Colorado, Boulder, Colorado, United States
Stephen Bougher, bougher@umich.edu

Laila Andersson, laila.andersson@lasp.colorado.edu

LASP / University of Colorado, Boulder, Colorado, United States

Using 1.5 Mars years of neutral density data collected by the neutral mass spectrometer on the NASA MAVEN spacecraft, we reconstruct an average Martian thermosphere between 160 and 220 km, 35ºS-35ºN latitude with a local time resolution of 15 minutes (3.75º). The results indicate the presence of several stationary features in both atomic oxygen, argon, and carbon dioxide number densities near the dusk and dawn terminators. The most significant feature near dusk is centered at a local solar time of 19.5 and has a magnitude of between 50-100% relative to the surrounding background densities. Near dawn, a night-time density enhancement occurs at a local solar time of 5 and has an amplitude between 50-200% relative to the surrounding densities. In both cases, the enhancements are observed during different seasons and across all altitudes analyzed in this study. The enhancement amplitude increases with height in most cases. The observed enhancements are interpreted to be a result of night-time adiabatic heating caused by converging winds. The approximate location of these large-scale features agree with past predictions made by global circulation models. In particular, the MGITM model predicts a prominent post-dusk enhancement consistent with that observed in the statistical analysis of MAVEN data. In this paper, we compare the MGITM modeling results and observations of neutral density enhancements in the Martian night-side.

C3.2-0012-18 GRAVITY WAVES IN THE MARTIAN UPPER ATMOSPHERE AS OBSERVED BY MAVEN AND STUDIED BY GENERAL CIRCULATION MODELS

Erdal Yiğit, eyigit@gmu.edu

George Mason University, Space Weather Lab, Fairfax, VA, Virginia, United States

Gravity waves (GWs) are ubiquitous features of all known planetary atmospheres. They have been extensively studied in Earth's upper atmosphere [Yiğit and Medvedev, 2015] and their importance for the Martian atmospheric dynamics is increasingly appreciated [Medvedev et al., 2013]. GWs are primarily produced via weather processes in the lower atmosphere. They propagate upward and dissipate due primarily to nonlinear interactions, molecular diffusion and thermal conduction in the Martian middle and upper atmosphere. Recent observations conducted by the Mars Atmosphere Volatile EvolutioN (MAVEN) mission demonstrate substantial GW activity in the Martian thermosphere, which can be studied by global scale models. This work reviews past and recent observations of GWs in the upper atmosphere [e.g., Yiğit et al, 2015] and uses three-dimensional general circulation modeling technique, incorporating a whole atmosphere GW parameterization [Yiğit et al, 2008], to interpret these observations.

The MAVEN (Mars Atmosphere and Volatile Evolution) mission is currently providing systematic observations of the Martian upper atmosphere (Jakosky et al., 2015, SSR). The NGIMS (Neutral Gas and Ion Mass Spectrometer) instrument on MAVEN is producing a new dataset of thermospheric neutral wind measurements (e.g., Bougher et al., 2016, Fall AGU). These are the first in-situ observations of thermospheric winds at Mars, and as such, provide a unique opportunity to add to our understanding of the dynamics of the Martian upper atmosphere. Furthermore, when these wind observations are compared to model simulations, the processes driving the winds (and their variations) in the upper atmosphere can be examined and better understood. Here, the Mars Global Ionosphere-Thermosphere Model (M-GITM) (Bougher et al., 2015, JGR) is utilized for these data-model comparisons.

NGIMS has the capability to measure horizontal winds in-situ along orbit passes from periapsis up to 200 km (Bougher et al., 2016). With this method, wind velocities can be determined for both cross-track and along-track flow (relative to the spacecraft ram direction). Horizontal winds can be measured up to 350 m/s with an accuracy of 30 m/s for cross-track winds and 100

m/s for along-track winds. Using spacecraft geometry, cross-track and along-track velocities are then converted to zonal and meridional velocities. Examining mean (longitudinally averaged)

winds over time allows seasonal and other trends in thermospheric winds to be more readily observable. Currently, the neutral wind datasets (i.e., mostly 5-orbit campaigns occurring once each month) span over half a Martian year.

A preliminary comparison with M-GITM simulations has shown that the NGIMS wind measurements in many cases do not match the simulated thermospheric winds in speed, direction, or both. The M-GITM model is currently primarily driven by solar EUV forcing at thermospheric altitudes. Thus, it is likely that for cases where simulated and observed winds are similar, EUV heating is the primary mechanism driving the thermospheric winds. Otherwise, non-solar driven processes may be responsible. In fact, gravity waves are thought to have large thermal and dynamical impacts in the thermosphere, and are expected to significantly modify the thermospheric structure and circulation (e.g. Medvedev and Yiğit, 2012, GRL). Presently, a whole atmosphere spectral nonlinear gravity wave parameterization (Yiğit et al., 2008, JGR) is being incorporated into M-GITM and tested to identify the relative importance of gravity wave impacts (i.e., momentum and energy deposition) during these MAVEN wind campaigns. Initial gravity wave simulations will be presented and compared to solar only driven simulations conducted previously.

C3.2-0014-18 ELEVATED ATMOSPHERE ESCAPE OF HYDROGEN FROM MARS INDUCED BY HIGH ALTITUDE WATER: DUST STORM INFLUENCES

Michael Chaffin, michael.chaffin@colorado.edu

University of Colorado at Boulder, Boulder, Colorado, United States Justin Deighan, justin.deighan@lasp.colorado.edu

LASP / University of Colorado, Boulder, United States Ian Stewart, ian.stewart@lasp.colorado.edu

United States

Nick Schneider, nick.schneider@lasp.colorado.edu LASP / University of Colorado, United States

Seasonal variability in Mars upper atmospheric hydrogen has been shown to be responsible for a 10-100x increase in escape of H to space in Mars Southern Summer. Competing explanations for the enhanced escape include the presence of a thermospherically generated hot hydrogen component, required by some observations of the corona, and an increase in the altitude of the hygropause, which can allow water at altitude to supply H to the upper atmosphere much more efficiently in Southern summer. In previous work, we explored the high-altitude water hypothesis using a 1D photochemical model. Here, we extend this modeling work to incorporate more realistic conditions for Mars Southern Summer, surveying a variety of dust conditions from clear to global dust storm. We will present an analysis of the competing influence of dust opacity, which tends to shield lower atmospheric water, and atmospheric heating, which allows water to penetrate to higher altitudes. In particular, we will address the question of whether the 2007 global dust storm caused a large enhancement in H escape, above and beyond what would be expected in Southern Summer alone.

C3.2-0015-18 IN-SITU OBSERVATION OF MARTIAN NEUTRAL EXOSPHERE: RESULTS FROM MENCA ABOARD INDIAN MARS ORBITER MISSION

Anil Bhardwaj, bhardwaj_spl@yahoo.com Physical Research Laboratory, Ahmedabad, India

MENCA is a quadrupole based neutral mass spectrometer, working in mass range 1-300 amu with unit mass resolution, aboard the first Indian Mars Orbiter Mission (MOM). The analysis of the data from MENCA has revealed unambiguous detection of the three major constituents which are amu 44 (CO2), amu 28 (which has both contributions from CO and N2) and amu 16 (atomic O), as well as a few minor species. Since MOM is in a highly elliptical orbit, the MENCA observations pertain to different local times, in the low-latitude region. MENCA observations have revealed significant orbit-to-orbit variability in densities of the three constituents. During the evening hours, the transition from CO2 to O dominated region is observed near 270 km, which is significantly higher than that at sub-solar point. The mean evening time exospheric temperature derived using these observations is 271±5 K. These observations corresponding to the Martian evening hours would help to provide constraints to the thermal escape models. We have also studied the altitude profiles of argon-40 (Ar) in the Martian exosphere using MENCA from four orbits during December 2014 (Ls = 250-257°), when MOM's periapsis altitude was the lowest. The upper limit of Ar number density corresponding to this period is 5 × 105 cm3 (250 km), and the typical scale height is 16 km, corresponding to an exospheric temperature of 275 K. However, on two orbits, the scale height over this altitude region is found to increase significantly making the effective temperature >400 K. Neutral Gas and Ion Mass Spectrometer (NGIMS) observations on the Mars Atmosphere and Volatile Evolution (MAVEN) mission also indicate that the change in slope in Ar density occurs near the upper exosphere (around 230- 260 km). These observations indicate significant suprathermal CO2 and Ar populations in the Martian exosphere. Significant wave-like perturbations are observed but only on certain days when suprathermal population is seen. These results will be presented and discussed along with some new analysis.

C3.2-0016-18 LATEST RESULTS FROM THE MAVEN RADIO OCCULTATION SCIENCE EXPERIMENT (ROSE)

Paul Withers, withers@bu.edu

Boston University, Boston, Massachusetts, United States Michael Mendillo, mendillo@bu.edu

Boston University, Boston, Massachusetts, United States Luke Moore, moore@bu.edu

Boston University, Boston, Massachusetts, United States Marianna Felici, mfelici@bu.edu

Boston University, Boston, Massachusetts, United States Bruce Jakosky, bruce.jakosky@lasp.colorado.edu University of Colorado, Boulder, Colorado, United States

A new observing capability was acquired by MAVEN for its extended mission - radio occultations. Observations by the MAVEN Radio Occultation Science Experiment (ROSE) provide vertical profiles of ionospheric electron density with vertical resolution on the order of 1 km, vertical range that can extend to 1000 km altitude, and measurement uncertainties on the order of 3000/cm3. Typically, two pairs of occultations are observed during each week in which occultations are geometrically possible. This cadence is limited by MAVEN's allocated DSN time.

MAVEN performs two-way radio occultations at X-band frequencies on occultation ingress and egress. This capability was demonstrated in a trial campaign in February 2016, and routine operations began in July 2016, shortly before the formal start of MAVEN's Extended Mission 2 in October 2016. Over 60 occultations have been observed to date. These observations are focused on the ionosphere, although data from which neutral temperature-pressure profiles can be obtained are also collected.

Radio occultation electron density profiles complement MAVEN's other ionospheric measurements, such as LPW electron densities, by covering altitudes below MAVEN's periapsis. The main ionospheric peak is usually below MAVEN's periapsis altitude and the lower ionospheric layer is always below MAVEN's periapsis altitude. Furthermore, these observations can provide an independent calibration for MAVEN's in situ density measurements. The MAVEN ROSE electron density profiles can be interpreted and analyzed in the context of simultaneous MAVEN observations of the solar irradiance, solar wind, and magnetospheric conditions, which will enhance research into how the state of the ionosphere is affected by these highly-variable external forcings. The topside ionosphere is of particular interest as a reservoir of escaping volatiles.

C3.2-0017-18 CHARACTERISTICS OF SOLAR X-RAY FLARES AND THEIR EFFECTS ON THE IONOSPHERE AND HUMAN EXPLORATION TO MARS: MGS RADIO SCIENCE OBSERVATIONS

Syed A. Haider, haider@prl.res.in

Physical Research Laboratory, Ahmedabad, Ahmedabad, India

P. Thirupathaiah, thiru@prl.res.in

Physical Research Laboratory, Ahmedabad, Ahmedabad, India Siddhi Y. Shah, siddhi@prl.res.in

Physical Research Laboratory, Ahmedabad, Ahmedabad, India

Responses of solar X-ray flares were observed in a layer of the Martian ionosphere at altitudes of 110 km from 35 electron density profiles obtained by radio science experiment onboard Mars Global Surveyor (MGS) during solar cycle 23. Of the 35 profiles recorded during flare periods, 10 were associated with X-class flares, 13 with M class, 10 with C class, and 2 with B class flares. Their flare E-peak densities vary with solar X-ray flux, Solar Zenith Angle (SZA), Solar Longitude (Ls), Universal Time (UT) and latitude. Ionospheric Electron Content (IEC) and E-peak electron production rates of these flare profiles are estimated in the E region ionosphere. We found a maximum increase of 200%, 140%, 90% and 20% in the time series of IEC for X, M, C and B-class flares respectively. The IEC of flare profiles also increase at high latitude region. The peak altitudes and peak densities of flare profiles behave like a Chapman layer at high SZA. The dependence of flare E-peak electron production rate with Ls is fitted by a sinusoidal function. We have also calculated biological doses 0.1 - 1.0 x 10-1, 1 - 8 x 10-3, 1

6 x 10-4 and 0.4-1 x 10-4 Gy for X, M, C and B-class flares respectively to study the human risk for exploration to Mars. Among 10 X-class flares X14.4 is a strong solar flare that gives highest dose, which is potentially lethal for humans.

C3.2-0018-18 PROCESSES DRIVING MARS ION ESCAPE VARIATIONS IN LIGHT OF BOTH MARS EXPRESS AND MAVEN MEASUREMENTS

Stas Barabash, stas@irf.se

Swedish Institute of Space Physics, Kiruna, Sweden Robin Ramstad, robin.ramstad@irf.se

Swedish Institute of Space Physics, Kiruna, Sweden

In this review talk we focus on the ion escape from Mars due to the solar wind interaction and do not consider processes and channels resulting in neutral escape. Mars Express ion measurements for more than a solar cycle (14 years) provide sufficient statistics to establish the dependence of the ion escape rate on the solar wind density, solar wind velocity, and solar UV flux as independent parameters. Also the ion escape rate variations due to position of magnetic anomalies with respect to the Sun can be established. The long duration of the Mars Express measurements provided opportunities to characterize the escaping ion fluxes during several rare extreme solar wind conditions. We compare the Mars Express findings with MAVEN results obtained for a shorter period.

The local acceleration processes resulting in ion escape are relatively well understood. The planetary ions are accelerated by the convective electric field, polarization electric field due to electron pressure gradients ("polar wind"), and the Hall electric field. However, what defines the total escape rates on the global scale is not clear. Is it the total energy transferred from the solar wind or the supply of ions from the ionosphere? Based on the review of the Mars Express and MAVEN measurements we attempt to answer these fundamental questions.

C3.2-0019-18 ON THE REPEATABILITY OF THE MAGNETICALLY CONTROLLED DENSITY STRUCTURES IN THE MARTIAN IONOSPHERE

Venkateswara Rao Narukull, nvrao@narl.gov.in

National Atmopsheric Research Laboratory, Tirupati, India P Mohana Manasa, mohanamanasa.mohana@gmail.com

Sri Venkateswara University, Tirupati, Tirupati, India Yaswanth Ch., yaswanth@narl.gov.in

National Atmospheric Research Laboratory, Tirupati, India Sarangam Vijaya Bhaskara Rao, drsvbr.acas@gmail.com Sri Venkateswara University, Tirupati, TIRUPATI, India

The Mars Advanced Radar for Subsurface and Ionosphere sounder (MARSIS) aboard the Mars Express spacecraft regularly detects the magnetically controlled density structures (MCDS) in the Martian ionosphere. In this paper, we examined the repeatability of these MCDS using long-term (more than a decade) MARSIS observations over a strong magnetic anomaly region. Instead of a conventional echogram analysis, we adopted a peak density echogram (PDE) analysis since the former may miss some vertical and oblique echoes if their peak frequencies are smaller than the frequency at which an echogram is constructed. The results of the present study suggest that the MCDS are in fact formed persistently on all dayside periapsis passes. However, clear discontinuities are observed on the hyperbola shape in a PDE display that appear at different locations on different orbital passes. In addition, the apices of the hyperbolas associated with an MCDS are observed at different latitudes on different orbital passes. From these results, we infer that the locations and shapes of MCDS are disturbed by some timevarying external factors so that some parts of the MCDS cannot give specular reflections. Nearly similar features are observed with the nightside MCDS but they occur only 60% of the passes. We surmise that wave dynamics associated with tides and gravity waves etc. might be responsible for altering the shape and location of MCDS, both on the dayside and nightside. The results of the present study are discussed in the light of the current understanding on the generation of MCDS.

The canonical picture of the magnetotail of unmagnetized planets consists of draped interplanetary magnetic fields (IMF) forming opposite-directed lobes, separated by the central plasma sheet. Mars possesses localized crustal fields, which make its magnetotail configuration more complicated. DiBraccio et al. [2018] shows that the Martian magnetotail has a twist from the expected location based on nominal IMF draping patterns. Magnetohydrodynamic (MHD) simulation results suggest that field lines connected to the planet that populate portions of the tail cause the twist. To validate the picture of a hybrid Martian magnetotail with observations, we compare the tail topology determined from MHD simulations and from data collected by the Mars Atmosphere and Volatile EvolutioN (MAVEN) spacecraft, in particular how each topology responds to the upstream IMF. Despite limited data coverage, the high-occurrence rate pattern for open field lines varies similarly

w.r.t Eest/West IMF from MAVEN data and MHD simulations. It suggests that Martian crustal fields have a global effect on the magnetosphere configuration and supports the picture of a hybrid magnetotail at Mars.

The deep Solar Cycle (SC) 23 minimum and the modestly active SC 24 maximum have produced generally weaker solar events and heliospheric conditions. Surprisingly, on September 10, 2017 late in the declining phase of SC 24, some of the strongest solar activity erupted from active region (AR) 12673, including an X-class solar flare and a fast coronal mass ejection (CME). Associated with this activity are the solar energetic particles (SEPs), which may be accelerated locally at the flare site or by the moving shock front propagating ahead of the CME. Although

AR 12673 was not centrally facing Mars (it was located about 67 degrees east in heliolongitude from the Sun-to-Mars line), the solar events impacted the local space weather environment. To name a few, some of the effects include flare heating of the upper atmosphere, flare-related enhancements of ion and neutral densities, high fluxes of SEP ions and electrons impacting the atmosphere and the surface, bright emissions of a diffuse (global) aurora, deep draping of the interplanetary magnetic field, and compression of the ionosphere due to the impact of the ICME and related shock. In this presentation we will give an overview of the observations at Mars obtained from various Mars missions, including MAVEN, MSL, and MEX. Numerical results from the Wang-Sheeley-Arge (WSA)-Enlil-cone model system together with observations at Earth/L1 and STEREO-A will also be presented to provide a more global heliospheric context of the event period.

We study the impact of the September 2017 extreme solar flare and interplanetary coronal mass ejection events on Mars using a sophisticated multi-species MHD model. The flare impact is examined by coupling with the Mars Global Ionosphere-Thermosphere Model. A great challenge of the study is that MAVEN was mostly inside the Martian bow shock during the events, and thus no direct solar wind measurement was available. To carry out reasonable simulations, we first simulate the events using steady-state assumptions with rough solar wind estimates. Although these simplistic time-stationary runs are able to capture the general features observed by MAVEN, they cannot represent the details of the large perturbations associated with the events. To describe the time variation during the space weather events, we estimate upstream solar wind conditions by fitting steady-state MHD model results to MAVEN observations in the sheath region. The obtained solar wind proxies are then used to drive a time-dependent MHD simulation. It is found that the data-model comparison is greatly improved, especially in the magnetosheath region. We are able to reproduce many detailed structures observed by MAVEN during the period despite the fact that no direct measurement of the solar wind is available. This model-data agreement confirms the validity of the derived upstream solar wind conditions. Using the time-dependent results, we examine in detail the impact of the events on the Martian system, including three plasma boundaries (Bow Shock, induced magnetosphere and ion composition boundaries) and ion loss rates. It is found that these plasma boundaries vary dramatically during the ICME and total planetary ion loss rates are enhanced by more than an order of magnitude.

C3.2-0023-18 LOSS OF THE MARTIAN ATMOSPHERE TO SPACE: PRESENT-DAY LOSS RATES FROM MAVEN OBSERVATIONS AND INTEGRATED LOSS THROUGH TIME

Bruce Jakosky, bruce.jakosky@lasp.colorado.edu University of Colorado, Boulder, Colorado, United States

Observations of the Mars upper atmosphere made from the Mars Atmosphere and Volatile Evolution (MAVEN) spacecraft have been used to determine the loss rates of gas from the upper atmosphere to space for a complete Mars year. Loss rates for H and O are sufficient to remove 2-3 kg/s to space. By itself, this loss would be significant over the history of the planet. In addition, loss rates would have been greater early in history due to the enhanced solar EUV and solar wind. Integrated loss would have been as much as 0.8 bar CO2 or 23 m global equivalent layer of H2O; these losses are likely to be lower limits due to the nature of the extrapolation of loss rates to the earliest times and due to additional loss likely to have been driven by solar storms. Combined with the lack of surface or subsurface reservoirs for CO2 that could hold remnants of an early, thick atmosphere, these results suggest that loss of gas to space has been the dominant process responsible for changing the climate of Mars from an early, warmer environment to the cold, dry one that we see today.

The Juno spacecraft carries with it a suite of instruments for both in situ and remote sensing observations of Jupiter's aurora and its response to variations in the polar magnetosphere. Observations by the particle instruments (JEDI and JADE) measure the energetic electron and ion distributions locally at the spacecraft, while the magnetometer (MAG) provides the instantaneous magnitude and orientation of Jupiter's magnetic field. Spectral imagers (UVS and JIRAM) perform remote sensing of H2 ultraviolet and H+ near-infrared auroral emissions to give context for the particles and fields instruments to help untangle the complex processes occurring in Jupiter's giant magnetosphere. Antennas (Waves) perform remote sensing and in situ measurements of complex jovian auroral radio emissions. Here we will present important and surprising results from the many successful perijoves to date.

C3.2-0025-18 SATURN'S MAGNETIC FIELD DURING THE CASSINI GRAND FINALE

Michele K. Dougherty, m.dougherty@imperial.ac.uk

The Blackett Laboratory, Imperial College, London, United Kingdom The Cassini Magnetometer Team there are 40 + members of the team based in UK, USA, Germany, Hungary and France.

During the Cassini Grand Finale orbits at Saturn the focus of the magnetometer investigation was determination of the internal planetary magnetic field as well as the rotation rate of the deep interior. The unique geometry of these orbits provided an opportunity to measure the internal magnetic field at closer distances to the planet than ever encountered before. The surprising close alignment of Saturn's magnetic axis with its spin axis (known about since the Pioneer 11 observations) has been confirmed, however external effects, observed even around periaspse are masking some of the magnetic field signals from the interior. The varying northern and southern magnetospheric planetary period oscillations and field aligned currents at both high and low latitudes are contributing to the magnetic signals observed. An overview of the magnetic field results from the Grand Finale orbits will be described, including confirmation of the extreme axisymmetric nature of the planetary magnetic field, detection of high degree magnetic moments and the behaviour of external magnetic fields.

Imperial College University of London, London, United Kingdom

Cassini's Grand Finale provided a treasure trove of data while flying between Saturn's atmosphere/ionosphere and the D ring. The INMS instrument measured both neutrals and light ions during this time period - observing the most complex mass spectra of the entire mission. The RPWS measured the electron density along track and registered the presence of heavy positive and negative ions. MIMI observed energetic ions as well as an important population of nanometer-sized grains. MAG observed field-aligned currents and characterized the magnetic field geometry. Taken together these data sets characterize the complex chemical and dynamical interconnection of the rings to Saturn's equatorial atmosphere/ionosphere. This presentation will emphasize the structure of the Saturn/ring atmosphere and the chemical coupling of ring material to the equatorial atmosphere of Saturn. It will also attempt to place this within the context of the other measurements that will be more completely covered in separate presentations.

C3.2-0027-18 MONITORING SATURN'S UPPER ATMOSPHERE DENSITY VARIATIONS USING HELIUM 584Å AIRGLOW

Christopher Parkinson, theshire@umich.edu

University of Michigan, Ann Arbor, Michigan, United States

The atmosphere of Saturn is mainly composed of H2 and neutral atomic helium. The study of He 584 Å brightnesses is interesting as the EUV (Extreme UltraViolet) planetary airglow have the potential to yield useful information about mixing and other important parameters in its thermosphere. Resonance scattering of sunlight by He atoms is the principal source of the planetary emission of He 585 Å. The helium is embedded in an absorbing atmosphere of H2 and since it is heavier than the background atmosphere, it's concentration falls off rapidly above the homopause. The scattering region (i.e. where the absorption optical depth in H2 is less than 1) generally lies well above the homopause. As the eddy diffusion coefficient, Kz, increases in the middle atmosphere, more helium is mixed into the scattering region and thus the reflected intensity increases.

Specifically, He emissions come from above the homopause where optical depth tau=1 in H2 and therefore the interpretation depends mainly on two parameters: He mixing ratio of the lower atmosphere and eddy mixing profile, Kz. The occultations of Koskinen et al (2015) give Kz with an accuracy that has never been possible before and the combination of these occultations and airglow analyses can therefore can provide estimates of the mixing ratio in the lower atmosphere.

Using Cassini UVIS data and powerful modeling and analysis techniques, we can address longstanding questions regarding the He mixing ratio in Saturn's atmosphere and upper atmosphere density variations using the He 584Å airglow. We discuss ongoing efforts to determine the mixing ratio of He and constrain dynamics in the upper atmosphere of Saturn.

C3.2-0028-18 UNDERSTANDING CALLISTO'S INTERACTION WITH THE JOVIAN MAGNETOSPHERE: A CASE STUDY OF THE GALILEO C10 FLYBY

Lucas Liuzzo, lucas.liuzzo@eas.gatech.edu

Georgia Institute of Technology, Atlanta, Georgia, United States Sven Simon, sven.simon@eas.gatech.edu

Georgia Institute of Technology, Atlanta, Georgia, United States

We apply a combination of data analysis and hybrid modeling to study Callisto's interaction with Jupiter's magnetosphere during the Galileo C10 flyby on 17 September 1997. This encounter took place while Callisto was located near the center of Jupiter's current sheet. Therefore, induction in Callisto's subsurface ocean and magnetospheric field line draping around the moon's ionosphere both made nonnegligible contributions to the observed magnetic perturbations. The induction signal during C10 was obscured by plasma currents to a significant degree, in contrast to previously studied Callisto flybys. Our analysis reveals that at large distances to Callisto, its magnetic environment was dominated by field line draping, leading to the formation of Alfvén wings. Closer to the surface and in Callisto's wake, Galileo encountered a quasi-dipolar "core region" that was partially shielded from the plasma interaction and was dominated by the induced field. When exiting this core region, the spacecraft crossed a rotational discontinuity where the magnetic field vector rotated by approximately 50°. The hybrid model is able to quantitatively explain numerous key features of the observed magnetic signatures, especially the transitions between drapingand dipole-dominated regimes along the C10 trajectory. The model also reproduces the electron number density enhancement by 3-4 orders of magnitude detected in Callisto's wake, requiring a substantial ionosphere to surround the moon during C10. For flybys with nonnegligible plasma currents, comprehensive knowledge of the incident flow conditions and properties of Callisto's atmosphere is required to refine existing constraints on the subsurface ocean (conductivity, thickness, and depth) based on magnetic field data. These findings are highly relevant for the upcoming JUpiter ICy moon Explorer (JUICE) mission, which will include multiple Callisto flybys.

The European Space Agency's Rosetta spacecraft was in orbit around comet 67P/ChuryumovGerasimenko from August 2014 to September 2016. Rosetta carried several instruments to investigate the comet's nucleus and surrounding neutral gas, dust, and plasma environment. Part of the payload was the Rosetta Orbiter Spectrometer for Ion and Neutral Analysis (ROSINA) that consisted of two mass spectrometers and a pressure sensor. ROSINA was designed for in situ measurement of the neutral gas, both in composition and in absolute abundance.

Comets are surrounded by an extended neutral gas and dust coma. As they journey around the Sun on eccentric orbits the production of volatiles from sublimation of ices in the nu- cleus undergoes strong variations. ROSINA observations in combination with sophisticated time-dependent models have shown that the neutral gas coma is very heterogeneous. This heterogeneity is driven in large parts by the complex shape of the nucleus and the varying illumination conditions associated with the comet's rotation and variation in heliocentric distance. Furthermore, the oblique rotation axis of the nucleus led to seasons, i.e., different evolutionary histories of the northern and the southern hemispheres.

In this presentation we will address some of the major findings of ROSINA and discuss their implications on the formation and thermal evolution of comet 67P/Churyumov-Gerasimenko.

C3.2-0030-18 ENERGETIC NEUTRAL ATOM IMAGING: INTERACTIONS BETWEEN PLANETARY PLASMA, EXOSPHERE, AND SURFACE

Yoshifumi Futaana, futaana@irf.se

Swedish Institute of Space Physics, Kiruna, Sweden

It is frequently said that 99% of all known matters in the universe is in the plasma state. To understand the universe, understanding of the behavior of the plasma is therefore essential. Traditionally, space plasma has been investigated using in-situ charged particle measurements, or electromagnetic emission (or absorption) lines. Recently, energetic neutral atom (ENA) imaging has open a new channel for space plasma investigations. Energetic neutral atoms are produced from the charge exchange mechanism. When an ion received an electron from neighboring neutral atom, the primary ion becomes an ENA. During the charge exchange process, the energy loss of the primary ion is usually negligible. Due to the neutrality, ENAs do not feel any electromagnetic force. Therefore, we can know the primary ion's velocity distribution function remotely using ENAs.

The ENA imaging has been utilized to not only terrestrial missions, but also to planetary missions. Low energy (1 keV) ENA instruments were carried to Mars, Venus, and the Moon. Interactions of these planets and the solar wind has been investigated. At Saturn, high energy (> keV) ENA imagers were operated to measure the magnetospheric plasma. As future missions, ENA sensors will be inserted to Mercury (with BepiColombo) and to Jupiter (with JUICE). In this review talk, we will overview planetary environments revealed by ENA imaging.

C3.2-0031-18 ON THE RELATIVE ROLES OF THE NEUTRAL DENSITY AND PHOTO CHEMISTRY ON THE SOLAR ZENITH ANGLE VARIATIONS IN THE V2 LAYER CHARACTERISTICS OF THE VENUS IONOSPHERE UNDER DIFFERENT SOLAR ACTIVITY CONDITIONS

Ambili Kailasam Madathil, ambilisadasivan@gmail.com

Indian Institute of Space Science & Technology, TRIVANDRUM, India Raj Kumar Choudhary, rajkumar.choudhary@gmail.com

Space Physics Laboratory, VSSC, Trivandrum, India Sneha Susan Babu, snehasmailin@gmail.com

Indian Iinstitute of Space Science and Technology, 695547, India

Using an in-house developed one-dimensional photo-chemical model (1D-PCM) which considers production and loss of 11 ions namely, CO+, CO+, C+, N+, N+, He+, O+(2D), O+(2P), O+(4S),

2 2

O+ and NO+, characteristics of the V2 layer in the Venus ionosphere has been studied. It was noted that existing ionospheric model for the Venus ionosphere, such as IonA model, not only over/ under estimated the peak electron density of V2 layer, it also had significant departures from the observations on the solar zenith angle and solar activity control. The IonA model had used VenusGRAM model as input for the neutral density which considers Venus atmosphere consisting of CO2, O, and N2 molecules only. In addition to this, it had oversimplified the ion chemistry by assuming Venus ionosphere to have O+ as the only dominant ion species.

Using VTS3 model which considered profiles of six neutrals (CO2, O, CO, He, N, and N2), we modified IonA model to find that it reproduced the height of V2 peak electron density quite well. The model however still lacked in reproducing observed peak V2 electron density. The ion-house developed 1D-PCM model not only reproduced the observed V2 peak density, the height of the peak V2 layer was also represented well. Our results with 1D-PCM calculations show the role of complex chemical reactions in determining the features of peak altitude and density of V2 layer during different solar activity periods. We surmise that difference between modelled peak altitude of V2 layer by IonA model, and observations was due to the limitations of VenusGRAM neutral density model. It also suggested that the height of peak V2 layer in Venus ionosphere is controlled by neutral density. 1D-PCM calculations showed that the complex chemistry including production and loss reactions of 11 ions could reproduce the variations in the peak density of Venusian ionosphere during different solar activity conditions. This fact further suggests that the ion-chemistry has control over the peak plasma density in the Venus ionosphere

C3.2-0032-18 MGS RADIO SCIENCE ELECTRON DENSITY PROFILES: LONGITUDINAL CHARACTERISTICS

Arun Kumar Upadhayaya, upadhayayaak@nplindia.org National Physical Laboratory India, New Delhi, India Sumedha Gupta, sumedha88@gmail.com

National Physical Laboratory India, New Delhi, India

Early analysis of the first few sets of electron density profiles returned by the radio science experiment aboard MGS spacecraft provided a strong evidence for planetocentric longitude dependence of the photochemical controlled E and F1 layers of the Martian ionosphere. This feature is not seen in the E and F1 layer of the Earth's ionosphere, which too are photochemical. In this study, with the availability of several MGS data sets containing a total of 5600 electron density profiles, we re-examine the longitude dependence of the observed peak parameters (viz. height and density) as well as of other derived parameters, like the electron content and the atmospheric scale height of the E and F1 layers. We find that though there is a lot of variability, the distribution with longitude for each of these parameters is nearly uniform most of time. However, exceptions are periods during late spring and early summer (northern latitudes) when the longitudinal variations indicate the presence of crests/troughs, in the observed as well as in the derived parameters, broadly spread around 0°, 70° and 140° E longitudes. On examining the characteristics of the electron density profiles located at these crests/troughs, we find a large difference between the two sets, with the peak height and peak density showing large excursions. Further, the peak density, electron content and atmospheric scale height show significant relationship with the excursions in peak height. These observations can be explained if there are rapid changes in Mars thermosphere.

C3.2-0033-18 EXOSPHERIC NEUTRAL COMPOSITION DATA SET OF MARS FROM INDIAN MARS ORBITER MISSION

Nagaraja Kamsali, kamsalinagaraj@bub.ernet.in Bangalore University, Bengaluru, India

Praveen Kumar Basuvaraj, praveenkumarbasuvaraj@gmail.com Bangalore University, Bengaluru, India

Praveen Kumar K, praveen@isro.gov.in

Indian Space Research Organization, Bengaluru, India

S.C. Chakravarty, chakravarty08@gmail.com Bangalore University, Bangalore, India

The raw data of exospheric composition of Mars for the period 24 September 2014 to 23 September 2015 has been utilized to prepare a spread sheet based calibrated and normalised data set. For this, the voluminous data is compressed to select the best values of partial pressures of the atmospheric species covering the mass spectrum between 1 to 100 amu values. Multiple data files were merged to consolidate the data for individual orbits of Mars Orbiter Mission (MOM) for which the Mars Exospheric Neutral composition Analyser (MENCA) payload operated for carrying out the observations. Depending on the height coverage, the total and partial pressure values are further analysed by suitable algorithms considering the rate of change of the pressure values with time. A total of 497 data files contain the MENCA data for the above period pertaining to 149 orbits of MOM. Individual plots of the total and partial pressures with altitude for the height region below 1000 km have provided a statistically significant variation of atmospheric constituents. The anomalous pressure values particularly during the first hour of switching on the quadrupole mass spectrometer have been carefully examined and only the consistent values have been retained. The main constituents with relatively higher partial pressures like H, N, O, H2O, (N2+CO), Ar, CO2 have been studied with their relative variation with height, surface co-ordinates, solar angles and solar activity. Sample results of these profiles are presented.

C3.2-0034-18 MAGNETIC FIELD ENVIRONMENT OF VENUS AND MARS

Vipin K Yadav, vkyadavcsp@gmail.com

Vikram Sarabhai Space Centre, Trivandrum, India

The magnetism is a universal parameter and an essential component of any planetary body. The magnetic field of a planetary body is the result of its internal movements taken place in the past and present as well as due to its interaction with the solar wind. The magnetic field imposes constraints on the planetary structure, dynamics and evolution. The magnetic field can be used as a potential tool to understand the interiors of a planetary body. Venus and Mars do not possess a global magnetic field unlike Earth. The absence of an intrinsic magnetic field in Venus is due to the lack of dynamo which is responsible for a strong global magnetic field due to the motion of an electrically conducting and convecting fluid inside the planet. It is believed that Mars had an intrinsic magnetic field is the past but the dynamo stops due to various factors. However, Mars does possess a weak magnetic moment due to the crustal magnetic anomalies. In the absence of a global magnetic field, the solar radiation (dominantly EUV) interacts deep into the atmosphere of Venus and Mars and ionizes large number of neutral atoms and molecules to generate the ionosphere. In the ionosphere of these two terrestrial planets a number of plasma phenomena take place. Some of these phenomena lead to the generation of plasma waves.

In this paper, the scientific understanding of the magnetic environment of Venus and Mars is presented with proposed studies that can be carried out in a future space mission to these planets.

C3.2-0035-18 INTERPLANETARY MAGNETIC FIELD PENETRATION INTO MERCURY'S MAGNETOSPHERE

David Parunakian, rumith@srd.sinp.msu.ru

Skobeltsyn Institute of Nuclear Physics, MSU, Moscow, Russia Igor Alexeev, alexeev@dec1.sinp.msu.ru

Skobeltsyn Institute of Nuclear Physics, MSU, Moscow, Russia Elena Belenkaya, elena@dec1.sinp.msu.ru

Skobeltsyn Institute of Nuclear Physics, MSU, Moscow, Russia

In this work we present the results of performing multi-parametric fitting of the paraboloid magnetosphere model (PMM) to magnetometer observational data obtained during a number of MESSENGER orbits around Mercury with the purpose of investigating the interplanetary magnetic field (IMF) coefficient of penetration into the magnetosphere. We analyze cases with multiple IMF states that satisfy the condition that during the inbound and outbound orbit segments the IMF vector is approximately the same; since Mercury's magnetosphere is quite small, any disturbances in the magnetosphere induced by abrupt changes in the IMF propagate rapidly, and the magnetosphere achieves a new meta-stable state shortly. We thus assume that the IMF is nearly constant and the magnetosphere is quasi-stationary during the whole duration of these orbit segments, and fit the PMM parameters (including the IMF penetration coefficient κ) to match the observations.

C3.2-0036-18 NEUTRALS - FORESHOCK ELECTRON IMPACT IONIZATION AT MARS FROM MAVEN SWEA OBSERVATIONS

Christian Mazelle, cmazelle@irap.omp.eu

IRAP, CNRS-Univ. of Toulouse-UPS-CNES, Toulouse, France

Backstreaming electrons emanating from the bow shock of Mars observed by the MAVEN SWEA instrument show a flux fall off with the distance from the shock. This feature is not observed at the terrestrial foreshock. The flux decay is only for electron energy E > 29 eV. A reported recent study indicates that Mars foreshock electrons are produced at the shock in a mirror reflection of a portion of the solar wind electrons. In this context and given that the electrons are sufficiently energetic to stay unaffected by the IMF fluctuations, the observed flux decrease appears problematic. We investigate the possibility that the flux fall off with distance results from the impact of backstreaming electrons with Mars exospheric neutral hydrogen. We demonstrate that the flux fall off is consistent with the electron-atomic hydrogen impact cross-section for a large range of energy. A better agreement is obtained for energy where the impact cross section is the highest. One important consequence is that foreshock electrons can play an important role in the production of pick up ions at Mars far exosphere.

C3.2-0037-18 DENSITIES INFERRED FROM ESA'S EXOMARS TRACE GAS ORBITER AEROBRAKING CAMPAIGN

Jean-Charles Marty, jean-charles.marty@cnes.fr CNES/GRGS, TOULOUSE, France

Sean Bruinsma, sean.bruinsma@cnes.fr

Centre National d'Etudes Spatiales, Toulouse, France Håkan Svedhem, hakan.svedhem@esa.int

European Space Agency, Noordwijk, Netherlands Michela Muñoz Fernández, michela.munoz@esa.int ESA/ESAC, Madrid, Spain

Ingo Mueller-Wodarg, i.mueller-wodarg@imperial.ac.uk Imperial College London, London, United Kingdom

The aerobraking phase of TGO, from March 2017 to February 2018, was used to reduce the orbital period from 24 hours to about 2 hours and an apocenter altitude of 1000 km. It was achieved by lowering the orbit perigee to approximately 105-110 km and rotating the solar array to be almost perpendicular to the satellite speed vector in order to enhance the atmospheric drag effect.

Data of the aerobraking phase will be processed to infer total densities. The attitude quaternions are used to correctly orient the spacecraft bus and solar arrays in inertial space, which is necessary to accurately compute the exposed surface in the ram direction. The (engineering) accelerometers provide measurements with a good signal-to-noise ratio at low altitude, close to the pericenter; at the beginning of the aerobraking phase, this results in one acceleration profile per day, whereas up to 12 profiles per day can be obtained at the end of the phase. The calibrated accelerations, essentially due to aerodynamic drag at low altitude, are then used to infer total density using a model for satellite shape and the aerodynamic drag coefficient Cd. The uncertainty in the derived density is the sum of a systematic part due to the uncertainty in Cd, and a noise and bias (not completely resolved after calibration) part due to the accelerometers. Preliminary results of the density calculations will be presented, and comparison to models such as MarsGRAM and MCD. In-situ thermosphere density measurements will be used to infer the global structure and variability of the Martian upper atmosphere, including analyses of atmospheric waves. Comparisons with simultaneous MAVEN atmosphere measurements will also be made in the future.

C3.2-0038-18 PROFILES, SEASONAL AND SOLAR CYCLE VARIABILITY OF ELECTRON DENSITIES IN THE UPPER MARTIAN IONOSPHERE: 11 YEARS OF MARSIS DATA

Coe College, Cedar Rapids, Iowa, United States

Mars Advanced Radar for Subsurface and Ionospheric Sounding (MARSIS) onboard the Mars Express (MEX) spacecraft has been providing valuable information about the ionosphere of Mars. Among these are the electron densities local to the spacecraft, obtained from the excitation of local plasma oscillations. This paper provides an overview of electron densities in the upper ionosphere of Mars. We investigated over 1200 orbits, about 360000 ionograms, over the course of 11 Earth years, 5.5 Martian years, which corresponds to a full solar cycle period. The data covers a wide range of SZA, latitude and longitude, with an altitude range between 250 km and 1500 km. The electron density profiles show large fluctuations within each orbit and also for a given altitude and solar zenith angle range. However, the median electron density is almost constant on the dayside at a fixed altitude range, with the exception of a dip at around 30°, at altitudes between 300 and 700 km. Interestingly, a decrease in the electron density similar to the dip we have seen, has been also observed in MAVEN data for lower altitudes. For a fixed SZA range, the median electron density decreases with increasing altitude. Full solar cycle data permit us to study solar cycle and seasonal dependence. Especially at higher altitudes a decrease in the electron densities during the solar minimum is evident. Also, an increase is seen during northern winter in some altitude and SZA ranges compared with northern summer. Crustal fields have a notable effect on the electron densities at lower altitudes: Electron densities are substantially higher above regions of strong fields.

C3.2-0039-18 IONOSPHERIC MAGNETIC FIELD AND CURRENT VARIATIONS OVER THE INSIGHT LANDING SITE

Matthew Fillingim, matt@ssl.berkeley.edu

University of California, Berkeley, Berkeley, California, United States

The InSight lander, scheduled to reach Mars in late 2018, will investigate the interior of Mars using seismic, heat flow, and radio tracking experiments. The InSight Flux Gate magnetometer (IFG), part of the Seismic Experiment for Interior Structure (SEIS), will measure the ambient magnetic field in order to decouple the magnetic field impacts from the seismometer recordings. As the first magnetometer on the surface of Mars, observations from IFG can also be used to investigate the behavior of ionospheric magnetic fields and ionospheric currents above the lander.

Here we use Mars Global Surveyor and MAVEN magnetic field measurements while the spacecraft were in the martian ionosphere above the nominal InSight landing site to investigate the variability in the ionospheric magnetic field and currents. The ionospheric magnetic field can be highly variable, depending largely upon the upstream interplanetary magnetic field and solar wind conditions. From these magnetic field observations, we estimate the ionospheric currents and the expected magnetic perturbations at the surface due to the estimated currents. Ionospheric currents are found to be on the order of μA m−2. These currents would result in a surface level magnetic field perturbation of a few nT, large enough to be easily measured by IFG. This analysis lays the groundwork for future investigations of the variability of ionospheric currents from IFG observations.

C3.2-0040-18 A MODEL ANALYSIS OF THE NORTHERN AND SOUTHERN HEMISPHERIC ELECTRON DENSITY PROFILES AT MARS

The Mars Express electron density (Ne) profiles near terminators have indicated more complicated structure of the Martian high-latitude ionosphere than previously thought. Some of these profiles over the northern hemisphere show wide and narrow shapes of the main Ne peaks while others over the southern hemisphere have shown anomalous characteristics of the topside plasma distribution. We use our 1-D chemical diffusive model coupled with the Mars - Global Ionosphere Thermosphere Model (M-GITM) to interpret both northern (67oN, 235oE and 66oN, 341oE) and southern (82oS, 180oE) hemispheric Ne profiles. Our model is a coupled finite difference primitive equation model which solves for plasma densities and vertical ion fluxes. The crustal magnetic field at the northern locations is mainly horizontal and does not allow plasma to move vertically. Thus, the primary plasma loss for the topside ionosphere at the northern locations is likely caused by diverging horizontal fluxes of ions, indicating that the dynamics of the upper ionosphere of Mars is controlled by the solar wind. The situation at the southern location is different where the field lines are nearly vertical and open to the access of solar wind plasma through magnetic reconnection with the interplanetary magnetic field. This can lead to the acceleration of electrons and ions during the daytime ionosphere. The downward accelerated electrons with energies >200 eV penetrate deep into the Martian upper ionosphere along vertical magnetic field lines and cause heating, excitation and ionization of the background atmosphere. The upward acceleration of ions resulting from energy input by precipitating electrons can lead to enhance ion escape rate and modify scale heights of the topside ionosphere. The primary source of ionization in the model is due to solar EUV radiation. An extra ionization source due to precipitating electrons of 0.25 keV, peaking near an altitude of 145 km is added in the model to interpret the measured ionospheric structure at the southern location. We find that an upward flux of O2+ of 1.8 x 106 cm−2 s−1 is needed to explain the northern topside electron density profile at 66oN while this value is increased by a factor of two at 67oN. However, the behavior of the topside ionosphere at the southern location is interpreted by the vertical plasma transport simulated by vertical ion velocities, whose values can be interpreted as drift velocities along magnetic field lines. We find that the variation of the topside Ne scale heights is sensitive to magnitudes of upward and downward drifts with an imposed outward flux boundary condition at the top of the model. The model requires an upward flux of more than 107 ions cm−2 s−1 for both O2+ and O+, and drift speeds of 200

m/s to interpret the measured topside ionospheric structure. The model results for both the northern and southern locations will be presented in comparison with the measured electron density profiles. This work is supported by MBRSC, Dubai, UAE.

C3.2-0041-18 THE BEHAVIOR OF THE BUNEMAN INSTABILITY IN DISSIPATIVE PLASMA

Eduard Rostomyan, eduard_rostomyan@mail.ru

Inst of Radiophysics and Electronics Armenian Nat Ac Sci, Ashtarack, Armenia

The Buneman instability (BI) [1] plays an important role in many scenarios in space physics and geophysics. It is invoked to explain many phenomena in the Earth's ionosphere [2] and in the solar chromosphere [3]. In double-layer physics as well as in collision-less shock physics, the same instability was found responsible in formation of nonlinear structures [4]. Development of the BI in ionospheric electrojets leads to a formation of plasma density irregularities, which have observational confirmations [5]. Studies of these irregularities have focused attention on the role of BI and other low frequency instabilities. Ionospheric irregularities and related phenomena in the equatorial and high-latitude E-region electrojets have been studied for many years by radars and rockets. It is now generally accepted that the most common irregularities are caused by the BI. In order to full understanding how the instability transforms given local equilibrium of plasma, how the irregularities have been created as well as calculate their level and/or spatial scales and estimate possible saturation mechanisms it is necessary to investigate the evolution of the instability in space and time [6]. In spite the BI is subject of many investigations, this (as well as some other) aspect of the instability remains unstudied. In present investigation the problem of time evolution of initial perturbation excited at the development of the BI in plasma with dissipation is solved. Developing fields are presented in form of wave train with slowly varying amplitude. It is shown that the evolution of the initial pulse in space and time is given by differential equation of third order. The equation is solved and the expression for asymptotic pulse shape is obtained. The expression gives the most complete information on the instability: the space-time distribution of the fields, growth rates, velocities of unstable perturbations, the influence of the collisions/ dissipation on the instability, its character (absolute/convective) etc. All these characteristics of the BI are carried out by analyzing the expression for the space-time distribution of the fields. It is shown with increase in dissipation the BI turns to instability of dissipative type. [1]. Buneman O. Phys.Rev.Let, v.1, p8, (1958); Phys Rev v.115, 503, (1959). [2]. Gogoberidze G. Voitenko, Y. C3.2-0042-18 NON-SIMILARITY SOLUTION FOR UNSTEADY ISOTHERMAL FLOW BEHIND A MAGNETOGASDYNAMIC SHOCK WAVE IN A ROTATIONAL AXISYMMETRIC GAS WITH EXPONENTIALLY VARYING DENSITY

Gorakh Nath, gn_chaurasia_univgkp@yahoo.in National Institute of Technology, Allahabad, India

The propagation of cylindrical shock wave in an ideal gas with or without rotational effects in the presence of a constant azimuthal magnetic field for unsteady isothermal flow is discussed. The ambient medium is assumed to have radial, axial and azimuthal components of fluid velocity. Non-similar solutions are obtained for one-dimensional isothermal flow behind a magnetogasdynamic shock wave by taking into account the vorticity vector and its components. The density of the gas, azimuthal and axial components of fluid velocity in the ambient medium are assumed to be varying and obeying an exponential law. The numerical solutions are obtained using the Runge-Kutta method of the fourth order. The effects of Alfven-Mach number; adiabatic exponent gamma and time are obtained. It is shown that in the presence of magnetic field the pressure and density vanishes at the inner expanding surface (piston) and hence a vacuum is formed at the line of symmetry, which is an excellent agreement with the laboratory condition to produce the shock wave. Also, the shock strength increases with increase in time in the absence of magnetic field but in the presence of magnetic field time has reverse affects on the shock strength. The shock waves in conducting perfect gas can be important for description of shocks in supernova explosions, in the study of central part of star burst galaxies, nuclear explosion, rupture of a pressurized vessel, explosion in the ionosphere and for upper atmosphere. Other potential applications of this study include analysis of data from exploding wire experiments and cylindrically symmetric hypersonic flow problems associated with meteors or re-entry vehicles etc. A comparison is made between the solutions in the cases of rotating and non-rotating medium with or without magnetic field. The obtained solutions are applicable for arbitrary values of time. Keywords: Shock wave; Magnetogasdynamics and Electro-fluid Mechanics; Rotating medium, Non-similarity solution.

C3.2-0043-18 DAYSIDE IONOSPHERIC CONDUCTIVITIES AT MARS OVER THE REGION OF CRUSTAL MAGNETIC ANOMALY

Shahd AlMutawa, miss.almutawa@gmail.com

American University of Sharjah, Sharjah, United Arab Emirates Tariq Majeed, tmajeed@aus.edu

University of Michigan, Ann Arbor, MI, Michigan, United States

A complex magnetic topology at Mars gives rise to diverging magnetic field cusps and closed magnetic loops with local magnetic conditions similar to those found above Earth's polar region. One of such cusps is located at 82oS and 180oE where the crustal magnetic field is nearly vertical and open to the access of solar wind plasma through magnetic reconnection with the interplanetary magnetic field. This reconnection can allow solar wind electrons to penetrate into the Martian upper atmosphere, causing ionization and heating, which leads to inflate the topside plasma distribution to high altitude and increase the topside electron density scale height. These characteristics of the Martian upper atmosphere at this southern location are confirmed from the Mars Express electron density profile. We use our 1-D chemical diffusive model from an altitude of 100 km to 400 km to interpret the measured electron density profile with the vertical plasma transport simulated by vertical ion velocities and by imposing an outward flux boundary condition. The output of this model and available crustal magnetic field information at Mars are used to estimate the vertical distribution of ionospheric conductivities. We find that the ionosphere is highly conductive in the Martian dynamo region between 100 and 250 km altitude, where plasma -neutral collisions permit electric currents perpendicular to the crustal magnetic field. The magnitudes of Pedersen and Hall conductivities are estimated to be 0.65 - 0.75 S/m, respectively, near the Martian ionospheric peak. We also estimated the magnitude of horizontal ionospheric currents driven by ion and electron motions in the Martian dynamo region. The model results will be presented in comparison with existing estimates of the Martian conductivities and ionospheric currents. We acknowledge support for this work from the Mohammed Bin Rashid Space Center (MBRSC), Dubai, UAE.

C3.2-0044-18 THE MAGNETOSPHERE OF MERCURY UNDER NOMINAL AND FAST SOLAR WIND CONDITIONS IN A GLOBAL HYBRID SIMULATION

Riku Jarvinen, riku.jarvinen@aalto.fi Aalto University, Espoo, Finland Markku Alho, markku.alho@aalto.fi Aalto University, Espoo, Finland Esa Kallio, esa.kallio@aalto.fi

Aalto University, Espoo, Finland

Tuija Pulkkinen, tuija.pulkkinen@aalto.fi Aalto University, Espoo, Finland

We analyze the interaction of the solar wind with the Hermean magnetic field including the formation of the bow shock, the magnetosheath and the magnetopause in a 3-dimensional global hybrid model. First we present the implementation of the numerical simulation model, where ions are treated as particles moving under the Lorentz force and electrons are a chargeneutralizing fluid. In the hybrid approach ion dynamics are self-consistently coupled with the propagation of the magnetic field by Faraday's law. The undisturbed solar wind flow is injected from the front wall of the simulation domain and the particles can reach the planetary surface, which is the inner boundary. Resistivity profiles of the planetary crust and core can be included as well. The incident solar wind can include, for example, conditions during nominal and highspeed streams and solar wind transient conditions like interplanetary coronal mass ejections. In the analysis we concentrate on how the solar wind plasma gains access to different regions in Mercury's magnetosphere and its boundary layers.

C3.2-0045-18 THE IMPACT OF CALLISTO'S ATMOSPHERE ON ITS PLASMA INTERACTION WITH THE JOVIAN MAGNETOSPHERE

Lucas Liuzzo, lucas.liuzzo@eas.gatech.edu

Georgia Institute of Technology, Atlanta, Georgia, United States
Sven Simon, sven.simon@eas.gatech.edu

Georgia Institute of Technology, Atlanta, Georgia, United States

The interaction between Callisto's atmosphere and ionosphere with the surrounding magnetospheric environment is analyzed by applying a hybrid simulation code, in which the ions are treated as particles and the electrons are treated as a fluid. Callisto is unique among the Galilean satellites in its interaction with the ambient magnetospheric plasma as the gyroradii of the impinging plasma and pickup ions are large compared to the size of the moon. A kinetic representation of the ions is therefore mandatory to adequately describe the resulting asymmetries in the electromagnetic fields and the deflection of the plasma flow near Callisto. Multiple model runs are performed at various distances of the moon to the center of Jupiter's magnetospheric current sheet, with differing angles between the corotational plasma flow and the ionizing solar radiation. When Callisto is embedded in the Jovian current sheet, magnetic perturbations due to the plasma interaction are more than twice the strength of the background field and may therefore obscure any magnetic signal generated via induction in a subsurface ocean. The magnetic field perturbations generated by Callisto's ionospheric interaction are very similar at different orbital positions of the moon, demonstrating that local time is only of minor importance when disentangling magnetic signals generated by the magnetosphere-ionosphere interaction from those driven by induction. Our simulations also suggest that deflection of the magnetospheric plasma around the moon cannot alone explain the density enhancement of 2 orders of magnitude measured in Callisto's wake during Galileo flybys. However, through inclusion of an ionosphere surrounding Callisto, modeled densities in the wake are consistent with in situ measurements.

C3.2-0046-18 VALIDATING SOLAR SOFT X-RAY IRRADIANCE MODELS WITH MODELMEASUREMENT COMPARISONS OF PHOTOELECTRON SPECTRA AT MARS

Solar x-ray ultraviolet (XUV, 0.1-10 nm) photons are a primary energy input into the upper atmospheres of Earth and other planets, and are distinct from extreme ultraviolet (EUV, 10-120 nm) photons in their capability to penetrate to lower altitudes, creating the E-region of the ionosphere at Earth for example. Predicting XUV photoionization requires spectrally resolved irradiance measurements or models because the cross-sections of many atmospheric constituents are highly structured near 2.5 nm. Although spectral irradiance at the shortest XUV wavelengths has been historically uncertain due to limited measurements, knowledge of the XUV spectrum from 0.2-2.5 nm has been significantly improved by the MinXSS CubeSat, which made full-disk spectral irradiance measurements from May 2016 to May 2017. These measurements have been incorporated into the Synthetic Reference Spectra (SynRef) model which can be driven by a number broadband XUV measurements that have been made nearcontinuously for the past two decades at Earth by SNOE, SORCE and TIMED; and at Mars by MAVEN since October 2014. Due to the lack of other spectrally resolved XUV measurements, directly validating SynRef for times when MinXSS was not making observations is not possible. An indirect method for validating XUV irradiance models is to input them into models for photoelectron

energy spectra and compare the modeled photoelectron energy spectra with measured photoelectron energy spectra. Measurements made by the MAVEN SWEA instrument currently in orbit at Mars provide such an opportunity. This study compares photoelectron measurements made at Mars by SWEA with predictions from SynRef-coupled photoelectron models in order to characterize SynRef over a range of solar activity occurring while MAVEN has been at Mars. This includes the declining phase of Solar Cycle 24, where activity declined from moderate to minimum conditions, and a number of solar flares.

SPACE STUDIES OF THE UPPER ATMOSPHERES OF THE EARTH AND PLANETS INCLUDING REFERENCE ATMOSPHERES (C)

IMPROVED DESCRIPTION OF THE IONOSPHERE THROUGH DATA ASSIMILATION (C4.1)

C4.1-0001-18 REALISTIC IONOSPHERE: A SUITE OF ASSIMILATIVE EMPIRICAL MODELS AND RESOURCES AT LGDC

Ivan Galkin, ivan_galkin@uml.edu

University of Massachusetts Lowell, Lowell, Massachusetts, United States Bodo Reinisch, bodo.reinisch@digisonde.com

University of Massachusetts Lowell, Lowell, Massachusetts, United States Dieter Bilitza, dbilitza@gmu.edu

George Mason University, Fairfax, Virginia and NASA, GSFC, Greenbelt, Maryland, United States

The Realistic Ionosphere (RI) [1] objective is to provide an accurate and prompt nowcast of the 3D global plasma density distribution in the subpeak ionosphere using high-frequency (HF) ionospheric sounding technology. It includes several remote sensing, modeling, and computer science resources. A multi-nation coordinated network of ionosondes, the Global Ionosphere Radio Observatory (GIRO) [2], provides near-real-time (nRT) low-latency measured data of the subpeak ionospheric plasma density. In addition to the conventional ionosonde data products like the ionogram-derived autoscaled records of electron density profiles and the standard URSI characteristics (foF2, hmF2, etc.) [3], GIRO acquires skymap-derived measurements of the local tilt of the ionosphere [4], and detects Traveling Ionospheric Disturbances (TIDs) using coordinated operation of its observatories [5]. A global 3D empirical nowcast of the ionospheric plasma density is then computed based on assimilative techniques of smoothly transforming the background International Reference Ionosphere (IRI) climatological model [6] into the optimal match with GIRO measurements. The resulting IRI-based Real-Time Assimilative Model (IRTAM) [7] releases nRT ionospheric weather nowcasts every 15 minutes with a 7.5 minute latency. The TID and local tilt observations are used to incorporate fine-scale description of the plasma structures in the Realistic Ionosphere, a 3D specification of the subpeak ionosphere density distribution. RayTRIX (RayTracing through Realistic Ionosphere eXplorer) uses numerical raytracing [8] to simulate the properties of HF signals propagating in the ionospheric channels specified by IRTAM with added knowledge of TID activity and local tilt of the ionosphere. The Lowell GIRO Data Center (LGDC) maintains a collection of computer software, database engines, and computer infrastructure for computations associated with RI nowcast and warning services, and open international data access for academia, students, radio enthusiasts, and space weather applications. Public service of RI is arranged via LGDC Open Data Portal at http://giro.uml.edu.

Since 1998, the International GNSS Service (IGS) Ionosphere Working Group has been continuously releasing global maps of vertical total electron content (VTEC) in rapid, final, and predicted schedules. The IGS Ionosphere Combination and Validation Center (ICVC) at University of Warmia and Mazury is responsible for an ensemble analysis of the global VTEC maps synthesized independently by several ISG Associate Analysis Centres by applying the observation uncertainty weights determined by validating the VTEC data against the original slant TEC measurements.

This work presents early results from a near-real-time ionosphere mapping system combining ionospheric data from two separate

sensor networks: IGS permanent GNSS receivers providing VTEC measurements and GIRO high-frequency ionosonde sounders providing data for 3D mapping of the bottomside ionospheric plasma density. Near-real-time mapping systems can be considered as a step towards real-time systems, at the moment an extremely important and difficult to solve problem, not only considering mapping process itself, but also data gathering from all over the world, data delivery to the computational center, quality control, validation, mapping and releasing of final product in possibly unnoticeable amount of time. The combination of IGS and GIRO real-time capabilities brings an intriguing possibility of evaluating dynamics of the topside ionosphere and plasmasphere, even though crudely, using only groundbased resources whose real-time performance can be engineered to accomplish below one minute latency of nowcast.

Comparison of the ICVC-released “weather” VTEC maps to their quiet-time “climate” counterpart is a powerful instrument in the space physicist toolbox: such deviation maps allow rapid evaluation of the anomalous near-space plasma dynamics as it responses to a wide variety of effects in the Sun-Earth system, ranging from the forces acting in the outer space to the processes on the surface and even underneath the Earth’s crust. However, development of such global reference quiet-time VTEC maps proved to be a difficult task, given the staggering complexity and dynamics of the constituent subsystems and the intersystem coupling mechanisms. Our approach to the task of building a reference for the deviation maps is to compute daily empirical 30-day running average VTEC. Such averaging is expected to smooth out effects from any ongoing events (that would otherwise distort the presentation of ionospheric/plasmaspheric climate) while still preserving the specifics of the annual cycle. The second objective of presented work is to introduce such global 30-day average empirical TEC maps into GAMBIT Explorer software used to build deviation maps for ionosonde-derived global maps of the bottomside ionospheric plasma.

C4.1-0003-18 INSTANTANEOUS MAPPING OF THE IONOSPHERIC SLAB-THICKNESS WITH IRI-PLAS MODEL

Tamara Gulyaeva, gulyaeva@izmiran.ru

Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation of the Russian Academy of Sciences (IZMIRAN), Moscow, Russia

Iwona Stanislawska, stanis@cbk.waw.pl

Space Research Centre of the Polish Academy of Sciences, Warsaw, Poland

Improvement to assimilation of ionosonde-derived F2 layer critical frequency foF2 (proportional to the peak electron density NmF2) and total electron content TEC with IRI-Plas model is described. Input of the foF2 critical frequency and hmF2 peak height is internal option of IRI, NeQuick and IRI-Plas models. Input of instant TEC alone by IRI-Plas system allows obtain the instant foF2, hmF2 and 3D electron density profile using the median slab-thicness τ -med obtained as ratio of TEC-ins to NmF2 prediction with CCIR or URSI maps. In conversion of global ionospheric maps GIM-TEC to GIM-foF2 by IRI-Plas, the residual error is determined for each cell of map processed in parallel. The residual error between the TEC-obs data and modelled TEC-mod is proposed to use for estimate of the instant τ -ins. It is found that τ -ins can differ from τ -med by ±20%. When both foF2 and TEC are assimilated by IRI-Plas, the instant τ -ins is obtained automatically equal to the ratio of TEC/NmF2 input. Evaluating τ -ins by IRI-Plas model in process of GIM-TEC assimilation improves accuracy of GIM-foF2 results and produce the instantaneous GIM-τ global maps as a new product for the science and applications.

C4.1-0004-18 ASSIMILATION OF MULTIPLE DATA TYPES TO MODEL REGIONAL IONOSPHERE DURING GEOMAGNETIC QUIET AND STORM DAYS

Chalachew Kindie Mengist, chalachewkindie@yahoo.com Chungnam National University, Daejeon, Korea

Ionosphere NmF2 provided by five ionosondes, and COSMIC; Slant Total Electron Content (STEC) from twenty-seven Global Positioning System (GPS) located over Korea and adjacent areas (200 600 N in latitude and 1100 1600 E in longitude) have been assimilated into International Reference Ionosphere (IRI) empirical model. Ionospheric Data Assimilation Four-Dimension (IDA4D) technique is used to assimilate those measurement data during geomagnetic quiet (March 15-16, 2015) and storm days (March 17-18, 2015) to investigate the performance of IDA4D model ability and ionosphere characteristics. The IDA4D run for multiple assimilation cases by using data from: (1) all GPS; (2) all GPS and five ionosondes; (3) five ionosondes; and (4) all GPS, five ionosondes, and COSMIC. GPS STEC has been assimilated during geomagnetic quiet and storm days as a benchmark. Jeju ionosonde was set aside to provide ground truth of foF2 values. The assimilated results are validated with foF2 values from ionosondes, and STEC from GPS. It was found that assimilation of all GPS STEC data improves the accuracy of IDA4D ionosphere foF2 values. The result also shows that, the average errors of foF2 after assimilation all GPS STEC and ionosonde NmF2 data were smaller than assimilation all GPS STEC data for Beijing, Kokubunji, and Wakkanai stations. Assimilation COSMIC NmF2 together with all GPS and ionosonde NmF2 data further increases the performance of IDA4D over areas not covered by GPS and ionosondes. Ionosphere foF2 from IDA4D shows that negative storm response on the recovery phase of 18 March geomagnetic storm.

Keywords: Ionosphere storm during 17-18 March 2015, Ionospheric Data Assimilation FourDimension (IDA4D), International Reference Ionosphere (IRI), Slant Total Electron Content, NmF2, foF2, negative storm response

C4.1-0005-18 TEC DATA ASSIMILATION INTO NEQUICK 2

Bruno Nava, bnava@ictp.it ICTP, Trieste, Italy

Anton Kashcheyev, anton.kascheev@gmail.com ICTP, Trieste, Italy

Katy Alazo Cuartas, katyalazo@yahoo.com ICTP, Trieste, Italy

Francisco Azpilicueta, azpi@fcaglp.unlp.edu.ar

NeQuick 2 is the ionosphere electron density model developed at the Abdus Salam International Centre for Theoretical Physics (ICTP) - Trieste, Italy in collaboration with the University of Graz, Austria. To provide 3-D specifications of the ionosphere electron density for current conditions, different ionosphere electron density retrieval techniques based on the NeQuick adaptation to Total Electron Content (TEC) data and ionosonde measured peak parameters values have been proposed. Recently, a procedure based on the Best Linear Unbiased Estimator (BLUE) has been implemented to incorporate ground and space-based GNSS-derived TEC data into NeQuick, considered as a background model. In the present paper an overview of the mentioned assimilation techniques will be given and the latest development concerning the assimilation of Radio Occultation (RO)-derived TEC data into NeQuick will be presented. As a first step, the results of a simulation experiment will be described to evaluate the relevance of the RO-derived TEC data assimilation in the topside electron density reconstruction. More specifically, it will be shown that the inclusion of RO TEC data can improve the description of the topside profile shape (scale height), but not always allows for a sufficiently accurate reconstruction of the peak density and height. Indeed, it will also be demonstrated how the background model slab thickness can play an important role in the analysis results. Subsequently, using experimental data, specific test cases will be illustrated where the BLUE algorithm is used to assimilate both ground a space-based TEC data. In particular, the effects of assimilating RO TEC data on the reconstruction of the ionospheric electron density at selected locations and epochs will be discussed and interpreted in light of the simulation outcomes. For this purpose, independent ground truth measurements like manually scaled F2 layer peak parameter values will be utilised to evaluate the performance of the proposed assimilation procedure.

C4.1-0006-18 MODELLING THE IONOSPHERE: GLOBAL AND REGIONAL HIGH-RESOLUTION VTEC REPRESENTATION BY MEANS OF B-SPLINES

The project OPTIMAP is a joint initiative of the Bundeswehr Geoinformation Centre (BGIC), the German Space Situational Awareness Centre (GSSAC), the German Geodetic Research Institute of the Technical University of Munich (DGFI-TUM) and the Institute for Astrophysics at the University of Goettingen (IAG). The main goal of the project is the development of an operational tool for ionospheric mapping and prediction. The software uses geodetic observation techniques that are sensitive to the free electrons within the Earth's ionosphere (GNSS, satellite altimetry, radio occultations, and DORIS) in order to provide representations of the Vertical Total Electron Content (VTEC) with high spatial and spectral resolution. Since the ionospheric observations from space-geodetic missions are distributed rather unevenly over the globe, an appropriate modelling approach has to be developed. Our modelling approach is based on a two-level strategy, with a global modelling part as the first and a regional modelling part as the second level. To be more specific, the global VTEC model suffers from the inhomogeneity of observations and thus contains a moderate spatial and spectral resolution while in areas with a dense measurement distribution, a regional VTEC model with higher resolution is set up. This Two-Level-Model (TLM) is based on B-spline series expansions. The unknown B-spline series coefficients and additional observation dependent unknowns such as GNSS Differential Code Biases (DCBs) are estimated from pre-defined global and regional data sets by means of parallel running Kalman Filter processes for the two levels. In this contribution, we present our two-level modelling approach and the corresponding high-resolution VTEC products with global maps with moderate resolution and regional maps with high resolution.

C4.1-0007-18 PERFORMANCE OF THE IRI AND NEQUICK MODELS ON ELECTRON CONTENT REPRESENTATION: SPACEBORNE RADIO OCCULTATION AND TOPSIDE GPS TEC MEASUREMENTS

Iurii Cherniak, tcherniak@ukr.net

University Corporation for Atmospheric Research, Boulder, Colorado, United States Irina Zakharenkova, zakharenkovai@gmail.com

University of Warmia and Mazury in Olsztyn, Poland, Olsztyn, Poland

The clarification of the ionosphere's structure and dynamics above the F layer peak is still a challenge for ionospheric model developers due to lack of topside ionosphere-plasmasphere data and measurements. Extension of current ionospheric models (first principal and climatological) to the plasmasphere together with improvement of the plasmasphere's part representation is actual now. During low solar activity and at night time the bottom side ionosphere contributes only about 20% of the ground-based total electron content (TEC), and the dominant contribution comes form the topside (>80%). So, reliable topside electron density representation is therefore of utmost importance for all ionospheric models. In this study we present new results of the concurrent analysis of the bottom and topside electron content values derived using unique 11 years database of COSMIC GPS Radio Occultation ionospheric profiles of electron density (ionPrf) product available on http://cdaac-www.cosmic.ucar.edu/, topside GPS measurements onboard the GOCE and TerraSAR-X satellites in order to estimate the electron content representation performance of the IRI, NeQuick-2 and IRI-Plas empirical models. The representative periods of low, moderate and high solar activities of the 24th solar cycle were analyzed. All three models were found to demonstrate good results for the bottom-side ionosphere's specification. The IRI and IRI-Plas models overestimate the electron content within the 250-500 km altitude interval for low solar activity and the topside total electron content (TEC) for the 500-20,000 km altitude range during daytime local time at low and moderate solar activities. The NeQuick 2 model demonstrates very similar to the IRI results for the 250-500 km region and the opposite behavior for the region above 500 km with underestimated values for all considered seasons and local time. The most important region for the model/model differences was found to be within the altitude range of 500-2000 km. The observed understatement in the NeQuick 2 topside TEC results can be related to the simplified extension of the electron density profile toward the GPS orbit altitude without adjustment of the specific plasmasphere model. However, the plasmasphere model included into the IRI-Plas leads to the noticeable overestimation of the TEC values derived from the spaceborne GPS measurements.

We can conclude that both IRI and NeQuick models have a need to be essentially improved in order to be able to specify more correctly the ionosphere-plasmasphere density above the F2 layer peak. It is strongly important because the profile-based empirical ionospheric models like IRI and NeQuick are required for the trans-ionospheric radiowaves propagation tasks, both navigation and communication.

C4.1-0008-18 BASE LEVEL TEC DERIVED FROM A GRIDDED REAL-TIME MODEL OVER THE INDIAN REGION

S.C. Chakravarty, chakravarty08@gmail.com Bangalore University, Bangalore, India Nagaraja Kamsali, kamsalinagaraj@bub.ernet.in Bangalore University, Bengaluru, India

A real-time model has been developed to provide the Total Electron Content (TEC) maps over the Indian region at 1°x 1° resolution in latitude and longitude. The input data is made available from a network of ground based dual frequency GPS (Global Positioning System) receivers deployed in India under the GAGAN (GPS Aided Geo Augmented Navigation) project. The multi-station diurnal runs of the model programme enables results of time-averaged TEC values at chosen intervals and grid sizes with graphical displays along with tabulated output. Apart from its utility for the navigation purpose, this real-time model is also well suited for off- line scientific applications to study TEC variations at high temporal and spatial resolutions. In this paper an attempt is made to generate a base-level standard of TEC variations for the low solar activity period of May 2007 to April 2008 separately for equatorial (11-18 °N)

and anomaly (19-24°N) latitude zones over India. The results are compared with the diurnal

TEC variations derived from IRI (International Reference Ionosphere) model under similar geophysical conditions. While there is a reasonably good agreement in the overall magnitudes of vertical TEC (VTEC) during different seasons, there are differences in the shape of the mean diurnal curve with IRI showing relatively smooth patterns compared to the real-time model results. Further the outcome of IRI model runs for a high solar activity year is compared with published data/results of GPS observations for similar periods from individual stations in India to check the effect of enhanced solar activity on the peak values and shapes of the diurnal pattern of TEC. The matches between IRI produced and observed VTEC for individual Indian stations for a high solar activity period of 2012 are better than those during 2007-08. Possible causes related to force functions from lower atmosphere need to be examined apart from the solar activity governed variations, particularly when the solar activity is low.

C4.1-0009-18 GLOBAL IONOSPHERIC AND PLASMASPHERIC ELECTRON CONTENT DERIVED FROM JASON-2/JASON-3 SATELLITES: COMPARISON WITH CLIMATOLOGICAL IONOSPHERIC MODELS

Irina Zakharenkova, zakharenkovai@gmail.com

University of Warmia and Mazury in Olsztyn, Poland, Olsztyn, Poland Iurii Cherniak, tcherniak@ukr.net

University Corporation for Atmospheric Research, Boulder, Colorado, United States Irk Shagimuratov, shagimuratov@mail.ru

West Department of IZMIRAN, Kaliningrad, Russia

Total Electron Content (TEC) derived from ground-based GPS/ GNSS measurements is one of the key ionospheric parameters widely used for ionosphere's research and space weather monitoring. Assimilation and adjustment of GPS/GNSS TEC to operational and assimilative ionospheric models is one of the most actual challenging task. Another important modeling effort relates to the accuracy improvement of the TEC representation by major climatological ionospheric models, like IRI and NeQuick, caused by known modeling issues for the topside ionosphere and plasmasphere.

The height of the GPS orbits is 20000 km above the Earth's surface. The ionized atmosphere surrounding the Earth at altitudes' range of about 80-100 km up to 3-5 Re represents a dispersive medium for GPS signals on their way to the ground-based GPS receivers. TEC, contributed by both the ionosphere and overlying plasmasphere along the ray GPS satellite

GPS receiver, is an integral value of electron density distribution in the ionosphere, iTEC, and the plasmasphere, pTEC. One of the limitations of the GPS TEC technique is impossibility to separate the GPS TEC value into its ionospheric and plasmaspheric parts, based on the ground-based GPS measurements only. We can gain new knowledge about plasma density distribution within the ionosphere-plasmasphere system using advantages provided by the space-borne GPS measurements. The satellite-borne up-looking GPS observations allows us to estimate directly the ionospheric/plasmaspheric TEC above the satellite altitude. We have investigated simultaneous measurements onboard the Jason-2/Jason-3 missions (altitude 1330 km): (1) the up-looking GPS measurement to derive global distribution of pTEC for altitudinal range of 1330-20000 km; (2) altimeter measurements over oceans to derive the iTEC distribution for altitudinal range of 100-1330 km. The present study is focused on a comparison of the iTEC/pTEC predictions provided by the IRI model (upper boundary limit of 2000 km) and by the models with plasmaspheric extension (assigned upper boundary to 20000 km), NeQuick-2 and IRI-Plas, with a unique data base of iTEC/pTEC as deduced from the Jason-2/Jason-3 satellites during four seasons of the years

2015-2017, moderate solar activity. We present major features of model-data discrepancies in a climatological domain for different longitudinal regions, local time and seasons.

The research is supported by the Russian Foundation for Basic Research, grant No. 16-05- 01077.

C4.1-0010-18 AN INSIGHT ON THE PERFORMANCE OF IRI MODEL IN ESTIMATING THE BOTTOM-SIDE AND TOP-SIDE ELECTRON DENSITY PROFILES DURING LOW AND HIGH SOLAR ACTIVITY CONDITIONS

Venkatesh Kavutarapu, venkatkau@gmail.com

Universidade do Vale do Paraiba, Sao Jose Dos Compos, Brazil
Paulo Roberto Fagundes, fagundes@univap.br

Universidade do Vale do Paraiba, São José Dos Campos, Brazil
Valdir Gil Pillat, valdirgp@univap.br

Universidade do Vale do Paraíba - UNIVAP, São José Dos Campos, Brazil

The equatorial and low latitude ionospheric variability is manifested by the typical electrodynamic phenomena namely, the Equatorial Ionization Anomaly (EIA). In the presence of large spatio-temporal gradients over the low latitudes, accurate estimation of ionospheric vertical electron density profiles and Total Electron Content (TEC) has gained significant importance in view of the satellite based communication and navigation applications. The present study gives a comprehensive report on the performance of IRI model in estimating different parameters in the bottom-side as well as the top-side profiles including the F-layer peak parameters and the TEC. The ground based ionosonde data and FORMOSAT-1 (formerly called ROCSAT) measured in-situ electron density in the topside ionosphere over the Brazilian equatorial and low latitude sectors during different solar activity conditions are considered for this study. The ionosonde derived bottom-side electron density profiles are used to validate the performance of three different options 'Gul-1987', 'Bil-2000' and the 'ABT-2009' in the IRI model. It is seen that the Gul-1987 method shows better predictions of the observed B0 at the equatorial and low latitudes when compared with the other options. The latest option 'ABT-2009' has shown improved predictions in the estimation of B1 compared with those from the other methods particularly during the night-time hours. A comparison on the seasonal characteristics of the day maximum values of B0 between observations and the three different options in IRI reveals that the Gul-1987 method shows better predictions of the seasonal variations in B0 while ABT-2009 method shows better predictions of seasonal variations in B1. The ground based ionosonde data in conjunction with the FORMOSAT-1 electron density are used to construct the top-side electron density profiles. A comparative study has been made on the diurnal and seasonal variations of F-layer peak parameters, top-side effective scale height (HT) and TEC between observations and IRI model simulations. It is observed that the models perform better in the prediction of NmF2 and hmF2 than in the prediction of TEC during day-time hours.

Further, it is observed that both IRI and the NeQuick2 models show considerable deviations in the estimation of the bottom

side profile parameters while more discrepancies are observed in the prediction of topside effective scale height values particularly during day-time hours.

C4.1-0011-18 PERFORMANCE OF MODEL OPTIONS OF IRI AS COMPARED WITH IONOSONDE DATA

Feza Arikan, arikan@hacettepe.edu.tr HACETTEPE UNIVERSITY, ANKARA, Turkey

Umut Sezen, u.sezen@ee.hacettepe.edu.tr HACETTEPE UNIVERSITY, Ankara, Turkey Tamara Gulyaeva, gulyaeva@izmiran.ru

Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation of the Russian Academy of Sciences (IZMIRAN), Moscow, Russia

International Reference Ionosphere (IRI) is one of the most acclaimed and widely used climatic models of ionosphere that is used to obtain various parameters of ionosphere and plasmasphere such as electron density distribution, critical layer plasma frequency, maximum ionization height and ion and electron temperatures between 60 km and 2.000 km in height. IRI uses CCIR or URSI background hourly-monthly median model coefficients in determination of F2 layer critical frequency, foF2. IRI offers different model options that incorporate the ongoing contributions of IRI task group for optimum representation of global ionosphere. In the online version of IRI-2016 available at www.irimodel.org, there are two sets of options for the F2 layer: 'Fpeak storm model' (on or off) and 'F-peak height' (BSE-1979, AMTB-2013, SHU-2015). The solar, ionospheric and geomagnetic indices that are used in the model can be listed as 12- month running mean of sunspot number (Rz12), Ionospheric Index (IG12), Daily Solar Radio Flux (F10.7D), 81-day Solar Radio Flux (F10.7 81D), 3 hourly Ap (3-h ap), daily Ap (daily ap) and 3 hourly Kp (3-h kp). In this study, foF2 and hmF2 options are compared with all available ionosonde values during the equinox months October for 2011 and March 2015, in Root Mean Square (RMS) and Normalized RMS (NRMS) sense. The ionosondes are grouped into global (all ionosondes available), midlatitude, high-latitude, equatorial, northern midlatitude, southern midlatitude, northern high-latitude and southern high-latitude regions. Daily and monthly averages of all RMS and NRMS values for foF2 and hmF2 are computed for all ionosonde stations as well as regions. It has been observed that URSI-88 and CCIR model options provide very similar differences for midlatitude and quiet days, whereas on disturbed days, CCIR model in midlatitude and URSI model in equatorial regions provide a better fit to ionosonde results for foF2. As for hmF2, AMTB-2013 height model gives a smaller RMS and NRMS value compared to SHU-2015 both in midlatitude and equatorial regions for disturbed days. This study is supported by TUBITAK 115E915.

C4.1-0012-18 PERFORMANCE OF INTERNATIONAL REFERENCE IONOSPHERE (IRI2016) AND INTERNATIONAL REFERENCE IONOSPHERE-PLASMASPHERE (IRI-PLAS) MODELS OVER LOW LATITUDE INDIAN REGION DURING 23RD TO 24TH SOLAR CYCLE

Sampad Kumar Panda, sampadpanda@kluniversity.in K L Deemed to be University, Guntur, India

Kanaka Durga Reddy Battula, rbkdurga1994@gmail.com K L Deemed to be University, Guntur, India

The present study is about ionospheric total electron content (TEC) over the low latitude Indian region from global positioning system (GPS) observables and comparative analysis with present version of International Reference Ionosphere (IRI-2016) and International Reference Ionosphere-Plasmasphere (IRI-Plas) models. With the recent revision of the solar sunspot number (SSN) time series, it insists re-examination of predictive efficiency of the above models whose underlying database have been updated with the recalibrated SSN values. Moreover, substantial improvements have been done in the 'IRI-Plas' model incorporating various solar proxy parameters (SSN1, SSN2, F10.7, Global Electron Content (GEC), TEC, IG, Mg II, Lyman-α and GEC_RZ). Hence, in the present work ionospheric TEC extracted from GPS stations at different latitudes across the Indian region covering the 23rd and 24th solar cycles are considered whose corresponding values are compared with IRI-2016 and IRI-Plas estimations with various solar proxy options. Also, the effectiveness of IRI-Plas by injecting observed TEC values into the model are analyzed taking diurnal, seasonal and solar cycle variability in to consideration. The studies report interesting interpretations, particularly in the IRIPlas model, leading towards sensible ionospheric model improvements over equatorial and low latitude region.

C4.1-0013-18 ELECTRON DENSITY MODELS OF PLASMASPHERE

Shigeto Watanabe, shw@ep.sci.hokudai.ac.jp Hokkaido University, Sapporo, Japan

Atsushi Kumamoto, kumamoto@stpp.gp.tohoku.ac.jp Tohoku University, Sendai, Japan

Electron densities at altitudes below 10,000km were estimated from the upper-hybrid resonance (UHR) emission observed by the plasma wave and sounder experiments (PWS) on Akebono satellite from February 22, 1989 to April 23, 2015. The electron densities at more than 4 million locations in the plasmasphere have been obtained for 26 years. We have constructed two kinds of electron density model of plasmasphere from the Akebono/PWS data. One is the empirical model by use of simple base functions with the parameters of longitude, latitude, local time, season and solar/magnetic activities. The other model is made with deep learning method with the same parameters to the empirical model. Both models show very good correlations with the satellite data. Both electron density models of plasmasphere were compared with International Reference Ionosphere model below 2,000 km altitudes. There are good agreements between IRI model and the plasmasphere models. However, we found some differences in the polar cap region. The electron density enhancements seen in the models and satellite data may be due to plasma heating and/or polar winds in the polar region. The models indicates that the plasmaspheric electron density contributes to TEC with a few percent.

C4.1-0014-18 COMPARING ISS FPMU TOPSIDE ELECTRON DENSITIES WITH IRI-2016 MODEL AND COSMIC RADIO OCCULTATION MEASUREMENTS

Joseph Minow, joseph.i.minow@nasa.gov

NASA Langley Research Center, Huntsville, Alabama, United States Victoria Coffey, victoria.coffey@nasa.gov

NASA Marshall Space Flight Center, Huntville, Alabama, United States Emily Willis, emily.willis@nasa.gov

NASA Marshall Space Flight Center, Huntsville, Alabama, United States

The Floating Potential Measurement Unit (FPMU) instrument suite on the International Space Station (ISS) provides redundant measurements of the electron density, electron temperature, and spacecraft potential along the ISS orbit. Deployed in August 2006, the FPMU includes a Wide Langmuir Probe, Narrow Langmuir Probe, Floating Potential Probe, and a Plasma Impedance Probe. The instruments are used for ISS engineering applications, ISS science payload support, and collaboration with the ionospheric science community. FPMU provides in-situ observations of plasma density and temperature at or above the peak plasma density in the F2-region ionosphere due to the typical 350 km to 400 km flight altitude of the ISS. This presentation will first compare the in-situ FPMU measurements of electron density and temperature with the IRI-2016 model and COSMIC radio occultation measurements of electron density. We then describe FPMU data that is now available to the space science community through NASA's Space Physics Data Facility, providing a new source of topside ionosphere plasma density and temperature values for use in working with the IRI model, other ionospheric physics models, and other satellite and ground based observations.

C4.1-0015-18 IMPROVING THE SOLAR ACTIVITY VARIATION OF THE IRI TOPSIDE ELECTRON DENSITY PROFILE

Dieter Bilitza, dbilitza@gmu.edu

George Mason University, Fairfax, Virginia and NASA, GSFC, Greenbelt, Maryland, United States

Chao Xiong, bear@gfz-potsdam.de GeoForschungsZentrum Potsdam, Potsdam, Germany

In situ measurements by the Low Earth Orbital (LEO) satellites, such as CHAMP, GRACE, and C/NOFS satellites have shown that the International Reference Ionosphere (IRI) model has shortcomings in describing the solar activity variation of the topside electron density. In particular IRI overestimates the measured densities during the very low solar activity reached during the last solar minimum (2008-2009). IRI is an empirical model and so if discrepancies are found between IRI and a reliable data set the logical next step is to use this data to improve the model. We have undertaken a study to correct the IRI topside profile not only with the CHAMP, GRACE, and Swarm in situ measurements but also with the data from the Alouette and ISIS topside sounder satellites. These data are used to introduce a solar activity term to the IRI-2016-corr option model for the topside electron density profile. We will discuss the improvement achieved by using theses satellites observations within the new IRI model.

C4.1-0016-18 ASPECT OF TOPSIDE ELECTRON DENSITY MEASURED BY RADIO OCCULTATION OF FORMOSAT-3/COSMIC SATELLITES AND DIGISONDES ON A GLOBAL SCALE WITH IRI

Tanmay Das, stanmaydas@gmail.com University of Calcutta, Kolkata, India

This study represents a comparison of the topside electron density of the F2-layer measured by FORMOSAT-3/COSMIC satellites in terms of GPS radio occultation technique and digisondes as manually scaled ionograms being provided by DIDBase (Digital Ionogram Database) with IRI. This study encompasses data from more than 40 locations for an extended period from January 2007 to December 2015. It utilises a subset of around 1000 very well matched (in terms of bottomside) FORMOSAT-3/COSMIC (Digisonde electron density profile pairs to compare the corresponding topside electron density profiles with IRI. The selection criteria for the electron density profile pairs, apart from coincidence of COSMIC and Digisonde electron density in the bottomside, is a collocation distance of less than 2.5o in terms of latitude and longtitude and 15 min maximum time difference in measuring NmF2 with the two techniques.

C4.1-0017-18 IMPROVING THE ELECTRON AND ION TEMPERATURE MODELS IN IRI

Institute of Ionosphere, Kharkiv, Ukraine

The International Reference ionosphere (IRI) model includes models of the electron and ion temperatures. For the electron temperature two options (TBT-2012 and Bil-1985) are available based on spherical harmonics expansion up to 8th order. The ion temperature in IRI is derived from the energy balance equation among ions, electrons and neutrals. In this study we will discuss recently available data sets (Swarm LP, ISS-FPMU, and Champ LP) to assess their potential for improvement of the electron temperature model especially its spatial resolution. We will present the global distributions of the electron temperature modeled using higher order of spherical harmonics and we will discuss their inclusion in the TBT-2012 option. We have re-examined ion temperature data from older satellites and combined them with newly available data from DMSP, C/NOFS, and others (primarily from SPDF: https://spdf.gsfc.nasa.gov/pub/data/) into a unified data-base. This data-base has been used to establish global patterns of the ion temperature and to determine Ti variation with solar activity. To better understand the solar activity variations of the ion temperature at different latitudes and local times we have used simulations with the Field Line Interhemispheric Plasma flow (FLIP) model. We will also present ratio of the electron and ion temperatures dependence on geophysical parameters and a comparison with recent measurements from another sources (e.g. Kharkiv Incoherent Scatter Radar). Finally, we will discuss future improvements of the plasma temperature models through data assimilation.

C4.1-0018-18 A COMPLETED 3D IONOSPHERIC ELECTRON DENSITY MODEL FOR USE AT HIGH LATITUDES: E-CHAIM

David Themens, david.themens@unb.ca

University of New Brunswick, Fredericton, Canada Thayyil Jayachandran, jaya@unb.ca

University of New Brunswick, Fredericton, Canada

Following the development of the Empirical Canadian High Arctic Ionospheric Model (ECHAIM)'s F2-peak and topside components, we have now undertaken the challenge of creating a matching bottomside for E-CHAIM. For this bottomside, we have developed a variable semiEpstein layer parameterization, where the scale thicknesses of this layer are represented by a sum of layer functions associated with the E-region, F1-layer, and F2-layer. The coefficients of each of these layers are independently modeled using a spherical cap harmonic expansion in magnetic latitude and magnetic local time to represent horizontal and diurnal variability. A Fourier expansion in day of year is used to represent seasonal variations. By modeling our bottomside in the scale thickness domain of a single layer, we avoid the need for an F1-layer occurrence trigger, such as that used by the International Reference Ionosphere (IRI). This study details the E-CHAIM bottomside profiler, whose development was informed by challenges that have been reported in the use of the IRI and NeQuick at high latitudes.

With the bottomside online, the E-CHAIM set of models is now a complete 3D electron density representation for the high latitude ionosphere. In this talk we will further demonstrate some of the capacities of the model and discuss the next step in model development, namely the incorporation a data assimilation framework.

C4.1-0019-18 AN EMPIRICAL MODEL OF GLOBAL DAND E-REGION ELECTRON DENSITY FROM GPS-RO OBSERVATIONS

Dong Wu, dong.l.wu@nasa.gov

Goddard Space Flight Center, Greenbelt, Maryland, United States

A background electron density (Ne) model is developed from the Dand E-region (80-120 km) ionosphere using GPS radio occultation (GPS-RO) observations in 2006-2017. While the background Ne morphology (monthly maps, zonal means and diurnal variations) retrieved from GPS-RO is in overall agreement with the IRI (International Reference Ionosphere) model, differences remain and can be readily seen in the seasonal transition and in the D-region ionosphere. The daytime GPS-RO Ne profiles can be well characterized by the Chapman function of three parameters (NmE, hmE and H), showing that the bottom of E-region is deepening and sharpening towards the summer pole. The empirical model of the background E-region Ne developed here is based on the Chapman function (Chapman, 1931a,b) but generalized for the nighttime Ne. Chapman (1931b) extended the near-nadir formula (Chapman, 1931a) with the intent to better describe twilight Ne profiles. The generalized function (Chapman, 1931b) is used to fit the GPS-RO observations, and the fitted coefficients are functions of solar zenith angle and the Lyman-α index. The empirical Ne model is able to capture most of daytime and twilight Ne variabilities in the Dand E-region ionosphere at scales from diurnal to solar 11-year cycles.

C4.1-0020-18 NUMERICAL MODELING OF SEASONAL AND DIURNAL VARIATIONS OF LOWER IONOSPHERIC REFLECTION PARAMETERS BASED ON IRI MODEL

S.N. Bose National Centre for Basic Sciences, Kolkata, India

Very Low Frequency (VLF) radio wave travels through the earth ionosphere waveguide and modulates according to the electron/ion density profile of the ionosphere. The Wait's two component model deals with ionospheric reflection parameters known as effective reflection height

(h1) and steepness parameter (β). Theoretically, β is the positive slope electron density profile curve as a function of height. We try to compute a range of values from the electron density profile of ionosphere. International Reference Ionospheric (IRI) model 2012 is an empirical standard model of the ionosphere, based on all available data sources. We compute the ionospheric reflection parameters (β and h1) from the true electron density profile as taken from

IRI model for the year 2016 from altitude range 65 km - 85 Km at IERCOO/ICSP, Sitapur (22.5°N, 87.48°E). We try to compute all sets of possible β and h1 for NWC-IERCOO path for different time of the day and for the entire 2016. By using β and h1 and LWPC code, a diurnal and seasonal trend of VLF signal amplitude profile is computed.

C4.1-0021-18 THE USE OF EFFECTIVE IONOSPHERIC AND SOLAR INDICES TO UPDATE THE IRI MODEL

Michael Pezzopane, michael.pezzopane@ingv.it

Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy Alessio Pignlaberi, alessio.pignalberi2@unibo.it

University of Bologna and INFN, Bologna, Italy Rolando Rizzi, rolando.rizzi@unibo.it

University of Bologna, Bologna, Italy Ivan Galkin, ivan_galkin@uml.edu

University of Massachusetts Lowell, Lowell, Massachusetts, United States

A method to real-time update the IRI model through data assimilated by a European ionosonde network is proposed, described and statistically evaluated under disturbed geomagnetic conditions. This method, called IRI UP (International Reference Ionosphere UPdate), relies on foF2 and M(3000)F2 ionospheric characteristics routinely recorded by a network of 12 European ionosonde stations. Assimilated data are used to calculate updated values of IRI indices IG12 and R12 (identified as IG12eff and R12eff) for every station's point; then, starting from this discrete dataset of values, two-dimensional maps of IG12eff and R12eff are generated through the universal Kriging. Five variogram models are used and statistically tested to verify which of these perform better for each effective index. Maps of IG12eff and R12eff are then used as input for the IRI model, which consequently gives as output updated values of foF2 and hmF2. In order to evaluate the ability of the proposed method to catch fast-time and smallscale changes that are usual under disturbed conditions, statistical quantities are calculated for two test stations (not considered in the assimilation process), Fairford (51.7 N, 1.5 W) and San Vito (40.6 N, 17.8 E), for the IRI model with the STORM option set to on, and for IRI UP and for IRTAM methods. The method here proposed turns out to be very effective, with significant improvements regarding foF2 and slight improvements for hmF2.

C4.1-0022-18 UNPHYSICAL BEHAVIOR IN IRI-2016 AND SUITABILITY FOR APPLICATIONS

David Rainwater, rain@arlut.utexas.edu

University of Texas at Austin, Austin, Texas, United States

We describe a number of unphysical features, such as discontinuities, observed in the International Reference Ionosphere 2016 model, when fed with real solar data input parameters observed in 2016 and 2017. We also describe how these unphysical artifacts impact various applications of researchers and space weather users.

C4.1-0023-18 CORRELATION OF IRTAM AND FPMU DATA CONFIRMING THE APPLICATION OF IRTAM TO SUPPORT ISS PROGRAM SAFETY

William Hartman, william.a.hartman2@boeing.com

Boeing Space Environments, Houston, Texas, United States William Schmidl, dschmidl@gmail.com

Boeing Space Environments, Houston, Texas, United States Ivan Galkin, ivan_galkin@uml.edu

University of Massachusetts Lowell, Lowell, Massachusetts, United States

A "Real-Time" plasma hazard assessment process was developed to support International Space Station (ISS) Program real-time decision-making providing solar array constraint relief information for Extravehicular Activities (EVAs) planning and operations. This process incorporates real-time ionospheric conditions, ISS solar arrays' orientation, ISS flight attitude, and where the EVA will be performed on the ISS. This assessment requires real-time data that is presently provided by the Floating Potential Measurement Unit (FPMU) which measures the ISS floating potential (FP), along with ionospheric electron number density (Ne) and electron temperature (Te), in order to determine the present ISS environment. Once the present environment conditions are correlated with International Reference Ionosphere (IRI) values, IRI is used to forecast what the environment could become in the event of a severe geomagnetic storm. If the FPMU should fail, the Space Environments team needs another source of data which is utilized to support a short-term forecast for EVAs. The IRI Real-Time Assimilative Mapping (IRTAM) model is an ionospheric model that uses real-time measurements from a large network of digisondes to produce foF2 and hmF2 global maps in 15-minute cadence. The Boeing Space Environments team has used the IRI coefficients produced in IRTAM to calculate the Ne along the ISS orbital track. The results of the IRTAM model have been compared to FPMU measurements and show excellent agreement. IRTAM has been identified as the FPMU back-up system that will be used to support the ISS Program if the FPMU should fail.

C4.1-0024-18 VALIDATION OF THE IRI-2016 MODEL WITH GPS-BASED GROUND OBSERVATION OVER A LOW LATITUDE INDIAN REGION FOR THE YEARS (2009-2014)

Kamlesh Pathak, drkamleshpathak@gmail.com

S V National Institute of Technology, Surat, India

The present study reports the analysis of GPS derived TEC from three different stations in the low latitude Indian region. The data are obtained in RINEX format from IGS stations IISC (geographic latitude 13.02°N, geographic longitude 77.57°E; geomagnetic latitude 4.58°N), HYDE (geographic latitude 17.25°N, geographic longitude 78.30°E; geomagnetic latitude 8.65°N) and a standalone GISTM receiver in operation at SURAT (geographic latitude 21.16°N, geographic longitude 72.78°E; geomagnetic latitude 12.90°N), for six years (2009-2014) in a period of low to high solar activity. The seasonal variations of the obtained GPS-TEC are plotted for all the stations (situated at latitude interval of 4 degrees) and compared with those obtained by latest IRI2016 model https://omniweb.gsfc.nasa.gov/vitmo/iri2016vitmo.html). The analysis is done to check the IRIp Quick and IRI01–corr for the year 2010.However, there are deviation in 2011–2014. Overall as we go towards the higher latitude (i.e., Anomaly crest), with an increase in solar activity the deviation increases from overestimation and underestimation of the TEC for anomaly crest station Surat.

C4.1-0025-18 COMPARISON OF GLOBAL IONOSPHERE MAPS USING DIFFERENT BASIS FUNCTIONS

Andreas Goss, andreas.goss@tum.de

Deutsches Geodätisches Forschungsinstitut, Technische Universität München (DGFI-TUM), München, Germany

Michael Schmidt, mg.schmidt@tum.de

Deutsches Geodätisches Forschungsinstitut, Technische Universität München (DGFI-TUM), Munich, Germany

Eren Erdogan, eren.erdogan@tum.de

Deutsches Geodätisches Forschungsinstitut, Technischen Universität München (DGFI-TUM), München, Germany

Several IGS (International GNSS Service) associated analysis centers (AC) provide ionosphere information in terms of global ionosphere maps (GIM). In general, GIMs represent the vertical total electron content (VTEC) as a 3-D function depending on latitude, longitude and time. Usually function representations on sphere-like surfaces are based on appropriately defined basis functions, such as spherical harmonics (SH), voxels or B-splines. The choice for appropriate basis functions for ionosphere modelling is a trade-off between the distribution of available data and their possibility to represent high-frequency ionosphere signals. However, the IGS associated ACs generate GIMs by the usage of different basis functions and represent the VTEC with different spectral and spatial resolutions. Hence, a comparison of their products in terms of VTEC maps seems not to be advisable. Within this contribution we define a procedure to compare VTEC models on the basis of their spectral and spatial resolutions. We use this procedure to compare SH models with B-splines representations and derive relations in terms of given resolution levels.

C4.1-0026-18 SIMILARITIES AND DIFFERENCES OF IONOSPHERIC PLASMA GRADIENTS DERIVED FROM GROUND-BASED REGIONAL TEC MAPS AND IRI MODEL

The ionosphere is a very important research area from the radio science and radio telecommunication based applications point of view, as it is a highly dispersive and refractive medium for radio waves. Moreover it is very unstable and multiple factors dependent. For decades the ionosphere has been widely monitored using various spaceand ground-based facilities and techniques. As result many empirical ionospheric models - such as International Reference Ionosphere (IRI) - were developed. The models quite well illustrate the general structure and variability of the ionosphere, but many impossible or difficult to predict fluctuations may interfere with the radio signal on the level that would seriously affect satellite or radio astronomical systems performance. The irregularities also have been extensively studied by different techniques, including ground-based GPS/GNSS observations. Ionospheric irregularities can be monitored with the maps, by studying horizontal gradients of the plasma density (total electron content, TEC) in time. We developed the TEC gradient maps based on the global UQRG product and high-resolution (0.5 degree in latitude and longitude) regional TEC maps covering Europe. GNSS-based ionospheric monitoring provides also instruments dedicated to plasma fluctuations detection. One of such well-know and widely used tools is the rate of TEC index (ROTI), which is currently available for whole community as an International GNNS Service (IGS) product (for the Northern hemisphere). Presented climatological characteristics of the spatial TEC gradients are superimposed and analyzed with the global and regional ROTI product and IRI in order to reveal development of highly intense plasma irregularities occurred at high and middle latitudes. During geomagnetic storm the complex of physical processes at auroal zone leads to development of intense ionospheric irregularities and traveling ionospheric disturbances (TIDs). We present results compared for the quiet time periods and geomagnetic storm events.

C4.1-0027-18 MORPHOLOGICAL STUDY ON THE SEASONAL VARIATIONS OF EQUATORIAL IONIZATION ANOMALY (EIA) OVER THE BRAZILIAN SECTOR USING GPS-TEC NETWORK AND IRI MODEL DATA DURING LOW SOLAR ACTIVITY

Maukers Alem Lima Dias, maukersdias@ifto.edu.br Univap, São José Dos Campos, Brazil

Paulo Roberto Fagundes, fagundes@univap.br

Universidade do Vale do Paraíba - UNIVAP, SÃO JOSÉ DOS CAMPOS, Brazil Valdir Gil Pillat, valdirgp@univap.br

Universidade do Vale do Paraíba - UNIVAP, São José Dos Campos, Brazil

The equatorial and Low-latitude ionospheric regions show solar cycle, seasonal and day-today space-time variations, due to strong electrodynamics and thermosphere-ionosphere coupling. Consequently, the Equatorial Ionospheric Anomaly (EIA) morphology and space-time evolution show a strong variability. In this study the EIA seasonal morphology and space-time variations are investigated using the observations from a network of 35 GPS-TEC receivers over the Brazilian sector during the low solar activity period from January 2016 to December 2016 (mean F10.7=89 10 -22 W/m2 Hz). Since the distances between the geographic and magnetic equators vary from 3 o to 10 o (350 to 1200 km) in the Brazilian sector, the EIA characteristics are investigated in 3 different longitudinal sectors. These longitudinal sectors are separated from each other by about 6 o longitude (700 km). It is noticed that the EIA is formed during daytime from 11:00 to 24:00 UT for the whole year. However, the EIA is much more intense from January to April and less intense from May to August. In addition, the pre-reversal electric field follows the similar behavior. In general the EIA in all 3 chosen sectors are quite similar. However, some differences are noted during the months of September and October. Also, a comparison between the GPS-TEC data and IRI model output is made and the results are discussed.

C4.1-0028-18 STATISTICAL PROPERTIES OF IONOSPHERIC EAND F1-LAYER MEASURED WITH THE CYPRUS DIGISONDE AND COMPARISONS WITH IRI PREDICTIONS

Haris Haralambous, eng.hh@fit.ac.cy Frederick Research Center, Nicosia, Cyprus Md Golam Mostafa, st009238@stud.fit.ac.cy Frederick University, Cyprus, Nicosia, Cyprus

Characteristics of ionospheric Eand F1-layer (critical frequency, peak height, and occurrence probability) derived from Digisonde measurements from 2009 to 2016 at the low-middle latitude European station of Nicosia, Cyprus (geographical coordinates: 35°N, 33°E, geomagnetic lat. 29.38°N, I = 51.7°) have been investigated. Manually scaled monthly median values of foE, hmE, foF1, and hmF1 are compared with IRI-2012 predictions with a view to assess the predictability of IRI.

SPACE STUDIES OF THE UPPER ATMOSPHERES OF THE EARTH AND PLANETS INCLUDING REFERENCE ATMOSPHERES (C)

DEVELOPMENT OF MODELS RELATED TO THE COSPAR INTERNATIONAL REFERENCE ATMOSPHERE (CIRA) AND TO ISO STANDARDS FOR THE ATMOSPHERE (C4.2)

C4.2-0001-18 THE ONGOING DEVELOPMENT OF THE COSPAR INTERNATIONAL REFERENCE ATMOSPHERE (CIRA) AND RELATED ISO STANDARDS FOR THE EARTH'S ATMOSPHERE.

David Rees, walnut1@easynet.co.uk

The Paradigm Factor, Robertsbridge, United Kingdom

This presentation will review the significant upgrades of global models that have provided the basic structure of CIRA. In addition, the formal extension of CIRA downward from 100 km to ground level is proposed. This extension is provided by the GRAM and MSIS-E-00 models which are currently adopted formally above 100 km) only and by reference to the assimilative model provided by ECMWF. The later model provides corrected high-resolution data on the atmosphere on a day-by-day basis.

C4.2-0002-18 EARTH GLOBAL REFERENCE ATMOSPHERIC MODEL (GRAM) OVERVIEW AND FUTURE IMPROVEMENTS

Patrick White, patrick.w.white@nasa.gov NASA/MSFC, Huntsville, Alabama, United States

NASA Marshall Space Flight Center's (MSFC) Earth Global Reference Atmospheric Model (GRAM) is a reference or standard atmosphere used for design and mission planning of various aerospace systems. Earth-GRAM was developed in response to the need for a design reference atmosphere that provides complete global geographical variability, complete altitude coverage (surface to orbital altitudes), and complete seasonal and monthly variability of thermodynamic variables and wind components. A unique feature of GRAM is that, in addition to providing the geographical, height, and monthly variation of the mean atmospheric state, it includes the ability to simulate spatial and temporal perturbations in these atmospheric parameters. The NASA/MSFC Natural Environments Branch recently released Earth-GRAM 2016 to the user community. A main feature in Earth-GRAM 2016 was converting the code from Fortran90 to C++. The Natural Environments Branch intends to make future improvements to EarthGRAM as well as investigate the availability and improvements of model reanalysis for data input. The paper will describe an overview of Earth-GRAM, examine future updates, and identify areas of needed improvement.

C4.2-0003-18 NRLMSIS 2.0: NEW FORMULATION, NEW DATA

Douglas Drob, douglas.drob@nrl.navy.mil

Naval Research Laboratory, Washington, District of Columbia, United States John Emmert, john.emmert@nrl.navy.mil

Naval Research Laboratory, Washington, District of Columbia, United States David Siskind, david.siskind@nrl.navy.mil

Naval Research Laboratory, Washington, District of Columbia, United States

J. Michael Picone, j.picone.ctr@nrl.navy.mil

Naval Research Laboratory, Washington, District of Columbia, United States

A major upgrade to the NRLMSISE-00 (Naval Research Lab Mass Spectrometer and Incoherent Scatter Radar Extended) empirical atmosphere model is presented. This model describes the temperature and eight atmospheric species as a function of position, time, solar activity, and geomagnetic activity. The new MSIS2.0 formulation includes 1) an effective hydrostatic species mass parameterization to represent the transition from a fully mixed atmosphere to diffusive separation; 2) an atomic oxygen (O) profile extending down to 50 km altitude, with a robust representation of peak O density and a chemistry-dominated region decoupled from temperature below 85 km; and 3) a temperature profile with C2 continuity throughout the atmosphere. Major new assimilated data sets include 1) lower atmospheric meteorological reanalyses; 2) space-based and ground-based measurements of temperature in the mesosphere and lower thermosphere (MLT); 3) space-based measurements of O and H densities in the MLT; and 4) upper thermospheric mass density derived from satellite orbit data (covering 47 years) and from accelerometers. The presentation will show new model output against the assimilated data, and highlight important differences between the outputs of MSIS2.0 and NRLMSISE-00. Work sponsored by NASA and the Chief of Naval Research Naval Research Laboratory Base Program.

C4.2-0004-18 THE UPDATED JB2008 SOLAR INDICES AND WHAT THEY INFER ABOUT THE CHANGING THERMOSPHERE

W Kent Tobiska, ktobiska@spacenvironment.net

Space Environment Technologies, Pacific Palisades, California, United States Bruce Bowman, brbstellar888@msn.com

Space Environment Technologies, Colorado Springs, Colorado, United States Dave Bouwer, dbouwer@spacenvironment.net

Space Environment Technologies, Thornton, Colorado, United States

The JB2008 thermospheric density model uses solar and geomagnetic indices to calculate the temperatures and densities of the upper atmosphere. On a periodic basis we review the indices and update them by comparing the derived densities in JB2008 with densities required to produce well-known calibration satellite drag phenomena. We describe the most recent update to the JB2008 solar activity indices using this methodology. One interesting feature is during the solar minimum timeframes of every solar cycle, including solar cycle 24 whose minimum we are now entering. The reduction in thermospheric densities in JB2008 required to match the collapsed density of the thermosphere as seen by the satellites is significant. This has historically been referred to as thermospheric cooling due to excess carbon dioxide cooling in the lower thermosphere. Because JB2008 does not account for this secular density reduction, we empirically use the strongest solar index, S10, as the input we can most effectively change to affect thermospheric densities. While the Sun irradiances in the 28.4 and 30.4 nm bands, as represented by S10, do not change to the extent we require, as measured by the SDO EVE satellite, we report on changes we make to S10 on the order of -30% during solar cycle 24 minimum to achieve the same densities above 200 km in JB2008 as seen by LEO satellites. We discuss implications for improvements to future measurements and model requirements.

C4.2-0005-18 THE H2020 PROJECT SWAMI (SPACE WEATHER ATMOSPHERE MODEL AND INDICES)

Sean Bruinsma, sean.bruinsma@cnes.fr

Centre National d'Etudes Spatiales, Toulouse, France David Jackson, david.jackson@metoffice.gov.uk

UK Met Office, Exeter, United Kingdom Claudia Stolle, cstolle@gfz-potsdam.de

GFZ German Research Centre for Geosciences, Potsdam, Germany Negrin Sandra, sandra.negrin@deimos-space.com

Deimos Space, Tres Cantos, Madrid, Spain

In the framework of the H2020 project SWAMI funded by the European Commission (EC), which started in January 2018, a new whole atmosphere model (0-1500 km) will be developed that can be used for: • launch operations, • re-entry computations, • orbit determination and prediction, • aeronomy and space weather studies. Such a model is currently not available in Europe, whereas models in the US and Japan have certain sometimes critical limitations and cannot be used in (operational) orbit computation.

The model will be constructed by blending two existing models, the Drag Temperature Model (DTM) and the Unified Model (UM). The CNES thermosphere specification model DTM2013, which was developed in a previous EC project (ATMOP), will first be improved by assimilating more density data to drive down remaining biases as a function of solar activity and seasons mainly. Secondly, a new high cadence Kp geomagnetic index, which will be developed as part of the project, will be used in order to improve storm-time performance. The whole atmosphere model will be made available in a user-friendly package in 2020.

In this presentation, the established benchmark (DTM2013-to-data comparisons and the adopted model performance metric) for the new thermosphere model as well as preliminary model results will be shown.

C4.2-0006-18 AN OPEN DISCUSSION OF CURRENT AND FUTURE DEVELOPMENT OF THE COSPAR INTERNATIONAL REFERENCE ATMOSPHERE AND RELATED ISO STANDARDS FOR THE EARTH'S ATMOSPHERE.

David Rees, walnut1@easynet.co.uk

The Paradigm Factor, Robertsbridge, United Kingdom

This is intended to provide an opportunity for open discussion of the current and future development of the COSPAR International Reference Atmosphere (CIRA) and related ISO Standards for the Earth's Atmosphere. The discussion is intended to include the ongoing work of SC-6, which it is hoped can be presented and discussed during the C4.2 / C0.1 Meetings held during the COSPAR-2018 Assembly.

C4.3-0001-18 UPDATING THE VENUS ATMOSPHERIC STRUCTURE FOR VIRA

Sanjay Limaye, sanjayl@ssec.wisc.edu

University of Wisconsin - Madison, Madison, Wisconsin, United States Tatiana Bocanegra Bahamon, bocanegra(at)jive.nl

JIVE and TU Delft, Netherlands Ludmila Zasova, zasova@iki.rssi.ru

Space Research Institute (IKI), Russian Academy of Sciences, Moscow, Russia

Many atmospheric profiles of the temperature structure have been obtained since the adoption of the Venus International Reference Atmosphere (VIRA) model in 1985 (Seiff et al., 1985) from occultations (Venus Express, Magellan and Akatsuki orbiters), passive remote sensing (VIRTIS on Venus Express) as well as balloons (VeGa 1 and VeGa 2) and descending probes through the atmosphere (VeGa 1 and VeGa 2 landers). Interim updates to the VIRA model were proposed by Moroz and Zasova (1997) and Zasova et al. (1996). Limaye et al. (2017) presented a comparison of post VIRA results on the atmospheric structure which included results from different Venus Express investigations as well as those from ground based observations. Akatsuki orbiter is currently obtaining radio occultation profiles of temperature (Imamura et al., 2017). These post VIRA data have expanded the coverage in latitude, longitude and local time and altitude, and thus updates to the temperature structure on Venus with altitude (pressure) and latitude and local time are possible and needed.

It is worth re-visiting the thermal structure data in light of the apparent confirmation of a gradient in the nitrogen mixing ratio (Peplowski Lawrence, 2016) as high as 64 km altitude from MESSENGER neutron spectrometer observations and was previously detected by (Oyama et al., 1980) but not explained. It is possible that this gradient exists because both the major constituents (carbon dioxide and nitrogen) of the Venus atmosphere should exist near the surface under supercritical conditions and the supercritical nature was not considered in any of the profiles. This density gradient can affect all calculations of altitude that involve the hydrostatic balance assumption and affect the adiabatic lapse rate (Lebonnois Schubert, 2017).

With the end of Venus Express in 2014, the focus of the scientific community has gradually moved from the study of Venus Express mono-instrumental data sets to cross-instrumental studies involving pure modeling as well. This is especially true for the clouds and hazes that surround most of the planet between 48 and 70 km. They play a major role at the crossroads of various atmospheric processes among which the radiative budget as well as the dynamical and chemical coupling between the lower and upper atmosphere. In order to support such efforts, ISSI has supported from 2013 to 2015 a "Clouds Hazes of Venus" scientific team involving Venus Express and ground-based observers as well as microphysical modelers. Together, they compared their results in order to achieve a more unified and consistent view of Venus' clouds and hazes, taking into account its spatial and temporal variability more in detail than previously available VIRA-1 and 2 cloud models. We will review the individual data sets and models that have been used, and then present our strategy towards a unified cloud model. We will first make available some observable parameters to the wider community through a web-based repository. Future steps may involve more advanced techniques (e.g. data assimilation) in order to achieve our objective of a unified Venus clouds haze model that encompasses its various variabilities as well as possible.

C4.3-0003-18 MODELING OF HIGH-PRESSURE MULTI-SPECIES TURBULENT MIXING APPLICABLE TO THE VENUS LOWER ATMOSPHERE

Josette Bellan, josette.bellan@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

The thermodynamic conditions in the Venus atmosphere, nominally at a pressure of 92 atm, a temperature of 750 K and having a global nominal composition of 96.5% CO2 and 3.5% N2 imply that heat and mass exchange processes in the atmosphere occur under supercritical conditions. In contrast to well-known heat and mass exchange processes at 1 bar, 298 K and Earth atmosphere composition, those on Venus must be described using real-gas thermodynamics, generalized species-mass and heat fluxes based on the formulation of dissipation-fluctuation theory and consistent high-pressure transport properties utilizing high-pressure valid mixing rules. The presence of minor (i.e. tracer) species in the Venus atmosphere - 150 ppm SO2, 70 ppm Ar, 20 ppm H2O and 17 ppm CO — may introduce some aspects, such as metastable states, that have not been considered so far. A comprehensive theory of high-pressure multispecies mixing is presented and salient results pertinent to the Venus atmosphere are discussed. Further, using this theory, simulations of CO2 and N2 mixing at high pressure and temperature are discussed and analyzed. To evaluate the model, spatial, rather than temporal simulations were performed of a N2 jet at 750 K injected into a chamber pressurized to 60 atm and containing CO2 at 450 K. The Direct Numerical Simulation computations reveal that the high density gradients observed in the five-species mixing are also present for CO2/N2 mixing and are of order 104 kg/m4. Time-averaged results exhibit a potential core near the inlet, downstream of which the density increases due to the mixing of N2 with the heavier CO2. The studies described above show the intricacies of multi-species turbulent mixing under Venus-like loweratmosphere pressure and temperature conditions. The model can be used to study the time evolution of a three-dimensional vertical slice of the Venus Planetary Boundary Layer with a domain having non-reflecting boundary conditions (i.e. domain size influence minimized). Since the near-ground Venus atmosphere composition is not known with certainty, additional to CO2/N2, other compositions, i.e. including minor species, can be simulated to determine whether the Venus atmosphere could be in a metastable state in which micro-drops are suspended into a fluid; then the interpretation of signals from probes moving vertically through the Venus atmosphere would require special interpretation, i.e. accounting from scattering from the micro-drops. The near-ground unstable temperature gradient may also be explained by such findings.

C4.3-0004-18 SOIR INFRARED SPECTRAL ATLASES OF THE VENUS' ATMOSPHERE

Belgian Institute for Space Aeronomy, Brussels, Belgium

Based on the entire set of SOIR spectra measured during the Venus Express mission (2006- 2014), spectral atlases have been produced. During its lifetime, SOIR measured 779 solar occultations, spanning the Venusian atmosphere with tangent heights from 65 to 180 km. The instrument combined an echelle spectrometer and an Acousto-Optical Tunable Filter (AOTF) for order selection. It measured spectra in the IR region (2.2 - 4.4 µm) at a resolution of 0.10 0.24 cm−1 [?]. This spectral range allows a detailed chemical inventory of the Venus atmosphere above the cloud layer with emphasis on the vertical distribution of gases (CO2, CO, H2O, HCl, HF.). Both the spectra and the derived profiles are accessible online through the ESA PSA archive1 and the VESPA interface2 [?], respectively.

To produce spectral atlases, the transmittances obtained in [?] have been averaged over latitudinal bins in different altitude ranges, for the morning and evening terminator respectively. A statistical analysis of the dataset has been performed leading to the creation of one atlas per bin of latitude/altitude/terminator. These atlases will be compared from different viewpoints in order to highlight molecular species variability.

In addition, the sensitivity of the SOIR instrument, coupled with the long absorption paths sounded during solar occultations, enable us to assign the ro-vibrational lines measured in the spectra. The assignment of the lines has been done using HITRAN2016 [?]. A tool of automatic 1https://archives.esac.esa.int/psa/ 2http://vespa.obspm.fr/planetary/data/epn/query/all/ assignment was developed and applied to each atlas leading to the creation of the wavenumber list of each absorption line.

The Global Reference Atmospheric Models (GRAMs) are engineering-level atmospheric models applicable for engineering design analyses, mission planning, and operational decision making. GRAMs are currently available for Earth, Mars, Venus, Neptune, and Titan. Over the past decade GRAM upgrades and maintenance have depended on inconsistent and waning projectspecific support. The first GRAM Virtual Workshop was held on September 21, 2017 and was attended by GRAM developers, GRAM users, planetary atmospheric modelers, and other interested parties. This workshop served to identify and prioritize user needs along with facilitating communication between modelers and developers. Based on the current status of the GRAMs as well as the workshop findings, the NASA Science Mission Directorate (SMD) has agreed to provide funding support in Fiscal Year 18 and 19 to upgrade the GRAMs. This presentation will provide an overview of the current status of Mars and Venus-GRAM, the findings from the GRAM Virtual Workshop, as well as the objectives, tasks, and milestones related to the Mars and Venus-GRAM upgrades funded by NASA SMD.

The latest Mars Climate Database (version 5.3) includes synthetic scenarios (namely the “clim” climatology scenario, representative of a standard Mars year without any global dust storm) as well as specific scenarios corresponding to eight actual Mars years, from Mars Year 24 to Mars Year 32.

At the COSPAR 2018 scientific assembly, we will address the validation of MCDv5.3 scenarios with available observations from spacecrafts and landers, and discuss more specifically of the obtained multi-annual climatologies and how these deviate over the years.

C4.3-0007-18 REFERENCE DATASETS FOR THE MARTIAN ATMOSPHERE USING SATELLITE DATA GRIDDING, KRIGING, AND ASSIMILATION

We provide a multiannual climatology of airborne dust from Martian year 24 to 33 using atmospheric observations from April 1999 to May 2017 made by the Thermal Emission Spectrometer (TES) aboard Mars Global Surveyor, the Thermal Emission Imaging System aboard Mars Odyssey, and the Mars Climate Sounder (MCS) aboard Mars Reconnaissance Orbiter.

Our methodology works by gridding the available retrievals of column dust optical depth (CDOD) from TES and THEMIS nadir observations, as well as the estimates of this quantity from MCS limb observations. The resulting (irregularly) gridded maps were validated with independent observations of CDOD by PanCam cameras and Mini-TES spectrometers aboard the Mars Exploration Rovers “Spirit” and “Opportunity”, by the Surface Stereo Imager aboard the Phoenix lander, and by the Compact Reconnaissance Imaging Spectrometer for Mars aboard MRO. Regular maps of CDOD are produced by spatially interpolating the irregularly gridded maps using a kriging method. These latter maps are used as dust scenarios in the Mars Climate Database (MCD) version 5, and are useful in many modelling applications. The two data sets (irregularly gridded maps and regularly kriged maps) for the ten available Martian years are publicly available and can be downloaded from the MCD website at http://www-mars.lmd.jussieu.fr/mars/dust_climatology/index.html .

We also use a much more sophisticated methodology to produce a reanalysis of fundamental atmospheric and surface variables for Mars, using data assimilation of TES retrievals of temperature profiles and CDODs, as well as MCS retrievals of temperature and dust opacity profiles. The Mars Analysis Correction Data Assimilation (MACDA) version 1.0 is a publicly available dataset that contains the atmospheric reanalysis covering a period of about four Martian years (MY 24 to 27) during the TES science mapping phase (February 1999 - August 2004). Data have been assimilated into a Mars global climate model (MGCM) using the Analysis Correction scheme developed at the UK Meteorological Office. The used MGCM is the UK (Oxford University and The Open

University) spectral version of the Laboratoire de Meteorologie Dynamique (LMD, Paris, France) MGCM. MACDA v1.0 is available from the UK Centre for Environmental Data Analysis (CEDA) at http://bit.ly/165Ulxd.

The MACDA reanalysis is currently being extended from MY 28 to MY 33. Improved dust assimilation, higher resolution, the use of the latest versions of TES and MCS retrievals, and improved validation are some of the key features of the new multiannual atmospheric reanalysis.

The Mars Express Radio Science experiment MaRS sounds the ionosphere of Mars since 2004. It started during the declining phase of the past solar cycle in 2004, went through a pronounced deep and long solar minimum in 2008 and 2009 and covers most of the current solar cycle through its solar maximum. The great advantage of the MaRS experiment compared to other radio sounding experiments at Mars performed at only a single frequency is the dual-frequency radio sounding at X-band simultaneously at S-band. This helps to identify the true electron density distribution and to separate true ionospheric features, in particular in the topside, from contributions caused by the spacecraft.

The large-scale daytime ionosphere shows a two-layer structure of a main layer M2 and a lower layer M1 formed by mostly solar EUV and solar X-ray and secondary ionization, respectively. The base is typically identified at 90 km. Sometimes additional electron density may be found below the M1 layer which is suspected to be caused by short solar X-rays interacting with the neutral atmosphere (see presentation by K. Peter et al.).

The topside is defined by a transport region with varying plasma scale heights. The ionopause is rarely seen, mostly when the general electron density noise background is low which coincides with observations during planetary opposition.

The M1 and M2 peak densities are clearly under solar control and follow the solar zenith angle and the solar cycle. The altitudes of both layers change also with the solar zenith angle. Variations in altitude for a given solar zenith angle may be caused by atmospheric waves propagating through ionospheric altitudes (see presentation by Tellmann et al.).

The vertical electron content follows also the solar zenith angle and is dominated by the M2 layer which contains at least 50% of the total.

This presentation reviews the MaRS ionospheric soundings over 13 years and a full solar cycle.

C4.3-0009-18 FLARE AND NON-FLARE ELECTRON DENSITY PROFILES IN THE D AND E REGIONS OF MARS' IONOSPHERE

Syed A. Haider, haider@prl.res.in

Physical Research Laboratory, Ahmedabad, Ahmedabad, India
Siddhi Y. Shah, siddhi@prl.res.in

Physical Research Laboratory, Ahmedabad, Ahmedabad, India
Masoom P. Jethwa, masoom@prl.res.in

Physical Research Laboratory, Ahmedabad, Ahmedabad, India

Solar X-ray flare responses in E region of Mars' ionosphere were observed from Mars Global Surveyor (MGS) on 6 April, 2001 and 17 March, 2003. We have developed a coupled model for the calculation of Ionospheric Electron Content (IEC), flare and non-flare electron density profiles due to impact of X-rays (0.5-90 Å) and Galactic Cosmic Rays (GCR) in the D and E regions of Mars' ionosphere simultaneously. In the non-flare profile D layer is produced at 25 km due to impact of GCR and hard X-rays (0.5-3 Å) with electron densities 1.0 x 102 cm-3 and 8 x 102 cm-3 respectively while E layer is produced at 110 km due to impact of soft X-rays (3-90 Å) with electron density 4 x 104 cm-3. The D peak density produced by hard X-rays is larger by about an order than that produced by GCR. The D and E flare peaks are produced for a short time at 30 km and 100 km with electron densities 2- 4 x 104 cm-3 and 1-2 x 105 cm-3 respectively. The predicted flare E-peak density is higher by factor of 2 than the measurements carried out by MGS. The D peak density of flare profile is larger by 1-2 orders of magnitude than that produced for non-flare profiles.

High Power HF Waves can be used to control both the electron density and electrostatic wave environment of the earth's ionosphere. Parametric decay of electromagnetic waves into other resident plasma wave modes requires satisfying the Manley-Rowe conditions for both frequency and wave number in the media. When these conditions are matched, high power electromagnetic waves launched from ground transmitters can efficiently disturb the Eand F-layers by heating, structuring, and ionizing processes depending on the transmission power and wave coupling process.

Breakdown of the neutral atmosphere at ionospheric altitudes can be achieved with high power HF waves that reflect on the bottomside of the ionosphere. For overdense heating (i.e., wave frequency < maximum plasma frequency in the F-layer), the largest electric fields in the plasma are found just below the reflection altitude. There, electromagnetic waves are converted into electron plasma (Langmuir) waves and ion acoustic waves. These waves are measured by scattering of the 430 MHz radar

at Arecibo to from an enhanced plasma line. The photo-electron excitation of Langmuir waves yields a weaker plasma-line profile that shows the complete electron profile with the radar.

Once HF enhanced Langmuir waves are formed, they can accelerate the photo-electron population to sufficient energies for neutral breakdown and enhanced ionization inside the HF Radio Beam. Plasma pancakes are produced because the breakdown process continues to build up plasma on bottom of the breakdown clouds and recombination occurs on the older breakdown plasma at the top of these clouds. Thus, the plasma pancake falls with altitude from the initial HF wave reflection altitude near 250 km to about 160 km where ion-electron recombination prevents the plasma cloud from being sustained by the high power HF. Experiments in March 2017 have produced plasma pancakes with about 100 Mega-Watts effective radiated power 5.1 MHz with the Arecibo HF Facility. Observations using the 430 MHz radar show falling plasma pancakes that disappear at low altitudes and reform at the F-layer critical reflection altitude. Sometimes the periodic and regular falling motion of the plasma pancakes is influenced by Acoustic Gravity Waves (AGW) propagating through the modified HF region. A rising AGW can cause the plasma pancake to reside at nearly constant altitude for 10 to 20 minutes. Dense cavities are also produced by high power radio waves interacting with the F-Layer. These structures are observed with the Arecibo 430 MHz radar as intense bight-outs in the plasma profile. Multiple cavities are seen simultaneously.

Using one-tenth the power of the HAARP HF Facility in Alaska, the Arecibo HF Facility in Puerto Rico has produced artificial plasma pancakes. The production at surprisingly low power is attributed to acceleration of natural photo electrons near 1 eV to suprathermal energies greater than 10 eV. The importance of this work is (1) less power than previously thought is required to produce artificial ionization in the upper atmosphere, and (2) the enhanced ionization regions can be examined with the high resolution Arecibo 430 MHz Incoherent Scatter Radar and HF sounders.

C5.1-0002-18 MAGNETIZED STIMULATED BRILLIOUN SCATTER EXCITED IN THE F REGION AND SPORADIC E AT ARECIBO OBSERVATORY

Frank Djuth, fdjuth@geospace-research.com

Geospace Research, Inc., El Segundo, California, United States Paul Bernhardt, bern@ppd.nrl.navy.mil

Naval Research Laboratory, Washington, Virginia, United States Liwei Zhang, ldzhang@geospace-research.com

Geospace Research, Inc., El Segundo, California, United States

With the previous Arecibo HF facility at Islote, Puerto Rico, Magnetized Stimulated Brillioun Scatter (MSBS) was strongly excited at an HF frequency, fHF, of 3.175 MHz under winter, nighttime, solar minimum conditions. The peak HF power of the Islote facility was only 80 MW ERP. When the HF beam was turned on in a cold unmodified F region plasma weak MSBS backscatter appeared within 10 s, but a large intensification occurred after 10 - 15 min. This coincided with the formation of strong spread F. Also the amplitude of detected lower hybrid waves increased as the MSBS intensified. In the F region the ion acoustic MSBS mode is dominant, and the electrostatic ion cyclotron mode is pumped but stable. At lower heights, strong excitation of MSBS in sporadic E occurs when vertical gradients are not too steep. The excitation of F region MSBS is feasible when FoF2 is between 3.5 and 4.5 MHz, and fHF is near 3.2 MHz. In this case, the electron-ion cooling rate is extremely low, and local losses near HF reflection are not large enough to constrain the HF-induced electron heating. As a result the electron temperature rises to measured values of 4000 K, which greatly decreases the MSBS threshold. Electron thermal conduction along geomagnetic field lines ultimately carries the locally deposited thermal energy to heat sinks above and below the deposition height. This limits the local electron temperature. To date, MSBS experiments performed with the new HF facility located at the Arecibo Observatory have yielded no new data. Despite the fact that the HF ERP increased to 100 MW ERP at fHF = 5.1 MHz and 200 MW ERP at fHF = 8.175 MHz the electron thermal loss rates due to electron-ion collisions disproportionally increase at these two higher frequencies. The older recovered Islote data are included in this presentation. However, the special circumstances under which MSBS may be generated with the new HF facility will be discussed.

High power electromagnetic (EM) waves transmitted from the ground interact with the lo- cal plasma in the ionosphere and can produce Stimulated Electromagnetic Emissions (SEEs) through the parametric decay instability (PDI). The classical SEE features known as wideband SEE (WSEE) with frequency offset of 1 kHz up to 100 kHz have been observed and studied in detail in the 1980s and 1990s. A new era of ionospheric remote sensing techniques was begun after the recent update of the HF transmitter at the High-Frequency Active Auroral Research Program (HAARP) in Alaska. Sideband emissions of unprecedented strength have been reported during recent campaigns at HAARP, reaching up to 10 dB relative to the reflected pump wave, which are by far the strongest spectral features of secondary radiation that have been reported. These emissions known as narrowband SEE (NSEE) are shifted by only up to a few tens of Hertz from radio-waves transmitted at several megahertz. One of these new NSEE features are emission lines within 100 Hz of the pump frequency and are produced through magnetized stimulated Brillouin scatter (MSBS) process.

Stimulated Brillouin Scatter (SBS) is a strong SEE mode involving a direct parametric decay of the pump wave into an electrostatic wave (ES) and a secondary EM wave that sometimes could be stronger than the HF pump. SBS has been studied in laboratory plasma experiments by the interaction of high power lasers with plasmas. The SBS instability in magnetized ionospheric plasma was observed for the first time at HAARP in 2010. Our recent work at HAARP has shown that MSBS emission lines can be used to asses electron temperature in the heated region, ion mass spectrometry, determine minor ion species and their densities in the ionosphere, study the physics associated with electron acceleration and artificial airglow.

Here, we present new observations of NSEE features at the new mid-latitude heating facility at Arecibo. This includes the direct mode conversion of pump wave through MSBS process. Collected data using ground-based SEE receiver, ISR, ionospgram, as well as satellite observations will be discussed. The different characteristics of parametric decay instabilities in the high and mid-latitude will be compared. Preliminary theoretical and computational modeling of mid-latitude NSEE will be presented.

C5.1-0004-18 EFFECTS ON GNSS AND HF FROM HEATING USING THE ARECIBO HF FACILITY

SRI International, Arecibo, Puerto Rico

Artificial Ionospheric Modification (AIM) attempts to temporarily alter a small region of the ionosphere in order to perturb the RF propagation environment. This can be achieved through injecting the ionosphere with aerosols, chemicals or radio signals. The effects of any such modification can be detected through the deployment of sensors, including ground based highfrequency (HF) sounders and dual-band Global Navigation Satellite System (GNSS) receivers. HF sounders allow measurements of the bottom-side of the ionosphere. GNSS receivers offer a convenient means of obtaining information about the ionosphere, including ionospheric disturbances through changes in the derived total electron content information.

The Heating EXperiment (HEX), which took place in March and May 2017, was designed to further our understanding of the phenomena caused by artificially heating a small region of the ionosphere, using the Arecibo facility in Puerto Rico. This was achieved by utilizing a HF measurement experiment spread between Texas and Trinidad and the deployment of a small scale travelling ionospheric disturbance (TID) detection network near the heater. The TID network comprised three GNSS receivers along baselines of approximately 4 km, located 20 km north of the heater. This paper presents HF and GNSS results from the HEX campaign, including evidence of heating-induced disturbances modifying HF propagation.

C5.1-0005-18 NEW OBSERVATIONS OF THE PLASMA LINE OVERSHOOT WITH THE ARECIBO OBSERVATORY HF FACILITY

SRI International, Menlo Park, California, United States

In the 1970's and 1980's, enhanced plasma waves were frequently detected with the 430 MHz radar at the Arecibo Observatory within 2 to 8 msec after the HF heater had been turned on (Showen, 1975). The enhanced plasma wave phenomenon is best described as a rapid increase in the return power level of the plasma line by one or two orders of magnitude, followed by a slow decay back to a lower "steady state" value associated with HF heating. The formation of short scale striations has frequently been cited as a plausible explanation of the plasma line overshoot. The idea is that as the striations form, they absorb or scatter energy from the HF heater wave. This diminishes the amount of power available to excite the plasma waves detected by the 430 MHz radar. Short scale striations are thought to form at the altitude where the frequency of the HF wave matches the upper hybrid resonance - below the altitude of HF reflection. In 1981, the decay of the plasma line overshoot was correlated with the rise of the short scale striations utilizing an HF pulse rate of 4 seconds on/off, with the HF transmitter tuned to 5.1 MHz, and an estimated E.R.P. of 38 MW (Coster et al., 1984). In July 2017, a series of HF heating experiments designed to examine the enhanced plasma line with the new Arecibo Observatory HF facility and the improved diagnostics of the modern system. These experiments were designed to study possible mechanisms responsible for the formation and decay of the plasma line overshoot. In the experiment, the HF heater was cycled on and off at various cycles:. 8 min on/off, 4 min on/off, and 2 min on/off, and enhanced plasma lines were detected throughout the experiment. We report on significant findings from this experiment

Exceptional data has been collected where the E -region plays an important role in the generation of the artificial ionosphere in the F region, opening the door to test theories about the natural phenomena of E and F-region interaction. Although, the HF Facility works at frequencies that are a higher than the typical maximum E-region plasma frequency.

During HF experiments at Arecibo, modulation of artificial field-aligned irregularities (AFAIS) in the F region was observed in the presence of natural billowy E region. Tsunoda and Cosgrove, 2001, proposed that the E-F region is electro-dynamically coupled in the presence of billowy sporadic E (Es). Hysell et al., 2011, suggested that the strong currents in the Es layers and the large polarization electric fields that drive them can be maintained, for example, when the currents are allowed to close in the F layer. Observational evidence of these theories has been challenging to find. However, a possible demonstration of the closed loop is seen under the effect of the artificial irregularities observed on March 18, 2017, when the remarkable resolution of the ISR at Arecibo allows to see the natural E-region activity and the F-region AFIS modulation.

The link between the theory and the observations is one example of how the HF Facility and the full diagnostics can be used as a center of space plasma physics to test ionospheric coupling theories.

The CARE II mission was launched from Andoya, Norway, in September 2015. The primary objective of CARE II was to study hypersonic expansion of dust and molecular clouds in the presence of an ambient ionosphere. This flight had a full set of plasma diagnostics to measure the charged dust density, the electron and ion densities, and the electrical fields associated with plasma waves produced by the release. The chemical release payload were solid rocket motors that releases about aluminum oxide dust particulates. A charged dense dust cloud was formed for detection as enhanced radar scatter. The in situ electric field measurements

determine the sources of some of the observed plasma waves launched by rocket engines that fire in the ionosphere. The CARE II payload trajectory and velocity profiles were nominal with the released on target for radar and sensor viewing. The rocket motor payload on CARE II was a good representation of commonly used solid rocket motors that fire in the ionosphere.

The CARE II rocket fired 37 rocket motors simultaneously to inject 66 kg of dust particles in the upper atmosphere at an altitude of 266 km (approximately 165 miles above Earth). The dust, composed of aluminum oxide particulates, was accompanied by 130 kg of molecules such as carbon dioxide, water vapor, and hydrogen. The large concentration of dust and exhaust material interacted with the ionosphere to produce dusty plasma with high-speed "pickup ions," a technical term for ionized or electrically charged (positive or negative) particles. The launch occurred just after sunset to place the dust particles in sunlight for easy viewing by cameras in darkness on the ground. Digital cameras were used onboard a Beechcraft B200 airplane to photograph sunlight scattered from the expanding dust cloud, and the captured images show a dispersal of the dust that appears almost spherical.

The electric field instrument on the CARE II rocket functioned as both a plasma wave sensor and fluctuation monitor. The instrument sensitivity was better than 100 μmicroVolt/m and with a frequency range extending above 10 kHz. These parameters were chosen to cover both low frequency waves from the dust and magnetohydrodynamic (MHD) components and higher frequency waves associated with ion acoustic fluctuations. The instrument used a 32 ks/s sampling rate with a 12-bit analog-to-digital converter. The individual samples from eight separate probes in double-double configurations provided multiple baselines for measuring electric fields between sensor pairs. Both low-frequency MHD waves and higher frequency ion waves have been identified in the data.

The plasma densities at CARE II instrument payload were measured with electron satura- tion current fixed-bias Langmuir probes (FLP), a sweeping Langmuir probe (SLP), and an impedance (or resonance) probe (IP). These probes yielded the background plasma before the CARE II release and the density reductions and plasma irregularities excited by the dust and molecule debris injection. The plasma density instruments used electron saturation currents or the frequency spectrum of the plasma probe impedance to measure the electron densities. The sensitivity of the plasma probes were chosen for electron density ranges between 2.0 103 and 1.6 106 cm−3. The range for the ions is 2.4 104 to 9.4 106 cm−3. The electron temperature is also measured between 0.02 and 1.0 eV. The plasma resonance probe covers the 1.2 104 to 1.2 106 cm−3 density range with increased accuracy. The sample rate on the Langmuir probes was 43 kHz for electrons and 10 Hz for electron temperature. The resonance probe was swept with a 10 Hz rate.

Our two-fold goal for ongoing theoretical study of CARE II data is to (1) explain the disturbance observations recorded by the CARE II sensors and (2) predict the magnitude of the plasma turbulence stimulated by the dust injection. The theoretical effort is supported by particle-incell and fluid models developed at Virginia Tech. The generation of MHD and Whistler wave modes by localized dust and molecule expansion in the ionosphere uses several wave excitation mechanisms. The MHD model for payload impulse response uses both fluid theory for the MHD shock-wave generation and anisotropic media ray tracing to predict the path of the disturbance wave. Irregularity generation and sensing involves dust and molecule streaming instabilities described by both fluid and kinetic theory. The physics of field aligned irregularities uses both fluid and kinetic descriptions.

C5.1-0008-18 ACTIVE SPACE EXPERIMENTS POSTER REVIEW I

James Sheerin, jsheerin@emich.edu

C5.1-0009-18 HAARP, A POWERFUL ACTIVE IONOSPHERIC LABORATORY OPEN FOR INTERNATIONAL RESEARCH

Bob McCoy, rpmccoy@alaska.edu

Geophysical Institute, University of Alaska, United States William Bristow, wabristow@alaska.edu

University of Alaska Fairbanks, Fairbanks, Alaska, United States Christopher Fallen, ctfallen@alaska.edu

University of Alaska Fairbanks, Fairbanks, Alaska, United States

The High-frequency Active Auroral Research Program (HAARP) is the most powerful and capable ionospheric heater in the world. High-power, high-frequency (HF) transmitters provide a means to study the ionosphere, upper atmosphere, and magnetosphere in ways not possible with traditional insitu or remote sensing observations. With an HF "heater" an overhead region of the ionosphere can be modified briefly to create a desired effect and then observe the ionosphere as it relaxes to its original state. By varying the frequency, amplitude, or on/off transmit time, the ionosphere can be used as an antenna to generate low frequency waves (ULF, ELF, VLF, Whistler, etc.) which propagate along magnetic field lines into the magnetosphere or are injected into the earth-atmosphere waveguide. High power HF energy can be used to create artificial airglow, perform radio science experiments and drive a variety of plasma instabilities, irregularities and turbulence. HAARP is powered by four 3600 HP diesel engines and can transmit 3.6 MW at multiple frequencies and multiple beams anywhere in the interval 2.8 - 10 MHz. HAARP has been used to create artificial airglow, long-lived artificial ionospheric layers, instabilities, irregularities and turbulence; and various forms of low frequency waves. The Geophysical Institute of the University of Alaska Fairbanks (UAF/GI) recently took ownership of HAARP from the Air Force Research Laboratory, restored the facility to operational status and has been conducting scientific campaigns for outside investigators. The HAARP facility is open to international researchers. The status and future plans for HAARP and a summary of recent experiments will be presented.

C5.1-0010-18 IONOSPHERIC TURBULENCE GENERATED BY HIGH POWER HF TRANSMITTERS

James Sheerin, jsheerin@emich.edu

Eastern Michigan University, Ypsilanti, MI, Michigan, United States

Active experiments in the ionosphere performed using high power ground-based HF transmitters may allow for the controlled generation and study of turbulence and density irregularities and their impacts on wave propagation through the ionosphere, (e.g. GPS scintillation). The largest HF transmitter built to date is the HAARP phased-array HF transmitter near Gakona, Alaska which can deliver up to 3.6 Gigawatts (ERP) of CW RF power in the range of 2.8 - 10 MHz to the ionosphere with millisecond pointing, power modulation, and frequency agility. With an ionospheric background thermal energy in the range of only 0.1 eV, this amount of power gives access to the highest regimes of the nonlinearity (RF intensity to thermal pressure) ratio. HAARP's unique features have enabled the conduct of a number of nonlinear plasma experiments in the interaction region of overdense ionospheric plasma including generation of artificial aurorae, artificial ionization layers, VLF wave-particle interactions in the magnetosphere, parametric instabilities, stimulated electromagnetic emissions (SEE), strong Langmuir turbulence (SLT) and suprathermal electron acceleration. Diagnostics include the Modular UHF Ionospheric Radar (MUIR) sited at HAARP, the SuperDARN-Kodiak HF radar, spacecraft radio beacons, HF receivers to record stimulated electromagnetic emissions (SEE) and optics for stimulated optical emissions. Recently, a new HF transmitter has begun operations at Arecibo Observatory. The new Arecibo heater is comprised of two arrays of three crosseddipoles each, at 5.1 MHz and 8.175 MHz located at the bottom of the 305 m dish feeding a subreflector suspended from the Arecibo platform. The vertical HF beam generated is rated at 100 MW ERP at 5.1 MHz and 200 MW at 8.175 MHz, making it comparable to the previous Arecibo heating facility at those frequencies. The most prominent diagnostic at Arecibo is the 430 MHz dual beam ISR with an ERP of 2 TW. Other diagnostics include HF receiver ar- rays to record SEE and HF scatter, spacecraft radio beacons, and optics for stimulated optical emissions. We report on short timescale ponderomotive overshoot effects, onset and growth of artificial field-aligned irregularities (AFAI), the aspect angle dependence of the intensity of AFAI, large-scale density cavities of depths exceeding 50% over tens of kilometers, the production of suprathermal electrons and related artificial ionization layers. Applications are made to the ionospheric turbulence and irregularities affecting spacecraft communication and navigation systems, as well as the controlled study of fundamental nonlinear plasma processes of relevance to laboratory plasmas.

C5.1-0011-18 HF POWER-RAMP EXPERIMENTS AT HAARP: EXPERIMENTAL DETERMINATION OF THRESHOLD POWER REQUIRED FOR THE ONSET OF HFENHANCED PLASMA LINES, AND ONSET OF ARTIFICIAL IONIZATION IN THE LOWER F-REGION IONOSPHERE.

Brenton Watkins, watkins@usa.net

University of Alaska Fairbanks, Fairbanks, Alaska, United States
Christopher Fallen, ctfallen@alaska.edu

University of Alaska Fairbanks, Fairbanks, Alaska, United States
Spencer Kuo, spk259@nyu.edu

New York University, New York, New York, United States

High-power HF radio waves transmitted from the HAARP facility produce HF-enhanced ionacoustic and Langmuir waves, and other effects such as artificial optical emissions and ionization. We present data from experiments where the HF power was slowly increased to determine the transmitted power levels for the onset of plasma waves and the onset of artificial ionization. The MUIR UHF radar (446MHz) was used as a diagnostic to detect plasma waves produced by HAARP. Past experiments have shown that power levels as low as 1% of full power can produce enhanced plasma waves. We have therefore used the unique capability of the HAARP phased array to extend the transmitted power to extremely low initial levels. This was accomplished by initially transmitting from only four dipoles from zero power upward in small power increments, and progressively adding more dipole transmitting elements. In this way it was possible to provide upward (or down-ward) power ramps from very low power (with no production of plasma waves) to full power. The HAARP antenna phasing was chosen for transmission in the direction of the earth's magnetic field and the transmitted power was determined at the center of the antenna beam in the direction of the magnetic field. Power densities and electric field values were calculated at 200km altitude, near the altitude of the observed plasma waves. The threshold electric field for the onset of plasma waves is about 50mV/m. However, the HF electric field near the HF reflection height is enhanced by the swelling effect of a factor about 4, thus the actual threshold electric field is about 200mV/m, which is consistent with theory.

Because the upper hybrid resonance layer is located below the HF reflection layer, upper hybrid waves may also be excited parametrically by the HF heating wave. Due to the field-aligned nature of the upper hybrid waves, these waves could not be detected directly by the UHF radar. On the other hand, the excitation of these waves may be manifested by the appearance of artificial ionization in the lower region. Short wavelength upper hybrid waves, which have high parametric excitation threshold, effectively energize electrons via finite Larmour radius effect implemented as a Doppler shifted harmonic cyclotron resonance interaction. The onset time of significant artificial ionization was

determined from the start of a sharp downward trend in the altitude of the plasma wave production; a threshold electric field value of about 700mV/m was calculated.

In addition, spectral analysis of the plasma-line cascade was performed to determine the progressive heating effect on the ion-acoustic wave frequency. The plasma-line cascade results from the parametric decay instability followed by successive Langmuir decay instability events. These spectral lines are separated in the frequency domain by intervals corresponding to the Doppler shifted ion-acoustic frequency appropriate for the wavelength of the diagnostic radar.

C5.1-0012-18 THE PRODUCTION OF ARTIFICIAL IONIZATION FROM HAARP: RESULTS AND EXPERIMENTAL APPROACHES FOR HF FREQUENCIES NEAR ELECTRON GYRO-HARMONICS

Brenton Watkins, watkins@usa.net

University of Alaska Fairbanks, Fairbanks, Alaska, United States
Christopher Fallen, ctfallen@alaska.edu

University of Alaska Fairbanks, Fairbanks, Alaska, United States
James Secan, jim@nwra.com

NorthWest Research Associates, Redmond, Washington, United States

We present observational results for high-power HF modification of the F-region ionosphere at the HAARP facility. There is a distinct difference between use of HF frequencies close, but higher than, gyro-harmonic values, compared with frequencies close, but below gyro-harmonic values. Experimental evidence demonstrates the production of artificial ionization is a minimum (or zero) for frequencies close to a gyro-harmonic. The altitude of the HF interaction region was determined from the production of HF-enhanced ion-acoustic and Langmuir waves as observed by a UHF diagnostic radar. Experiments were all conducted by directing the HAARP HF antenna and the UHF radar antenna along the direction of the earth's magnetic field. For experimental cases where the HF frequency is chosen above the gyro-harmonic value the HF interaction altitude initially decreases due to production of artificial ionization, but this production stops when the HF interaction altitude approaches the height of the local gyro-harmonic value. Subsequently, following chemical recombination, the HF interaction height rises and artificial ionization resumes. In this way, a continuous ionization production is maintained. As this generally occurs for heights about 200-300km, the continuous upward heat flux results in continuous upward plasma outflow from the ionosphere with corresponding enhanced plasma densities in the top-side ionosphere (and presumably far into the magnetosphere). Experimental satellite data at about 1000km altitude has verified this effect. These enhanced densities and plasma fluxes may be maintained for extended periods and could serve as waveguides for VLF waves produced by HAARP. The primary source of the ionization in the topside ionosphere is daytime photo-ionization. For experimental cases where the HF frequency is chosen to be less than the gyro-harmonic the production of artificial ionization results in decreasing altitude of the HF interaction. When the interaction altitude drops to about 150km or less, the HF interaction stops due to collisional effects, chemical recombination takes place and the cycle resumes. We show that using an FM sweep of the HAARP transmission produces a controlled slow descent of the artificial ionization production in the lower F-region ionosphere. Future development of this technique may permit us to maintain long-lived ionization structures in the lower F-region (about 180-200

km). The mechanism for the production of ionization in the lower F-region ionosphere is primarily due to electron acceleration from the action of upper hybrid and electron Bernstein waves; this has been extensively discussed in the literature. The selection of HF frequencies is critical for the success of the above experimental approaches. The HF frequency must be chosen to suit the local foF2 value and also the proximity to a gyro-harmonic. Other ionospheric modification facilities with limited choices of available HF frequencies will not in general be able to duplicate these results. Appropriate choice of HF frequencies with spacing as small as 10-50 kHz can be significant.

C5.1-0013-18 NEW PERSPECTIVE OF STIMULATED ELECTROMAGNETIC EMISSIONS AND FIELD ALIGNED IRREGULARITIES PRODUCED DURING IONOSPHERIC HEATING: TOWARDS MAXIMUM RESONANCE

Haiyang Fu, haiyang_fu@fudan.edu.cn Fudan University, 200433, China Wayne Scales, wscales@vt.edu

Virginia Tech, Blacksburg, Virginia, United States Paul Bernhardt, bern@ppd.nrl.navy.mil

Naval Research Laboratory, Washington, Virginia, United States

This talk will report on new observations of the complex dynamics of wideband stimulated electromagnetic emission (SEE) generation with simultaneous measurement of field aligned irregularities (FAIs) near the third electron gyroharmonic frequency by high power high frequency HF radio waves from High Frequency Active Auroral Research Program (HAARP) facility. The time evolution of the wideband SEE spectral component is more clearly investigated with the benefit of tilted beam angle heating experiments. It is observed for the first time that HF radar echoes intensify for pump frequencies above electron gyroharmonic frequencies at HAARP, which indicates correlation between enhanced FAIs and the formation of the so-called Broad Upshifted Maximum BUM spectral line. The polarimetry of SEE spectral lines are also analyzed to reveal that the downshifted maximum DM spectral line has a higher degree of circular polarization for heating above gyroharmonic frequencies.

To explain the asymmetric enhanced FAIs and correlated BUM emissions, a four-wave parametric process is investigated by using two-dimensional electrostatic particle-in-cell simulations for the first time. The variation of the four-wave decay instability is investigated for a range of plasma and pump wave frequency parameters. The numerical simulation results show the dependence of the maximum parametric decay process on the wave propagation angle with respect to the magnetic field, which agrees with theoretical analysis. The threshold of the BUM and 2BUM is also investigated for different electron oscillating velocity and pump wave frequency near electron gyroharmonics. The temporal-spatial characteristics for small scale plasma irregularities is also obtained. The comparison of the BUM observations with theoretical models provides a powerful tool for specifying nonlinear processes for plasma irregularity excitation.

C5.1-0014-18 PROPOSED ELF/VLF WAVE INJECTION EXPERIMENTS FROM AN HF HEATING FACILITY: GENERATION OF ELF/VLF WAVES AND ARTIFICIAL DUCTS

Vikas Sonwalkar, vssonwalkar@alaska.edu

University of Alaska Fairbanks, Fairbanks, Alaska, United States
Amani Reddy, areddy1@alaska.edu

University of Alaska Fairbanks, Fairbanks, Alaska, United States
Brenton Watkins, watkins@usa.net

University of Alaska Fairbanks, Fairbanks, Alaska, United States

Using an ionospheric HF heater to simultaneously generate ducts and ELF/VLF waves, we propose a new generation of wave injection experiments. Highly successful whistler mode wave injection experiments from SIPLE station, Antarctica, have established the importance of such experiments to study magnetospheric wave-particle interactions, and for cold and hot plasma diagnostics [Helliwell and Katsufrakis, 1974; Sonwalkar et al., 1997]. Modulated heating experiments from HAARP have shown that it is possible to launch ELF/VLF waves into the magnetosphere that can be observed on the ground after one-, two-, and multi-hop ducted propagation [Inan et al., 2004]. Past research has also shown that ionospheric heating experiments using an HF heater can lead to the formation of magnetospheric ducts [e.g. Milikh et al., 2010]. Recently it was shown that modulated HF heating from HAARP at frequencies about 50-100 kHz greater than gyro frequency harmonic just below F2 peak can generate and sustain ducts during day time [Watkins et al., 2013]. Collectively, these results indicate that an ionospheric heater can be used to form ducts on nearby L shells as well as to inject and trap heater generated ELF/VLF waves in those ducts. The ELF/VLF source region of heater generated waves is in the F-region ionosphere [Moore et al., 2012] permitting injection of waves at a greater range of wave normal angles not possible with ground-based wave injection experiments. These new generation experiments also provide control over duct generation and sustenance. Using raytracing studies, we demonstrate, as an example, the feasibility of a new generation of wave injection experiments from the HAARP transmitter (L 4.9). Ray tracing calculations using a model magnetosphere show that ducts of width dL 0.1-0.3 and enhancement factor dNe/Ne 10-20% or more can trap ELF/VLF waves in ducts with L shells near the HAARP heater. The plasmapause location with respect to transmitter plays a role in the nature of trapping. The duct locations and parameters required for trapping ELF/VLF waves inside the ducts are consistent with past observations of ducts generated by the HAARP transmitter. Trapped wave normal angles obtained from ray tracing calculations combined with estimated ELF source power can be used to estimate wave intensity inside the duct, on the ground, and on satellites such as Van Allen probe, and planned DSX, and to calculate resonant energetic electron energy. This new generation of wave injection experiments from an ionospheric heater will provide new understandings of ducts, ELF/VLF wave propagation, wave-particle interactions, and radiation belt physics.

C5.1-0015-18 INVESTIGATION OF THE ARTIFICIAL IONOSPHERIC TURBULENCE AT THE HAARP FACILITY USING MULTI-FREQUENCY DOPPLER SOUNDING

Alexey Shindin, shindin@rf.unn.ru

Nizhny Novgorod State University, Nizhni Novgorod, Russia Evgeny Sergeev, esergeev@nirfi.sci-nnov.ru

Radiophysical Research Institute, Nizhny Novgorod, Russia Savely Grach, sgrach@rf.unn.ru

Lobachevsky State University, Nizhny Novgorod, Russia

The dependence of the electron concentration profile modification was analyzed, in the ionosphere at various pump-wave frequencies at the fourth electron cyclotron frequency harmonic (fc), below and near it, and the preliminary results are presented. They were obtained from the data of the 2014 experiments on phase sounding of the perturbed ionosphere at the HAARP facility (Alaska, USA). The position of the pump wave frequency with respect to 4fc was determined by the spectrograms of stimulated electromagnetic emission. The inverse problem of reconstructing the electron concentration profile from the phase variations of broadband probe signals in the 450 kHz - band, including the pump wave plasma resonances, is solved for the six frequencies of the action of 5540, 5570, 5600, 5630, 5660 and 5730 kHz (fc 5690-5700 kHz); the Doppler frequency variations maps of the of radio signals, variations in the altitudes of their reflection, and virtual vertical velocities of the displacement of equal-concentration lines are plotted. In [1] the data obtained under the action at a frequency of 5500 kHz are analyzed in detail. The results are as follows:

All artificial perturbations of these quantities were observed on the background of natural changes in the plasma's electron density.

For all cases of plasma pumping, the effects of plasma expulsion from the plasma resonance region near the pump wave reflection level were observed already on the first second of pumping and, on the contrary, the concentration increase (lowering of the plasma layer) below the pump wave upper-hybrid resonance level.

The effect of plasma expulsion was characterized by an increase in the reflection height of the diagnostic pulse by $\sim$ 250 m at the velocity of $\sim$ 75 m/s.

Regarding the upper hybrid resonance level during pumping at the frequencies below the 4th gyroharmonic plasma expulsion (more significant than in the plasma resonance level) on the 2-3th second of pumping and the profile restoration after pumping were observed.

At the frequency of 5730 kHz (above the 4th gyroharmonic), the plasma expulsion effect at the upper hybrid resonance level was not present, on the other hand, the effect of increasing the electron concentration on the entire probe wave's network was mainly observed (and the most significant for lower values of the frequencies).

The results 1-3 correspond to the results obtained at the Sura facility (Nizhni Novgorod region, Russia) [2], although the HAARP facility used effective radiated power (400 MW) is approximately eight times higher than that of the Sura heating facility. In order to make definite conclusions on the effect of pump wave frequency offset with respect to 4fc on the plasma expulsion effect additional experiments are required. This work was supported by the RSF grant 17-72-10181, by RFBR grants 16-02-00798 and 18-02-00622.

We present results of concurrent observations of stimulated (secondary) electromagnetic emissions (SEE) and incoherent high frequency plasma line (HFPL) backscatter from the MUIR radar during HF pumping of the ionosphere by the HAARP heating facility (62.4° N, 145.15° W, magnetic inclination 75.8°) with the pump wave (PW) slow (by 30 kHz once in a 5 min, by 20

kHz once in 2 min) and fast (once in 0.2 s by 1 kHz) frequency stepping about the fourth electron gyroharmonic (4fc). Result were obtained in 2011 and 2013. Relations between dynamic Broad Upshifted Maximum SEE spectral feature, descending and ascending HFPL generation regions, altitudes of the 4th electron gyroresonance of the pump wave and artificial ionization layers in the ionosphere are discussed.

C5.1-0017-18 ELF/VLF PLASMA ANTENNA BASED ON SUPER-PARAMAGNETIC NANOPARTICLES (SPN): RADIATION BELT REMEDIATION (RBR) REVISITED

Konstantinos (Dennis) Papadopoulos, dennis.papadopoulos@gmail.com University of Maryland, College Park, College Park, Maryland, United States Tom Wallace, tom.wallace@vesperix.com

Virginia, United States

Chia-Lie Chang, chia-lie.chang@vesperix.com

Vesperix Corporation, Falls Church, Virginia, United States

Earth's Radiation Belts (RB) were the first major discovery of the Space Age. Following the 1957 prediction of Nick Christofilos the presence of the RBs was confirmed in 1958 by Jim Van Allen. Interestingly their prediction and discovery was related to what is known as the grandest scientific experiment ever, the Argus series of High Altitude Nuclear Detonations (HAND), that resulted in injection of beta decay MeV electrons in the inner RB, increasing the natural MeV flux by several orders of magnitude. The artificial RBs, whose formation is also known as the "Christofilos Effect", deliver a lethal dose to Low Earth Orbit (LEO) satellites destroying their electronic capability within weeks with great economic and military consequences. The need for a Radiation Belt Remediation (RBR) system was recognized long ago and systems were explored following a Defense Threat Reduction Agency (DTRA) briefing in 2001 that concluded that one 10 kT HAND above 150 Km altitude will incapacitate 90% of LEO satellites in less than a few months and the Rumsfeld II report that called such an event a "Pearl Harbor in Space". Given the recent N. Korea capability to conduct high altitude nuclear tests and the possibility of a HAND caused by the salvage fusing of a US ballistic missile intercept, lack of credible RBR system limits the range of available responses. For example, does a HAND causing material damage justify a nuclear attack? A deterrent based on an RBR system is urgently needed. From the physics point of view the solution is evident, since experiments reinforced by recent results from the NASA Van Allen mission, indicate that whistler waves in the 2-3 kHz range and EMIC waves in the 100 Hz range interact strongly with MeV electrons causing pitch angle scattering into a cone (loss cone) that leads to precipitation into the atmosphere and out of the RBs. This process operating at the average whistler amplitude of 10 pT will bring back the MeV electron flux to the natural level in several years. However, if this amplitude is artificially enhanced by a factor of 3-5 the time to return to equilibrium becomes a couple of weeks clearly before significant damage to the fleet of satellites. RBR schemes based on injection of ELF/VLF waves by space based transmitters have been proposed, but was determined that the power required and the associated number of radiating satellites to achieve precipitation before significant spacecraft loss was unacceptably high. Experiments and theory indicated that the power and satellite number would be significantly lower if the wave-particle interaction amplified the injected waves by 10-20 dB

i, a process that has been observed experimentally but is difficult to predict and control. The objective of this presentation is to show that use of novel metamaterials in the form of SuperParamagnetic Nanoparticles (SPN) as ELF/ VLF transmitters in the RB plasma can increase the efficiency of generation of ELF/VLF by more than 10-20 dB, reduce the compactness of the system so that it can be placed on CubeSat's and provide propagation ducts that act as fibers to guide the injected power to the desired location. SPNs can be described as ensembles of non-interacting magnetic moments with m=104 105μB each and when driven by a magnetic field B energyE=-mB. Matrices containing SPNs behave like ordinary paramagnets, but with ferromagnetic susceptibility. An ensemble of SPNs embedded in a liquid or solid non-conducting matrix is driven to rotation or oscillation at the desired ELF/VLF frequency by RF coils surrounding the matrix. The near field electric field associated drives field aligned plasma currents such as were observed in Rotating Magnetic Field (RMF) experiments at the UCLA/LAPD chamber [Gigliotti et al., Phys. of Plasmas 16:092106, 2009; Karavaev et al., Phys. of Plasmas 17(1):012102,2010]. The magnetic moment of the AC coil is amplified by the SPN ensemble that depending on the grain size, material and volume can reach relative permeability μ=100-500. Preliminary estimates indicate that less than 1 kg of SPN grains driven by RF power of the order of 10 W can inject in the radiation belts EMIC and whistler waves with amplitude more than 100 pT and controlled chirp.

C5.1-0018-18 THE MAGNETOSPHERE-IONOSPHERE CONNECTIONS EXPLORER (CONEX): A MISSION TO CONNECT THE DYNAMIC MAGNETOSPHERE AND AURORAL IONOSPHERE

Los Alamos National Laboratory, Los Alamos, New Mexico, United States

On the nightside of the Earth the magnetic connections between the dynamic ionosphere and magnetosphere have a great deal of uncertainty. Since the 1990s, the space plasma physics group at Los Alamos National Laboratory (LANL) has been working on a mission concept to connect magnetospheric physical processes to auroral phenomena in the ionosphere by firing an electron beam from a magnetospheric spacecraft along magnetic field lines and optically imaging the beam spot in the ionosphere [1,2]. This concept can address some central outstanding scientific questions in our field:

1. Why do the aurora occur when and where they do 2. How do magnetospheric processes produce the conditions where auroras can occur? 3. How accurately can ionospheric and auroral observations specify the state of the magnetosphere?

The magnetospheric spacecraft will carry a steerable electron accelerator, a power-storage system, a plasma contactor, and instruments to measure magnetic and electric fields, plasma, and energetic particles. The spacecraft orbit will be coordinated with a ground-based network of cameras to (a) locate the electron beam spot in the upper atmosphere via its optical airglow

emission and (b) monitor the aurora. Recently, a LANL-led multi-institution team has made rapid advancements in this mission concept. The advancements are based on (1) a new understanding of the dynamic spacecraft charging of the accelerator and plasma-contactor system in the tenuous magnetosphere based on ion emission rather than electron collection [3], (2) a new understanding of the propagation properties of pulsed MeV-class beams in the magnetosphere, and (3) the design of a compact high-power 1-MeV electron accelerator and power-storage system. An overview is presented of the mission concept, the spacecraft-charging problems, the accelerator, the ground-based ground network, and the magnetospheric measurement instrumentation. The overview will include a discussion of the accelerator-energy tradeoffs between reducing spacecraft charging, avoiding loss-cone-drift issues [4] and improving beam detectability, and will include a discussion of a strategy to reduce of spacecraft charging when the accelerator is fired. This strategy to (a) determine the magnetosphere-to-ionosphere magnetic connections and (b) reduce accelerator-platform charging responds to one of the six emerging-technology needs called out in the most-recent National Academies Decadal Survey for Solar and Space Physics: "Magnetosphere-to-Ionosphere Field-Line Tracing Technology". Our overview will also address a range of outstanding auroral physics questions that can be addressed with this mission concept.

C5.1-0019-18 IN-SITU OBSERVATIONS OF IONOSPHERIC HEATERS BY THE E-POP RADIO RECEIVER INSTRUMENT

Gordon James, james@phys.ucalgary.ca Natural Resources Canada, Ottawa, Canada Vladimir Frolov, frolov@nirfi.unn.ru

EISCAT Scientific Association, Ramfjordbotn, Norway

Since its launch on 29 September 2013, the e-POP Radio Receiver Instrument (RRI) on the Canadian small satellite CASSIOPE has been commanded to operate in the vicinity of ionospheric heaters on a number of occasions. RRI has been turned on to observe heater RF fields on over 145 passes near the following facilities: SPEAR, HAARP, Sura, EISCAT Heating and Arecibo Observatory. At mission outset, it was anticipated that the 81° inclination and the 325-km perigee of the CASSIOPE orbit would present ongoing opportunities for close measurements of heating physics in the F region. The RRI observations have established the tendency of ionospheric density structure to complicate propagation in the F region and thereby affect conditions whereby nonlinear processes leading to ionospheric modification can be achieved. Density irregularities, either spontaneous in the background plasma or enhanced by heating effects, play major roles in the intensities and the directions of propagation of pump radiation in the F layer. D/E region absorption may mitigate against pump-field intensities needed to destabilize nonlinear processes in the F-layer, since RRI spectra are found to contain few indications of Raman or Brillouin scattering. As the CASSIOPE future orbital altitudes diminish with time, perigee altitude may offer unusual experimental opportunities. These might include new observations of wave physics in collisional plasmas, in particular where the (de)focusing effects of horizontal gradients are less important than in the dense F-layer peak in the measurement of heater radiation patterns.

The geospace environment harbors a wide variety of linear and nonlinear phenomena. Knowledge of the various signatures and driving mechanisms gives insight into the local conditions not only at the instant that the observations are made, but also into how the conditions may evolve in time. Comprehensive, controlled investigations of the underlying physics associated with space plasma phenomena are difficult to accomplish through in situ methods alone. Consequently, properly scaled laboratory experiments can offer a complementary approach to investigating the space plasma dynamics. Laboratory devices have been utilized to investigate space plasma phenomena including instability mechanisms, wave generation, growth, and propagation characteristics, wave-particle interactions, and nonlinear effects to name a few. In this talk, we review examples of scaled laboratory investigations of space phenomena conducted in the Naval Research Laboratory's Space Physics Simulation Chamber, the associated space observations, and comparisons to theory.

C5.1-0021-18 EXCITATION OF PLASMA IRREGULARITIES IN THE F-REGION

Farideh Honary, f.honary@lancaster.ac.uk Lancaster University, Lancaster, United Kingdom Nikolay Borisov, borisov@lpi.ru

Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation of the Russian Academy of Sciences (IZMIRAN), Troitsk, Russia

Excitation of articial plasma irregularities in the auroral ionosphere by high frequency X-mode radio wave will be presented. This is done by introducing a new theory based on two step process. As a rst step the thermal self-focusing instability excited in the F-region of the ionosphere under the action of a strong high-frequency (HF) radio wave is adopted. This instability causes the formation of perturbations of the electron temperature and plasma concentration across the magnetic eld. In addition, the plasma becomes depleted in the regions of the electron temperature enhancements and vice versa, since the gradients of plasma concentration and the electron temperature have opposite signs. In such conditions the temperature gradient instability comes into play. As a second step we consider this instability to be responsible for the generation of irregularities with transverse sizes smaller than the typical scales of the self-focusing instability. Alternative mechanisms such as excitation of drift instabilities (the gradient-drift and the current-convective in-stabilities) which are often attributed to the generation of plasma irregularities in the F-region and can contribute to the formation of articial irregularities in the case of X-mode heating are also discussed.

C5.1-0022-18 OBSERVATIONS OF SYSTEMATICALLY RECURRING TOPSIDE IONLINE ENHANCEMENTS DURING HF MODIFICATION EXPERIMENTS NEAR ELECTRON GYROHARMONIC FREQUENCIES

Theresa Rexer, theresa.rexer@uit.no University of Tromso, TROMSØ, Norway Björn Gustavsson, bjorn.gustavsson@uit.no University of Tromsø, Tromsø, Norway Thomas Leyser, tbl@irfu.se

NORUT, Tromsø, Norway

Observations of electron gyro harmonic effects in the polar ionosphere were made during experiments in March 2016 and October 2017, with the European Incoherent SCATer (EISCAT) UHF radar and Heating facilities near Tromso, Norway. During transmission of a high power, high frequency radio wave, the HF-pump frequency was slowly stepped around the double resonance of the 3rd and 4th multiple of the electron gyro frequency and the local plasma frequency in the F-region ionosphere. Simultaneous to the previously well-documented enhancements on the bottom side of the F-layer at the HF reflection height, a smaller, but clear, ion-line enhancement was observed above the F-region peak. Topside enhancements occurred systematically when the pump frequency was close to multiples of the electron gyro harmonic frequency for numerous heating ON cycles during both experiments. We present ISR observations of these topside enhancements and the results are discussed in terms of possible L-mode propagation through the F-region peak.

C5.1-0023-18 OBSERVATION AND SIMULATION STUDY OF PARAMETRIC INSTABILITY AND LANGMUIR TURBULENCE

Chen Zhou, chenzhou@whu.edu.cn Wuhan University, Wuhan, China

Parametric decay instability (PDI) is an important process in ionospheric heating. HFPLs and HFILs in spectra of ISR are the direct observational evidence of PDI excitation. Stimulated electromagnetic emissions (SEE), enhanced airglow and artificial ionized layer are also closely related to PDI. The focus of this talk will be on the generation of PDI and Langmuir turbulence based recent observational and simulational study. This presentation includes a few topics: (1) Recent heating experiments presented excitation of PDI during the X-mode heating period by EISCAT. We suggest that the full dispersion relationship of the Langmuir wave can be employed to analyze the X-mode parametric instability excitation. A modified kinetic electron distribution is proposed to satisfy the matching condition of parametric instability excitation. (2)The simulation results of 1D and 2D Zakharov model show that caviton collapse dominates in higher altitude area and cascade dominate in lower altitude, which is consistent with strong Langmuir theory (SLT). Based on the spectrum analysis, the development of PDI to Langmuir turbulence is investigated in details. (3) Langmuir turbulence leads to strong electron acceleration. Generation mechanism of Langmuir turbulence and electron acceleration are also discussed with the help of numerical simulations.

The question of how much energy is dissipated has long been a central question in the field of high-power HF radio-wave ionospheric modification experiments. This report presents EISCAT incoherent scatter radar observations of electron temperature variations during daytime experiments with EISCAT Heating. Observations were made with rapid scanning of the radar making it possible to determine the three-dimensional variation of the enhanced electron temperature. By combining the radar observations with modelling of the electron temperature we determine the spatio-temporal variation of electron heating, with respect to time, altitude and direction. The results will be compared and contrasted with previous estimates of efficiency of producing artificial aurora at 6300 Å (Pedersen et al. 2008) and of electron heating in magnetic zenith (Senior et al. 2012).

C5.1-0026-18 THE 3D DISTRIBUTION OF ARTIFICIAL AURORA INDUCED BY HF RADIO WAVES IN THE IONOSPHERE

Andreas Kvammen, akv020@post.uit.no University of Tromso, Tromso, Norway Björn Gustavsson, bjorn.gustavsson@uit.no University of Tromsø, Tromsø, Norway Tima Sergienko, tima.sergienko@irf.se

University of Tromsø, Tromsø, Norway

We present 3D volume emission rate estimates of artificial aurora in the ionospheric F-layer, induced by high frequency (HF) radio waves from the EISCAT heating facility. Simultaneous imaging of the artificial aurora was done at four separate ALIS stations, permitting tomographylike 3D auroral reconstruction in the enhanced atomic oxygen emissions at 5577 Å (green), 6300 Å (red) and 8446 Å (infra-red). Inspection of the aurora models suggest that the distribution of energized electrons are less extended in altitude than predicted by transport simulations of energized electrons. We propose that an anisortopic electron acceleration, with an extended electron acceleration distribution perpendicular to the magnetic field, can explain the resulting 3D volume emission rates.

C5.1-0027-18 RECENT (2010-2017) STUDYING OF ARTIFICIAL AIRGLOW AT THE SURA FACILITY (SHORT REVIEW)

A short review of the investigations of the artificial airglow in the red (630 nm) and green (557.7 nm) lines of atomic oxigen obtained at the SURA facility in 2010-2017 is presented. The attention is payed to the following.

Excitation of magneic field aligned bands (strata) in the red line emmission registered by CCD camera.

Excitation of the redline artificial emission in the magnetic zenith independently on the pump wave incident angle.

Dependence of the arthificial airglow brightness on the ratio between the pump wave frequency anf the 4th electron gyrohamonic.

Studying spatial characteristics of the red line (630 nm) artificial airglow generations region By be-static registrations with CCD cameras.

Suppression and following recovery of the red line airglow background during ionospheric plasme heating.

Correlation ot the total electron content of the ionosphere spatial behavior on the GPS signal path and artificial airglow brightness at 630 nm.

C5.1-0028-18 CORRELATION OF TOTAL ELECTRON CONTENT OF THE IONOSPHERE SPATIAL BEHAVIOR ON THE GPS SIGNAL PATH AND ARTIFICIAL OPTICAL EMISSION IN THE RED LINE (630 NM) OF THE ATOMIC OXYGEN AT THE "SURA" FACILITY.

Results of simultaneous measurements of the ionosphere total electronic content (TEC) on the GPS signal path and artificial airglow of the ionosphere in the red line of atomic oxygen ($\Lambda = 630$ nm) during HF pumping of the ionosphere by the "Sura" heating facility radiation are presented.

Totally during 5 years we had only 5 nights of lucky experimental conditions: the satellite passed over the "Sura" facility antenna pattern when the sky were clear and ionosphere critical frequency exceeded the pump wave frequency. The latter condition is needed for effective excitation of plasma waves, providing the electron acceleration until the excitation levels of the ionosphere neutral atoms (the O1D for the red line of the oxygen). The former conditions is necessary for the airglow registration.

GPS receiver and optical device (CCD camera S1C/079-FP(FU)) were situated close (<500 m) to each other and to "Sura" facility. It was established that when the signal propagation path 'navigation satellite - GPS receiver' intersected a spot of the artificial airglow, maximum brightness of the latter on the line of optical device sight on the navigation satellite was observed in the region of the TEC minimum.

C5.1-0029-18 OBSERVATION OF THE LOWER IONOSPHERE C-REGION USING ARTIFICIAL PERIODIC IRREGULARITIES CREATED BY THE SURA HEATING FACILITY

Nataliya V. Bakhmetieva, nv_bakhm@nirfi.unn.ru

Lobachevsky State University of Nizhni Novgorod, Nizhni Novgorod, Russia

We present some results of the observation of the ionospheric C-region which is developing at altitudes below the normal D-region height. In other words, we observed the stratification of the D-region. Our observations are based on measurements of the amplitude and the decay time of the signal scattered by artificial periodic irregularities that were created by the power transmitters of the SURA heating facility (56,1 N; 46,1 E). APIs are formed by the powerful standing radio wave produced by interference of the incident wave and reflected one from the ionosphere. In the F-region the ponderomotive force causes the API formation and relaxation processes near the altitude of the power wave reflection. In the E-region they are caused by the ambipolar diffusion. In the D-region APIs are caused by the temperature dependences of the attachment rate of electrons with oxygen molecules during three-body collisions (V.V.Belikovich, E.A.Benediktov, A.V.Tolmacheva, N.V.Bakhmet'eva. Ionospheric Research by Means of Artificial Periodic Irregularities – Katlenburg-Lindau, Germany. 2002. Copernicus GmbH. ISBN 3-936586-03-9). Irregularities disappear after the heating turn off. Ionosphere diagnostics bases on the API relaxation (or decay) stage by their pulse sounding. Amplitudes and phases of the API back scattered signals are measured. For the first time we observed the D-region stratification in April, 2004 and in September, 2005. It turned out that the dependence of the amplitude of the scattered signal vs. altitude had two maxima. One of them was located in altitudes of 62-64 km. The altitude of the second maximum was in the region of 72-76 km while the API relaxation time changed with altitude in the usual way. We assume that the lower maximum of the amplitude is associated with the appearance of the C-layer at these heights. Our long-term API observations showed that in summer the amplitude of the scattered signal had one maximum at altitudes of the D-region about 74-78 km. Since the amplitude of the signal is proportional to the electron concentration, this allows us to assume that its minimum is due to a minimum in the electron density profile. At first, we believed that the C-region exists only at certain times of the year, for example, in the spring and in the autumn possibly. However, our recent observations in 2014-2017 have shown the C-region exists in the summer, too. We observed the stratification of the D-region before the sunset and the sunrise. Our observations demonstrate that APIs are a good tool for the observation and the investigation of the D-region stratification.

C5.1-0030-18 ARTIFICIAL IONOSPHERIC IRREGULARITIES INVESTIGATIONS WITH RAPID RUN IONOSONDE

Kamil Yusupov, kamil.usupov@kpfu.ru Kazan Federal University, Kazan, Russia Takashi Maruyama, tmaru@nict.go.jp

Natl. Inst. of Info. and Comm. Tech., Tokyo, Japan Adel Akchurin, adel.akchurin@kpfu.ru

Kazan Federal University, Kazan, Russia Ruslan Sherstyukov, sherksu@mail.ru Kazan Federal University, Kazan, Russia

Powerful HF radio emission to the Earth's ionosphere can be a reason of complex phenomena, which leads to the generation of artificial ionospheric turbulence. One of the most important components of turbulence is artificial ionospheric irregularities with a transverse dimension from a fraction of a meter to ten or more kilometers. The investigations of their spectral and dynamic characteristics makes possible to study the instabilities properties caused by the powerful radio wave and to study the features of dynamic processes in the ionosphere, and also to determine the possible influence of artificial irregularities to the different ranges radio waves propagation. Therefore, in May 2010, a few heating experiments were carried out at the SURA heating stand. The experiments were carried out during several days at the day and evening hours. The ionosphere disturbance was performed by transmitters with power of 150/180/160 kW. The radio waves had next properties - frequency of 4.7 MHz, repetition rate - 15/3/12 seconds, pulse durations - 20/30/16 ms and extraordinary polarization. Observation of generated irregularities occurred at a distance 170 km from the SURA stand at the observatory of Kazan Federal University (near Kazan) with ionosonde Cyclone. The control system of the ionosonde was set to the fast mode of ionograms recording (1 ionogram per minute), which allowed observing the temporal and height dynamics of excited artificial ionospheric irregularities. A possible mechanism of the observed effect is discussed.

The work is performed according to the Russian Government Program of Competitive Growth of Kazan Federal University

The first results of two-dimensional TEC perturbation mapping to investigate the artificial plasma perturbations caused by powerful HF radiowave emitting of the ionosphere are presented. We analyze the results of measurements while SURA heating in the daytime between 14:45 and 17:30 UT on October 1, 2016 with a 15-minute emitting interval and 15-minute pause interval. To observe the ionosphere modification the dense GPS/GLONASS receiver's network was used. It was found that heating of the ionospheric plasma by powerful radio waves is able to effect on characteristics of natural TIDs, e.g. increasing their amplitude and wavelength.

C5.1-0033-18 THE E-REGION DISTURBANCES UNDER THE INFLUENCE OF THE POWERFUL HF RADIO EMISSION

Nataliya V. Bakhmetieva, nv_bakhm@nirfi.unn.ru

Lobachevsky State University of Nizhni Novgorod, Nizhni Novgorod, Russia

We present results of new experimental researches of artificial disturbances of the E-region of the ionosphere and its irregular structure during the HF heating period. Experiments have been carried out on base of the SURA heating facility (56.1 N; 46.1 E) in 2014-2017. Experiments were carried in the morning, afternoon and evening hours LT. The probing of the artificial disturbed E-region were carried out at two observation sites. One of them was located near Vasil'sursk 1 km from the SURA facility and the other site was located at the observation point of Kazan State University (55.85 N; 48.8 E) from 170 km to the East. Pumping time was varied from 5 s to 15 min. Antenna of the SURA heating facility was pointed at zenith, or was inclined at 12º to the south in the magnetic zenith direction. The disturbed region of the ionosphere in Vasil'sursk was probed by the vertical sounding technique using the partial reflexions radar at the frequency of 2.95 usually. Sometimes ionospheric sounding was conducted alternately at two frequencies 2.95 and 4.7 MHz. For the oblique sounding of the disturbed region the modied ionosond Cyclon-M operated at ten frequencies from 2.01 to 6.51 MHz was used at the Kazan site. Under modification of the ionosphere by O-mode and sometimes by X-mode of the pumping wave of the SURA facility at frequencies range of 4.3, 4.7 and 5.6 MHz with EPR of 50-120 MW artificial disturbances of the probe signal were obtained. On many heating sessions simultaneous variations of the probing partial reflection signals in Vasil'sursk and backscattered signals in Kazan site were observed at the height at 40-120 km below the reflection height of the pumping wave. These observations were correlated with the pumping periods of the SURA facility. Observation results showed that perturbations of the E-layer of the ionosphere and the lower part of the layer F1 influenced on probe wave at the frequency of 2.95 MHz the most likely. The growth of the electron density in the lower ionosphere during the heating period and an evolution of its irregular structure could provide the emergence of additional signals during pumping period. Estimates made on the base of the electron density profile recovered from the ionograms of the vertical sounding showed that these signals could appear due to an increase of the electron density of 5-10% in the pumping session. Such an increase of the electron density corresponds to theoretical estimations of the heating of the E-region by passing radio waves with EPR about 80-100 MW. Additional (in Vasil'sursk) and backscattered (in Kazan) signals were often received in two point located in the distance of 170 km simultaneously. The artificial disturbances propagated at altitudes of 40-120 km downward from the height of the reflection of the powerful waves that is significantly below the height of the resonant interaction of highpower radio waves with ionospheric plasma. They are probably related to the development of irregularities and the perturbation of the electron density in the E-region.

Acknowledgments. The work is supported by Russian Foundation for Basic Research under grants No. 18-05-00293.

C5.1-0034-18 FEATURES OF AII GENERATION UNDER X-MODE HEATING.

Ilya Bolotin, g-bolt@bk.ru

University of Nizhni Novgorod, Nizhny Novgorod, Russia Vladimir Frolov, frolov@nirfi.unn.ru

University of Nizhni Novgorod, Nizhny Novgorod, Russia

The absence of resonant interaction between the ionospheric plasma and the powerful HF radio wave of extraordinary (X) polarization, should limit the excitation of artificial ionospheric irregularities (AII). In the report we present new experimental results on the effects observed under X-mode heating of the mid-latitude ionosphere. During the X-mode heating at the SURA heating facility the AII in a wide range of their scales were investigated. The decameter AII (with l = 10 - 50 m), which are well excited during O-mode heating near a pump wave reflection level in the ionosphere disturbed volume (IDV), were never detected during X-mode heating. This can be explained by the fact that the generation of decameter AII is determined by the thermal (resonance) parametric instability. The middle-scale AII (l = 50 - 200 m), which were detected in the IDV, demonstrated 6 dB lower intensity comparing to the O-mode heating. This can be explained by the fact that the generation of such AII depends on both resonant and self-focusing effects [1]. The large-scale AII (l > 200 m), which were detected in the IDV by its sounding by means of GPS satellite signals, also demonstrated 10 dB lower intensity comparing to the O-mode heating [1].

HF heating at frequencies slightly higher than multiples of the electron gyrofrequency leads to generation of the super-small-scale (l=10-20 cm) artificial ionospheric irregularities (SSSI) in the plasma density [1]. In the report we present new experimental results on their features. During the first group of experiments for SSSI detection the method of ionosphere disturbed volume (IDV) sounding by the signals from GPS satellites was used. During the gyroharmonic ionosphere pumping with the schedule [10s - on, 10s - off] the appearance of TEC variations with the period consistent with the heating facility operation schedule was observed. The strongest variations were registered near the area of the magnetic zenith for the pump wave. The obtained results allow concluding that the generation of SSSI is more efficient in the magnetic zenith area. Another group of experiments was based on the fact that the value of spectrum widening of the signals scattered from the decameter irregularities depends heavily on the location of the scattering surface in the IDV and on the fact whether it passes through the magnetic zenith [2]. The widening itself, according to [1], is connected with generation of SSSI inside the decameter irregularities. The results of processing of scattered signals received in the observation point for eight measurement series demonstrated that together with the increase of the scattered signal power, more spectrum widening was detected. Taking into account that the increase of scattered signal intensity indicates the approaching of the scattering surface to the magnetic zenith, we can conclude that both widening of the scattered signal spectrum and efficiency of SSSI generation have their maximum in the magnetic zenith area.

C5.1-0036-18 ENERGETIC ELECTRON PRECIPITATION INDUCED BY THE SURA FACILITY

Aleksandr Riabov, ryabovalol@yandex.ru NIRFI, Nizhni Novgorod, Russia Vladimir Frolov, frolov@nirfi.unn.ru

University of Nizhni Novgorod, Nizhny Novgorod, Russia

In the report experimental results regarding to features of energetic electron precipitation HFinduced by means of O-mode powerful radio waves emitted in the ionosphere by the SURA heating facility are presented. Registration of energetic electrons in the energy range from 70 keV to about 0.8 MeV were made in 2005 - 2010 using the IDP spectrometer placed on the French micro satellite DEMETER [1]. The obtained results have been allowed to determine the following features of such precipitation. 1) The precipitation was observed only when a pump wave frequency was below the F2 region critical frequency, f0F2, and ionosphere modification was conducted under evening or nigh conditions with the effective radiation power higher than 40 MW. 2) The precipitation was registered along a satellite orbit from 300 km to the south to 700 km to the north from the center of the HF-disturbed magnetic flux tube resting on the ionosphere disturbed volume, in which strong plasma perturbations are excited due to developing parametric instabilities. The maximal flux of the energetic electrons is observed in the HF-disturbed magnetic flux tube, sometimes the presence of a plasma density duct was the cause of increasing the value of the electron flux. 3) In most cases the precipitation of energetic electrons with E 125 keV and the flux value of about 90 (part/seccm2srkeV)were registered. The work of V.L. Frolov was supported by the RFBR grant 17-05-00475. The work of A.O. Ryabov was supported by the Russian Education Ministry grant 3.1844.2017.

C5.1-0037-18 EXCITATION OF ARTIFICIAL PLASMA TURBULENCE IN THE OUTER IONOSPHERE

Aleksandr Riabov, ryabovalol@yandex.ru NIRFI, Nizhni Novgorod, Russia Vladimir Frolov, frolov@nirfi.unn.ru

University of Nizhni Novgorod, Nizhny Novgorod, Russia Ilya Bolotin, g-bolt@bk.ru

University of Nizhni Novgorod, Nizhny Novgorod, Russia

In the paper experimental results regarding to features of plasma perturbations HF-induced in the outer ionosphere are presented. For ionosphere modifications O-mode HF radio waves radiated by the SURA facility were used. Testing of plasma disturbances were made using the onboard equipment of three European SWARM satellites flying at heights of 450 - 500 km. Experiments were conducted in 2016 - 2017 [1]. The obtained results allowed formulating necessary conditions for the excitation of the plasma density and temperature perturbations. They are: a) pumping has to be carried out under evening and nigh conditions; b) a pump wave (PW) frequency (f0) has to be lower than the F2 region critical frequency, f0F2; c) the effective radiation power has to be higher than 40 MW; d) PW reflection height has to be higher than 200 km. It has been found that strong plasma density and temperature variations (up to 10%) were observed at altitudes of 450 - 500 km. It was registered the enhancement of plasma temperature on the average but was not observed plasma density structures like the ducts, which were revealed at altitudes of 660 km in SURA-DEMETER and HAARP-DEMETER experiments. The work of A.O. Ryabov was supported by the Russian Education Ministry grant 3.1844.2017. The work of V.L. Frolov was supported by the RFBR grant 17-05-00475.

In March 2011 a set of experiments at the HAARP facility were performed aimed to study of artificial ionospheric turbulence using stimulated electromagnetic emission (SEE) measurements at different incident angles of the pump wave on the ionosphere. The main attention was paid to zenith (vertical) and magnetic zenith (MZ, along the magnetic field, the inclination of 14.2° to the South in the magnetic meridian plane) directions of the pump beam radiation. In addition, the experiment with a change of the pump beam incident angle from α = 28° (north) to α = +28° (south) in the magnetic meridian plane with a step of 7° was performed. For each angle, the pump wave frequency f0 was swept in the range 5930 5730 5930 kHz (near the 4th harmonic of the electron cyclotron frequency 4fc) during 80 s. SEE receiving was carried out at three sites situated along the magnetic meridian at 113 km (A), 82 km (B) and 11 km to the south from the HAARP facility. The results are as follows:

Under low duty cycle of pumping (pulse duration ≤ 50 ms) it was established that during vertical impact, the SEE spectrum has a "continuum" type in the range 80 < Δf = f0 fSEE < 0 kHz without the any prominent special features. During MZ pumping, after 20 ms a number of narrow equidistant peaks appear in the SEE spectra at frequency shifts

Δf = 8, 16 kHz more pronounced for more remote receiving sites. These offsets are close to the first and second harmonics of the lower hybrid frequency in the region of the pump wave interaction with the ionospheric plasma. At the site C (near the facility), the SEE intensity during vertical pumping exceeded the intensity during the MZ pumping by 3-4 dB, while in the site A, mostly remote from the facility, there is an reverse picture:

the SEE intensity during the MZ pumping is larger by ~ 10 dB.

During pump frequency sweeps the intensity of the upper-hybrid related downshifted maximum (DM) SEE feature increased monotonically from the minimum at fDM = 4fc which varied from 5.73 till 5.74 MHz at different incident angles till maximum at f0 > 5.9 MHz. The DM intensity at the gyroharmonic was maximum at the MZ pumping. The broad upshifted maximum (BUM) intensity peak occurred at the ΔfBUMpeak 60 kHz for the incident angle α = 28° and then approached to the pump wave frequency with motion of the incident angle to the South. Its frequency shift achieved ΔfBUMpeak 5–

25 kHz at α = +(14°–28°). With an increase of the pump beam inclination to the north, the SEE intensity decreased at all receiving sites, especially noticeable in the site A. At the maximum inclination to the south, the SEE intensity at the site A increased.

During the MZ pumping, when the additional ionization layer appeared and manifested in SEE spectra as an additional "dynamic" BUMD feature [1], some weakening of the other upper hybrid related SEE features was observed.

This work was supported by the RSF grant 17-72-10181 and by RFBR grant 16-02-00798.

C5.1-0039-18 MODELING OF THE DYNAMICS OF RADIO WAVES ABSORPTION DUE TO ELECTROMAGNETIC DRIVE OF STRONG LANGMUIR TURBULENCE IN SMOOTHLY INHOMOGENEOUS PLASMA

Andrey Kochetov, kochetov@appl.sci-nnov.ru

Institute of Applied Physics of RAS, Nizhny Novgorod, Russia

Experiments on the investigation of self-action of radio wave incident on the ionosphere from ground base transmitter at the so-called Langmuir effect stage initiate this study. Emphasis is placed on the influence of "self-sustained" turbulent plasma radio wave absorption excited in the smoothly inhomogeneous plasma layer with unperturbed linear density profile under the wave amplification in resonance region. Absorption and reflection indexes dynamics is obtained numerically depending on the intensity of the pumping wave and dumping peculiarities. Calculations of "soft" and "hard" regimes of anomalous absorption development and hysteretic modes with the differing several times "on" and "off" thresholds are carried out. The study and the obtained results could served as the basis of more adequate and thorough simulation for the interpretation of experimental Langmuir stage observations.

C5.1-0040-18 DUAL ION-LINE STRUCTURES OBSERVED AT THE HAARP IONOSPHERIC MODIFICATION FACILITY.

Brenton Watkins, watkins@usa.net

University of Alaska Fairbanks, Fairbanks, Alaska, United States
Christopher Fallen, ctfallen@alaska.edu

University of Alaska Fairbanks, Fairbanks, Alaska, United States

We present results for experiments using high-power O-mode HF waves generated by the HAARP ionospheric modification facility. The data pertain to ion-line data resulting from the parametric decay instability (PDI). The HF interaction with the F-region ionosphere occurs near, but below, the HF reflection height. For the upgoing HF electromagnetic wave the PDI results in a forward scattered Langmuir wave and a backscattered ion-acoustic wave. After the subsequent reflection the down-going HF wave again participates in the PDI resulting in a down-going Langmuir wave and upgoing ion-acoustic wave. A UHF diagnostic radar was used to detect the HF-enhanced ion-acoustic waves. Since the diagnostic radar has only one receiver it was not possible to additionally detect Langmuir waves. In most cases the up and down-going plasma waves occur at approximately the same altitude. However we show that in many cases the up and down-going ion-acoustic waves occur at two separate heights separated by as much as 5-7 km. We suggest this height difference results from wave propagation effects near the reflection height. Doppler spectral analysis of the scattered radar signals indicate that the plasma wave intensity is greater for the height layer with downward ion-acoustic waves, corresponding to the upgoing HF electromagnetic wave. This altitude layer with stronger wave scattering may occur above or below another layer with weaker wave activity that corresponds to the downward HF electromagnetic wave after reflection. These observations are consistent with many past ion-line observations at HAARP and other facilities that show the downward travelling HF-enhanced ion-acoustic waves generally show greater scattered power than upward waves. The new aspect of these observations is the frequently observed separation in altitude of the two layers, and we have found that this behavior depends on the particular HF frequency used. For example we show from an experiment that stepped in 10kHz increments of the HF frequency 4.10, 4.20,4.30,4.40,4.50 MHz that the ion-lines separated into two distinct height layers only for the 4.20 and 4.50 MHz cases. In some examples the height layer with upgoing ion-acoustic waves is extremely weak or non-existent. We suggest that the weaker or non-existent PDI wave structures that correspond to the downward electromagnetic wave after reflection likely results when the power of the HF wave falls below the threshold for the PDI.

C5.1-0041-18 ELECTRON ACCELERATION BY PARAMETRIC DECAY INSTABILITY AND LANGMUIR TURBULENCE IN IONOSPHERIC HEATING

Moran Liu, moranliu@whu.edu.cn Wuhan University, Wuhan, China Chen Zhou, chenzhou@whu.edu.cn Wuhan University, Wuhan, China

Ionosphere modified by powerful radio transmitters from ground has been observed in the 1970s. Since then many phenomena had been observed and many physical mechanisms are proposed. Parametric decay instability (PDI) is an important process in ionospheric heating, which are proved to be excited by HFPLs and HFILs observed in spectra of ISR. Langmuir waves and ion-acoustics waves are excited in PDI process and Langmuir turbulence (LT) could be generated. The electrons acceleration, which could lead to enhanced airglow and artificial ionized layer in ionospheric heating, is also related to PDI process and LT. Electron acceleration in ionospheric heating has been an active topic for many years. In this study, we investigate electron acceleration due to Langmuir turbulence in two different approaches. In the first approach, excitation of parametric instability (PDI) and subsequent Langmuir turbulence (LT) is investigated by a two-fluid Zakharov model. Electron acceleration is described by a FokkerPlanck model with an effective diffusion coefficient calculated from Langmuir wave spectrum. The results demonstrate that both PDI process and LT could accelerate plasma electrons but the diffusion coefficient in LT is larger than PDI process, which lead to the electrons acceleration more effectively in LT than in PDI process. The electron temperature increase from 0.2 eV to 5 eV according to the simulation results. In another approach, we investigate the electron acceleration process by using a direct kinetic Vlasov-Poisson system. Simulation results present the evidence of generation of Langmuir cavitons and corresponding electric field maxima at the initial stage. Collapse of the cavitons and cascade of spectra are then found in the simulation results. At this stage, the electrons were generally accelerated form 0.2 eV to 2.7 eV. The nonlinear saturation of temperature is presented in the last stage. Last but not least, we will briefly discuss the consistency and difference between these two approaches.

C5.1-0042-18 BRAZILIAN SUBORBITAL LAUNCH OPPORTUNITIES FOR SCIENTIFIC EXPERIMENTS AND RESEARCH

Carlos Eduardo Quintanilha, eduardo.quintanilha@aeb.gov.br Agencia Espacial Brasileira AEB/MCTI, Brasilia DF, Brazil

The Brazilian Space Program has, for a long time, been supporting scientific research developed by research centers, students and universities interested in suborbital rocket launches experiments. The record shows that, the first space activities held in Brazil about Ionospheric research with sounding rockets are dated from as far as 1960. Those activities were initiated and carried out at Centro de Lançamento da Barreira do Inferno (CLBI) almost sixty years ago. Scientific probes were used to collect data from space with dedicated instrumentation and experiments set perform specific scientific experiments. The first Brazilian probe, developed by the Instituto Nacional de Pesquisas Espaciais (INPE), was launched in 1965. To realize these launches, the Instituto de Aeronáutica e Espaço (IAE) first developed a family of four sounding rockets - SONDA I, SONDA II, SONDA III, SONDA IV. More advanced space vehicles have been under planning and development such as, the VS-30, the VSB-30, the VS-40, and the VS-43 vehicles, thus building and increasing the capacity to take more heavy and complex space probes to orbit. Two major solid propellant rocket engines, the S30 and the S31, can be assembled together to be used to perform suborbital flights to study the Earths high altitude atmosphere. Those motors can also be combined with the American artifact the Orion vehicle to assemble a vehicle suitable to a required mission and performance. By 2020 there will be a VSB-30 launch opportunity which could carry a scientific probe and experiments from interested researches. In this work, the author reports achievements obtained so far and the future vehicles and platforms that will be available for suborbital launches. Also, it is presented the planning for future high atmospheric sounding rocket launches and directions on how to join these initiatives.

C5.1-0043-18 SPECTRAL SIGNATURES RECORDED BY WHISPER SOUNDER MODE ON BOARD CLUSTER2 MISSION INSIDE DIFFERENT MAGNETOSPHERE REGIONS: PLASMA FREQUENCY DETERMINATION

The Wave of High frequency and Sounder for Probing of Electron density by Relaxation (WHISPER) performs the measurement of the electron density on the four satellites of the CLUSTER2 mission. The two main purposes of the WHISPER experiment are to record the natural waves and to make a diagnostic of the electron density using the sounding technique, the various working modes and the fourier transforms calculated on board provide a good frequency resolution obtained in the bandwidth 2-80 kHz and a well instrumental adaptability to determine the electron density in various plasma. In this presentation, we focus our attention to the active mode when WHISPER is working as a sounder. Cluster2 orbits cross various plasmas around the earth with a weak or a strong magnetic field (solar wind, magnetosheat, cusp, aurora zones, magnetotail etc). Plasma response is strongly different following region. Spectra exhibit numerous resonances where it is difficult to recognize the plasma frequency .We shall show the characteristics features in each region and we shall describe the methods to identify observed resonances as electron gyro frequency and harmonics, plasma frequency, upper-hybrid frequency and Bernstein modes.

C5.1-0044-18 ACTIVE EXPERIMENTS WITH THE DSX MISSION

Air Force Research Laboratory, Kirtland AFB, New Mexico, United States

This year, the Air Force Research Laboratory will launch its Demonstration and Science Experiments (DSX) mission to investigate wave-particle interactions, to characterize the distribution of natural and man-made VLF waves, and to map the radiation and plasma environment in medium Earth orbit (MEO). Active experiments will be carried out with onboard VLF transmitters and receivers, the Loss Cone Imager (LCI) particle detector, and the Low-Energy Electro-Static Analyzer (LEESA) to investigate VLF transmission, propagation, and interaction with charged particles. DSX will also observe the natural wave population and explore the basic physics of an antenna in a plasma. We will describe the capabilities of these instruments, science plans, and opportunities for collaboration.

C5.1-0045-18 PARAMETRIC EXPERIMENTS IN MITIGATING SPACECRAFT CHARGING VIA PLASMA CONTACTOR

Grant Miars, gmiars@umich.edu

University of Michigan, Ann Arbor, Michigan, United States Omar Leon, omarleon@umich.edu

University of Michigan, Ann Arbor, Michigan, United States Brian Gilchrist, gilchrst@umich.edu

University of Michigan, Ann Arbor, Michigan, United States Gian Luca Delzanno, delzanno@lanl.gov

Los Alamos National Laboratory, Los Alamos, United States Federico Lucco Castello, federico.luccocastello@gmail.com Royal Institute of Technology, Stockholm, Sweden

Spacecraft charge mitigation in tenuous space plasmas can be a difficult problem. It is especially difficult and essential during active experiments that feature ion or electron beams, as collection from the ambient plasma is often insufficient to balance the beam emission current. For electron emission, the use of a plasma contactor that emits an ionized gas is the only practical option. A series of parametric chamber experiments were completed to address how spacecraft charge mitigation using a plasma contactor may scale in tenuous space plasmas. Experiments focus on how spacecraft potential scales with beam emission current, contactor current (the rate at which the contactor generates quasi-neutral plasma), and contactor propellant mass (ion mass). These experimental results are compared to scaling laws derived via Curvilinear Particle-In-Cell (CPIC) simulations for further validation and physical insight. Implications for enabling future active experiments such as the Connections Explorer mission are discussed.

C5.1-0046-18 EXPERIMENTAL INVESTIGATION OF COLLIDING PLASMA FLOWS USING PULSED POWER DEVICE

Andrew Hamilton, andrew.hamilton.8@us.af.mil AFRL, WPAFB, Ohio, United States

We are investigating colliding plasma flows in which the opposing magnetic fields are frozen in the flows. The magnetized plasma expands radially away from a dual-wire explosion until collision in the stagnation region, between the wires. This region exhibits characteristics that are highly suggestive of magnetic reconnection. To better understand this process and its relation to astrophysical events such as CME's from our sun and colliding winds in binary star systems, the Plasma Physics and Sensors Laboratory, located at Wright-Patterson AFB, developed an experimental setup to study the colliding flows using wire explosion techniques in a controlled setting. Fine metallic wires are placed in a parallel configuration inside our vacuum chamber, and a pulsed power source is used to deliver enough energy to the wires to expel their material in an ionized and gaseous state. We have verified through light emission experiments that there are two distinct time phases that represent this process. The first time phase is characterized by interpenetration and mixing of the leading parts of the flows comprising of hot and fully ionized coronas. This initial corona is primarily composed of light ions and electrons of which had naturally formed on the porous surface of each wire. The colliding coronas produce a collisionless shock in the stagnation region generating weak light emission. We believe these observations of the initial time phase, lasting about 250 ns, are due to wave turbulence in the stagnation region. In the second time phase, the much cooler and denser gas emanating from the wire core provide the separate regime. During this second phase, from 250 750 ns, the weakly ionized gas is driven towards the stagnation region resulting in a collisional shock. Here, intense light emission is observed due to the collisions and deceleration of the gaseous particles. We will present experimental results and analysis of the colliding flows from Al wire explosions. Spatial and temporal observations of light emissions are recorded with an ICCD and simultaneously encompass an end-on and perpendicular view of the stagnation region. Spatial and temporal observations of the electron density will be presented through interferometry. Thermal fluctuations in the stagnation region are obtained with spectroscopy and line ratio analysis.

C5.1-0047-18 BEAM-PLASMA COUPLING PHYSICS IN SUPPORT OF ACTIVE EXPERIMENTS

Kateryna Yakymenko, kyakymenko@lanl.gov

Los Alamos National Laboratory, Los Alamos, New Mexico, United States Gian Luca Delzanno, delzanno@lanl.gov

Los Alamos National Laboratory, Los Alamos, United States Vadim Roytershteyn, vroytersh@gmail.com

Space Science Institute, Boulder, Colorado, United States

The recent development of compact relativistic accelerators might open up a new era of active experiments in space, driven by important scientific and national security applications. Examples include using electron beams to trace magnetic field lines and establish causality between physical processes occurring in the magnetosphere and those in the ionosphere. Another example is the use of electron beams to trigger waves in the near-Earth environment. Waves could induce pitch-angle scattering and precipitation of energetic electrons, acting as an effective radiation belt remediation scheme.

In this work, we revisit the coupling between an electron beam and a magnetized plasma in the framework of cold-plasma theory. We show that coupling can occur through two different regimes. In the first, a non-relativistic beam radiates through whistler waves. This is well known, and was in fact the focus of many rockets and space-shuttle campaigns aimed at demonstrating whistler emissions in the eighties. In the second regime, the beam radiates through extraordinary (R-X) modes. Nonlinear simulations with a highly-accurate Vlasov code support the theoretical results qualitatively and demonstrate that the radiated power through R-X modes can be much larger than in the whistler regime. Test-particle simulations in the wave electromagnetic field will also be presented to assess the efficiency of these waves in inducing pitch-angle scattering via wave-particle interactions. Finally, the implications of these results for a rocket active experiment in the ionosphere and for a radiation belt remediation scheme will be discussed.

C5.1-0048-18 A COMPARISON OF PARAMETRIC INTERACTIONS FOR THE NON-LINEAR GENERATION OF WHISTLER WAVES

Nathan Zechar, nzechar@riversideresearch.org Riverside Research, Beavercreek, Ohio, United States Vladimir Sotnikov, sotnikov@gmail.com

Air Force Research Laboratory, WPAFB, Ohio, United States

We report on experiments utilizing the simultaneous generation of varying plasma waves in the afterglow of a cold-magnetized helium plasma for the purpose of the non-linear excitation of whistler waves. Two cases which non-linearly excite whistler waves are compared. The first scenario employs electrostatic lower-oblique-resonance waves (LOR) with slightly offset frequencies. The second scenario applies an electrostatic ion-acoustic wave (IAW) with a LOR wave. Plasma is generated using a high-density helicon plasma source in a one meter long, half meter diameter, cylindrical chamber. The spatial and temporal data of the electromagnetic and electrostatic components of the plasma waves are then captured with in-house developed diagnostics such as Langmuir probes, B-dot probes, and dipole probes. Obtained wave spectra and observed time domain data will be analyzed and reported.

C5.1-0049-18 HARMONICS OF ELECTROSTATIC ION CYCLOTRON WAVES IN THREE COMPONENT MAGNETISED PLASMA

Indian Institute of Geomagnetism, Navi Mumbai, India Gurbax Singh Lakhina, gslakhina@gmail.com

Indian Institute of Geomagnetism, Navi Mumbai, India

Electrostatic ion cyclotron (EIC) waves and their instability (electrostatic ion cyclotron instabilityEICI) have been observed in various regions of magnetosphere, by various satellites, e.g., Cluster, FAST and THEMIS, as well as in laboratory plasmas. EIC waves propagate nearly perpendicular to ambient magnetic field, with a small finite wave number along ambient magnetic field. EIC waves have gained importance as they provide perpendicular heating of the ions in the magnetosphere. EICI pertaining to the higher harmonics of proton and Helium cyclotron modes is investigated in a three-component magnetized plasma consisting of beam electrons, protons and doubly charged Helium ions. Fewer harmonics of proton cyclotron waves with decreased growth rates and higher number of Helium harmonics with decreased growth rates can be seen with increase in the angle of propagation. Except for one particular case where second harmonic also become unstable, in most of the scenario only odd Helium harmonics are excited. The growth rate of the instabilities enhances with the increase in number density of ions, however, temperature of ions has adverse effect on the growth rate. In addition to this, as the electron beam speed is increased, the number of harmonics as well as peak growth rate increases. Our results are relevant to laboratory and space plasmas where field-aligned currents exist.

C5.1-0050-18 KINETIC ALFVEN WAVES DRIVEN BY ION BEAM AND VELOCITY SHEAR

Krushna Chandra Barik, kcbarik17@gmail.com

Indian Institute of Geomagnetism, Navi Mumbai, India Satyavir Singh, satyavir@iigs.iigm.res.in

Indian Institute of Geomagnetism, Navi Mumbai, India Gurbax Singh Lakhina, gslakhina@gmail.com

Indian Institute of Geomagnetism, Navi Mumbai, India

A plasma model for the excitation of the Kinetic Alfvén Wave (KAW) by the ion beam and velocity shear will be discussed. The three components model comprising of the cold stationary background ions, hot electrons and hot ion beams will be presented. A general dispersion relation is derived where all the three components are assumed to have drifting Maxwellian distributions and velocity shear. As a special case, the results with ion beam and ion velocity shear will be presented and applied to Earth's auroral regions where the kinetic Alfvén have been observed. It is found that in the presence both velocity shear ion beam are, they have to be opposite to each other in order to have a reasonable growth rate. The effect of other parameters such as ion beam density temperature is also discussed.

C5.1-0051-18 IONOSPHERE AS ASTROPHYSICAL DETECTOR: EXTRACTING SPECTRAL AND TIMING INFORMATION OF CELESTIAL TRANSIENTS USING VLF STUDIES

Sourav Palit, souravspace@gmail.com

Universidade Presbiteriana Mackenzie/CRAAM, São Paulo, Brazil Suman Ray, sumanray07@gmail.com

Gobardanga Hindu College, Gobardanga, India Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

The increased electron and ion densities at lower part of earth's ionosphere during astrophysical transient events, like solar flares are the combined effect of ionization by the soft X-rays and the recombination of the electrons and ions with neutrals. The rate of ionization and it's variation with altitude depend on the incident spectra. Hence the altitude variation of electron density values in lower ionosphere modulated by such sources should bear information on soft X-ray spectra of those events. We found that by analyzing the Very Low Frequency (VLF) amplitude modulation during different classes of solar flares we can uniquely determine the approximate soft X-ray spectra during the evolution of those flares. In addition, careful investigation of the peak time delay between the VLF signal amplitude and the transient lightcurve provides us important hints on the intensity and time evolution during the peaks of those events. Specifically, for solar flares uninterrupted monitoring of X-ray spectra is necessary to derive the information on time evolution of non-thermal electron acceleration, transport and interaction during flares in the solar atmosphere. Considering the limitations with space based satellite observations due to restricted window of the instruments to avoid saturation, our method of reconstruction of flare spectra from VLF data may provide us a continuous and uninterrupted mean of monitoring those events. Higher energy photons from flares (in hard X-rays) produce most of the ionization at much lower heights. The hard X-ray and gamma ray from extra-galactic transients like, SGR, GRB etc. penetrate even deeper in the atmosphere ionizing the molecules present there. With suitable means of observation of electron densities and proper extension of our deconvolution method for those heights, we should be able to extract information of hard X-ray spectra of solar flares and those of extra-galactic transients also. The outline is that the earth's atmosphere may be an excellent and ever-present gigantic detector of ionizing extra-terrestrial events with VLF and any other suitable means of detection of it's modulation in plasma properties in different parts of the atmosphere.

C5.1-0052-18 A NEW INTERPRETATION OF THE UPPERAND LOWER-FREQUENCY CUTOFFS OF LIGHTNING GENERATED NONDUCTED MAGNETOSPHERICALLY REFLECTED (MR) WHISTLERS: REMOTE SENSING OF MAGNETOSPHERIC PLASMA DENSITY AND COMPOSITION

Vikas Sonwalkar, vssonwalkar@alaska.edu

University of Alaska Fairbanks, Fairbanks, Alaska, United States Jacob Butler, jbutler12@alaska.edu

University of Alaska Fairbanks, FAIRBANKS, Alaska, United States Amani Reddy, areddy1@alaska.edu

University of Alaska Fairbanks, Fairbanks, Alaska, United States

Nonducted whistlers resulting from lightning and observed on a magnetospheric satellite appear on a spectrogram as a series of magnetospherically reflected (MR) traces with characteristic dispersion (time delay versus frequency) and upperand lower-frequency cutoffs. We explain the upperand lowerfrequency cutoffs of MR whistlers in terms of interior and exterior caustics associated with ELF/VLF waves injected from lighting into the magnetosphere [Dantas, 1972; Sonwalkar et al., 1994]. Caustics are the boundaries that define a region of space that is accessible to waves arriving from a certain source. In a smooth magnetosphere, the locations of the caustics depend on frequency, range of injection latitude, magnetospheric plasma density and composition, and any irregularities present in the magnetosphere (e.g. plasmapause or cross-L density drop-offs). At a given frequency, the accessibility of waves injected from lighting to a certain location in the magnetosphere is determined by the locations of interior and exterior caustics. This in turn determines the upperand lower-frequency cutoffs of MR whistlers observed in the magnetosphere. We demonstrate our new interpretation of MR whistler frequency cutoffs with the help of ray tracing calculations in a smooth magnetosphere. The previous works explained MR whistlers cutoffs in terms of Landau damping that requires the presence of hot electrons at specific energies [Thorne 1968, Bortnik et all., 2003] or propagation effects that require cross-L shell plasma density drop offs [Edgar, 1976]. Our explanation of MR whistler frequency cutoffs does not require the presence of hot electrons or density drop-offs, though either of these, if present, may play a role in the determination of frequency cutoffs. Ray tracing calculations show that caustics as well as MR whistler frequency cutoffs are strong functions of plasma composition (or $O^+/(H^+ + He^+)$ transition height) but are weak functions of plasma density. On the other hand, the dispersion of MR whistler traces is a strong function of the plasma density but is a weak function of plasma composition. This leads to a simple and efficient ray tracing inversion method to determine magnetospheric plasma density and composition from observed MR whistler dispersion and frequency cutoffs. This ray tracing inversion method has been demonstrated on case studies of whistlers observed on the

OGO 1 and Van Allen Probe (RBSP-B) satellites [Sonwalkar et al., 2017]. The results imply an important role that caustics may play in magnetospheric nonducted wave-particle interactions, and they highlight the possible role that ions may play in the physics of wave-particle interactions.

C5.1-0053-18 STUDY OF THE EFFECTS OF VARYING LOCATION OF LIGHTNING-INDUCED ELECTRON PRECIPITATION (LEP) EVENTS OVER A CHOSEN VERY LOW FREQUENCY (VLF) RADIO WAVE PROPAGATION PATH ON THE SIGNAL AMPLITUDE

Suman Chakraborty, suman.chakrabarty37@gmail.com Indian Centre for Space Physics, Kolkata, India Sourav Palit, souravspace@gmail.com

Universidade Presbiteriana Mackenzie/CRAAM, São Paulo, Brazil Sudipta Sasmal, meet2ss25@gmail.com

S.N. Bose National Centre for Basic Sciences, Kolkata, India

The lower layer of the Earth's ionosphere and the ground forms a waveguide that guides Very Low Frequency (VLF) radio waves over long distances without much attenuation. There may be various sources of such waves, both natural and man-made. When a lightning discharge occurs, it emits electromagnetic waves in all directions, the majority of which gets trapped within the earth-ionosphere waveguide. But a small portion of it enters the magnetosphere where it moves along the magnetic field lines in a whistler mode wave and interacts with the radiation belt electrons. As a result of such wave-particle interaction, some of the electrons get trapped within the ionosphere and they precipitate resulting in localized enhanced ionization. In the present study, our aim is to determine the effects of such lightning-induced electron precipitation (LEP) events on Very Low Frequency (VLF) signal amplitude. We analyzed the VLF data collected by Indian Centre for Space Physics (ICSP) for paths VTX-IERCOO and NWC-IERCOO. Both positive and negative shifts in amplitude are observed which are characterized by fast rise and exponential decay. For this, we calculated the ionization rate per ion pairs formed with altitude and then by using the D region ion chemistry model, we determined the electron density variation over ionospheric heights. We then used these electron density profiles in the well-known Long Wavelength Propagation Capability (LWPC) Programme to obtain the signal amplitude. Finally, we varied the location of such disturbance region over a chosen VLF path (transmitter-receiver) so that we can understand its effect on the signal amplitude. From our study, we found profound influence of the variation of the location of the disturbance region on the signal amplitude. We found that the maximum effect on the signal amplitude is obtained when the disturbance region is near the transmitter end while if it's near the receiver end, very little or no influence is imposed on the signal amplitude. Also, the location of the disturbance region is the key factor in determining the nature of shift, i.e., positive or negative of the signal amplitude and the spatial extent influences the degree of signal modulation.

C5.1-0054-18 QUANTITATIVE MODELING OF LOWER IONOSPHERIC RESPONSE DURING SOLAR X-RAY EVENTS: A PROPAGATING RADIO WAVE SIMULATION APPROACH

Tamal Basak, tamalbasak@gmail.com Amity University, Kolkata, India Sudipta Sasmal, meet2ss25@gmail.com

S.N. Bose National Centre for Basic Sciences, Kolkata, India

The surplus solar X-ray radiation during solar flares causes an enhancement of ionization in the lower ionospheric D-region and hence affects sub-ionospherically propagating Very Low Frequency (VLF) radio wave signal amplitude and phase. VLF signal amplitude and dynamic phase perturbation (ΔA) and amplitude time delay (Δt) (vis-á-vis the corresponding solar Xray as measured by GOES-15) of several VLF transmitters such as NWC/19.8 kHz, VTX/18.2 kHz etc. signals have been computed for solar flares. In the first part of the work, using the well-known Long Wave Propagation Capability (LWPC) technique, we simulated the flare induced excess amount of lower ionospheric electron density profile by amplitude perturbation method. Unperturbed D-region electron density is also obtained from simulation with the help of the 2-component exponential D-region model and compared with International Reference Ionosphere (IRI) model results. Further, in the second part, we compute the corresponding 'sluggishness' through Δt and effective electron recombination coefficient (αeff) analysis. We find that while Δt is anti-correlated with the flare peak energy flux (ϕmax) and the correlation factor is dependent on solar zenith angle values.

C5.1-0055-18 NUMERICAL MODELING OF LONG-PATH PROPAGATION CHARACTERISTICS OF VLF RADIO WAVES AS OBSERVED FROM INDIAN ANTARCTIC STATION MAITRI AND BHARATI

Long path VLF radio wave propagation has a distinctive feature that during its propagation it experiences large variations of solar irradiation and degree of ionization. The propagating waveguide modes and modal conversion is completely different that for shorter path (<3000 km). Study of radio signal characteristics in Antarctic region during summer period in the Southern Hemisphere gives us a unique opportunity to explore such interesting phenomena. In addition, there is an extra feature in this path during summer which is whole day presence of solar radiation and hence the D region in at least some sections of the propagation path. We present long-distance propagation characteristics of VLF signals transmitted from VTX (18.2 kHz) and NWC (19.8 kHz) from India and Australia respectively recorded simultaneously at Indian permanent stations Maitri (Lat. 70°45'S, Long. 11°40E) and Bharati (Lat. 69°24'S, Long. 76°10'E). A very stable diurnal variation of the signal (both amplitude and phase) has been obtained with no signature of nighttime fluctuation due the presence of 24 hours of sunlight for both the stations. We reproduce the spatial signal amplitude variation by using advanced GPI ion chemistry model by calculating the ionization rate. We compute D-layer electron density profile over the entire path using the model. Using solar zenith angle profile and the Wait's two component model we reproduce the temporal signal amplitude variation for all possible VLF baselines. We present the attenuation rate of the dominant waveguide modes and the effects of Antarctic polar ice on the attenuation of propagated VLF signal. We observed strong attenuation in signal amplitude during propagating over Antarctic ice mass and we corroborate this by numerical simulation.

C5.1-0056-18 UNUSUAL SHIFTS OF THE TERMINATOR TIMES OF THE VLF SIGNALS FOR VTX-SALTLAKE (KOLKATA) PROPAGATION PATH BEFORE TWO MAJOR EARTHQUAKES, OCCURRED IN JUNE, 2010.

Suman Ray, sumanray07@gmail.com Gobardanga Hindu College, Gobardanga, India

Sandip Kumar Chakrabarti, chakraba@bose.res.in

S.N. Bose National Centre for Basic Sciences, Kolkata, India

We have presented the results of the analysis of the VLF signals transmitted from NWC (latitude 21.8°S, longitude 114.15°E) at 19.8 KHz and received at Salt Lake, Kolkata (latitude 22.56°N, longitude 88.4° E). We have analyzed the amplitude of the VLF signals for the period of 5th June, 2010 to 25th June, 2010. During this time period two major earthquakes of lowdepth (10 Km) and high magnitude (M>5), occurred near the propagation path of the VLF signals. The first one occurred on 13th June, 2010 at Nicobar Islands, India (latitude 7.8°N, longitude 92.0° E). The magnitude of it was 5.1 (in Richter scale). The second one of magnitude 6.0 (in Richter scale), occurred on 19th June, 2010 at Andaman Islands, India (latitude 13.4°

N, longitude 93.0° E). For both of these two earthquakes, we found that the terminator times of the VLF signals (mainly sun set terminator time), are shifted towards night time just one day before the event and hence the VLF-day-length (defined as the time difference between the sun set terminator and sun rise terminator time) became anomalously high one day before the earthquakes. To explain this effect we are trying to make a model using ion-chemistry and LWPC code.

C5.1-0057-18 THE SOLAR ENERGETIC PARTICLE BACKGROUND ESTIMATION IN THE SOLAR ORBITER/STIX MEASUREMENTS

Space Research Centre, Polish Academy of Sciences, Wroclaw, Poland

Spectrometer/Telescope for Imaging X-rays is one of ten instruments on board the Solar Orbiter (SO) mission. It will be launched in 2020 into heliocentric orbit. After three years of cruise phase and series of gravitational assist SO will reach first scientific orbit with perihelion distance equal to 0.3 AU. The STIX is Fourier X-ray imager which will provide spectra and images of solar sources within a range of 4-150 keV. On the heliocentric orbit with short perihelion distance the spacecraft will be highly affected by streams of energetic particle from the Sun. On the perihelion distance we expect fluxes of the SEP to be almost 10 times higher than at 1 A.U. Therefore we performed Geant4 simulation of particles interaction with instrument for different distances from the Sun and corresponding intensities of SEP events. We calculated detectors direct hits as well as secondary radiation from instrumental parts. We have found that the latter may influence measured X-ray spectra and reconstructed images.

C5.1-0058-18 SIMULATIONS OF CALISTE-SO DETECTORS

Jaromir Barylak, jbarylak@cbk.pan.wroc.pl

Space Research Centre, Polish Academy of Sciences, Wroclaw, Poland Aleksandra Barylak, abarylak@cbk.pan.wroc.pl

Space Research Centre, Polish Academy of Sciences, Wrocław, Poland Tomasz Mrozek, mrozek@astro.uni.wroc.pl

Space Research Centre, Polish Academy of Sciences, Wroclaw, Poland

The Caliste-SO is CdTe pixelized X-ray detector designed for STIX instrument. Our aim was to simulate a response of the detector to X-ray flux using Geant4 and compare it to laboratory measurements. The detectors were illuminated with X-ray sources Am241 and Co57 in several configurations (various temeperatures, voltages etc.). Moreover, Monte Carlo simulations of the detector response have been performed for each laboratory configuration. Obtained results allowed us to calculate Detector Response Matrices for each pixel with Fano noise, hole tailing, charge sharing, and other detector effects included. Final set of DRMs will greatly improve actual solar X-ray spectra analysis after Solar Orbiter launch in 2020.

C5.1-0059-18 SOLACES - A NOVEL APPROACH IN ABSOLUTE CALIBRATION FOR SOLAR EUV RADIOMETRY

Robert Schaefer, robert.schaefer@ipm.fraunhofer.de Fraunhofer IPM, Freiburg Im Breisgau, Germany Raimund Brunner, raimund.brunner@ipm.fraunhofer.de Fraunhofer IPM, Freiburg, Germany

Gerhard Schmidtke, gerhard.schmidtke@t-online.de Germany

SolACES monitored the solar EUV radiation from 17 nm to 134 nm during a nine year mission period (ISS-SOLAR, 2008 to 2017). Severe degradation effects as caused by ageing effects and hydrocarbons from ISS supply vehicles required reliable in-orbit re-calibration capability of the EUV spectrometer system. For this task, SolACES was equipped with a gas-refillable double ionization chamber, operated as a primary detector standard, to serve as tool for absolutely calibrating the obtained spectral data. In this context, the SolACES team will present requirements and constraints for using ionization chambers as primary detector standard, as well as the principles of operation of such a device in space. A further improvement of the calibration procedure (and thus of the calibrated data) depends on the better understanding of the secondary ionization effects. For this reason, a mock-up of the SolACES ionization chamber was investigated at the MLS synchrotron of the PTB in Berlin enabling to derive data sets of even higher accuracy.

C5.2-0001-18 DUST ASTRONOMY WITH THE MISSION DESTINY+

Ralf Srama, srama@irs.uni-stuttgart.de University of Stuttgart, Stuttgart, Germany

Hillier, Jürgen Schmidt, Sascha Kempf, Sean Hsu, Mihaly Horanyi, Georg Moragas-Klostermeyer, Thomas Albin, Heiko Strack, Jonas Simolka, Anna Mocker, Katherina Fiege, Zoltan Sternovsky, Ernesto Palomba, Veerle Sterken, Eberhard Grün

The interplanetary probe Destiny+ of the Japanese space agency JAXA/ISAS is a mission to the inner solar system and the active asteroid 3200 Phaethon. The launch of the mission is planned for 2022 and the flyby of the asteroid Phaethon is scheduled for 2026. The mission uses a solarelectric propulsion system and a dust telescope is used as a scientific payload. The telescope is a further development of the Cassini dust spectrometer and it is optimized for new in-situ observations in the field of Dust Astronomy. High resolution measurements to determine the elemental composition of individual micrometeoroids are combined with trajectory information. Main scientific questions are: What is the origin and nature of the dust particles that constantly fall onto the earth? What is the fraction and composition of organic material in interplanetary and interstellar matter? How do active asteroids work?

The discovery of interstellar dust in the outer and inner solar system in recent decades has enabled a new innovative approach to the characterization of galactic cosmic dust. The in-situ methods of Dust Astronomy complement and extend the results achieved so far. Destiny+ is the next logical step after the successful missions of Stardust, Rosetta and Cassini. In particular, the following questions are addressed: - In-situ analysis of the elementary and isotopic composition of individual cosmic dust particles including their organic constituents - Characterization of dust emission of the active asteroid 3200 Phaethon - Determination of the size distribution of interstellar dust - Characterization of the interaction of interstellar matter with the heliosphere - Determination and criteria for cometary and asteroidal interplanetary dust particles - Improvement of meteoroid models for the inner solar system

The Destiny+ Dust Analyzer (DDA) determines the particle density, composition, charge and mass of the smallest dust particles. It consists of two sensor heads, a 2-axis gimbal mechanism and an electronics box. The measuring principle is based on impact ionization, time-of-flight mass spectrometry and charge influence. The sensitivity (particle size, trace elements) and mass resolution has been improved up to a factor of 10 compared to the Cassini dust instrument.

C5.2-0002-18 INTERPLANETARY DUST: THE VIEW FROM NEAR AND FAR

Andrew Poppe, poppe@ssl.berkeley.edu

Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, United States

Interplanetary dust is present throughout the solar system and provides a key connection to fundamental planetary building blocks. IDP grains are produced via several processes, including asteroidal disruption, cometary outgassing, and grain-grain mutual collisions, from several parent sources, such as the asteroid belt, Jupiter-family, Halley-type, and Oort Cloud comets, and Edgeworth-Kuiper Belt objects. The relative density and flux of IDPs from any individual source at a given location in the solar system is a complex function of both dust production rates and subsequent gravitational and non-gravitational interactions. We describe recent modeling and observational efforts directed at understanding and constraining both the individual components and overall morphology of the interplanetary dust cloud throughout the solar system.

We also briefly discuss two new mission concepts regarding interplanetary dust. The first, i2DUNE, would measure interplanetary and interstellar dust from an Earth-orbiting (or nearEarth) spacecraft making use of next-generation trajectory and mass composition dust detectors. The second, Interstellar Probe, is a mission to leave the Solar System in order to gain a unique vantage point for look-back imaging of the interplanetary dust complex. IP would provide global imaging of our solar system's debris disk in analogy with the plethora of observations of exozodiacal disks around other stars. Both of these missions present exciting opportunities to revolutionize our view and understanding of dust both near and far.

C5.2-0003-18 STUDENT DUST COUNTER: STATUS REPORT AT 40 AU

Southwest Research Institute, Boulder, Colorado, United States

Information on the distribution of interplanetary dust particles (IDPs) provides constraints to the origin and evolution of planetary bodies. IDPs are subject to gravity, radiation pressure, EM forces, and Poynting-Robertson drag and will migrate throughout the solar system, often getting trapped in resonances with or scattered by the giant planets. Being able to accurately map the distribution of IDPs will provide insight into the sources, sinks, and dynamics of dust grains as well as the overall evolution of the solar system. The Student Dust Counter (SDC) is an in-situ dust detector aboard the New Horizons spacecraft observing the distribution of IDPs in the mass range of 10−12 < m < 10−9 g or approximately 0.5 - 5 μm in radius. New Horizons was launched on January 19th, 2006 and performed a fly-by of the Pluto system on July 14th,

2015. SDC has nearly continuously mapped the dust density distribution along the trajectory of New Horizons from Earth to 40 AU. We present results of the dust density distribution and compare these measurements to existing theoretical models.

C5.2-0004-18 DUSTY SPACE PLASMA DIAGNOSIS USING TEMPORAL BEHAVIOR OF POLAR MESOSPHERIC SUMMER ECHOES DURING SOLAR PROTON EVENT

Alireza Mahmoudian, mahmoudian.a@gmail.com

Interamerican University of Puerto Rico, Bayamon, Puerto Rico, United States Andrew Senior, a.senior

Lancaster University, Lancaster, United Kingdom Wayne Scales, wscales@vt.edu

Virginia Tech, Blacksburg, Virginia, United States Michael Kosch, mkosch@sansa.org.za

NCAR/HAO, Colorado, United States

Natural dusty plasma formed by disintegration of meteors appears in the atmosphere's mesosphere region between 50 and 80 km altitude. Climate change and human activity have caused decreasing mesospheric temperatures and increasing water vapor content via increased methane concentration. Noctilucent clouds (NLC) occur in cold polar summer mesopause and are the direct visual manifestation of freezing of water vapor on the dust particles and formation of ice-coated meteoric dust particles. In-situ measurements using sounding rockets have shown deep depletion of electron density due to charging on mesospheric dust particles (Rapp, 2009; Robertson et al., 2009). Accumulation of free electrons on the ice particles produces electron density structures, which cause the reflection of radar waves. Polar Mesospheric Summer Echoes PMSE are strong coherent radar echoes produced by electron density fluctuations in the vicinity of polar mesopause and at the half the radar wavelength (Rapp and Lubken, 2004). The first VHF radar echoes from the high-latitude mesosphere were observed using the Poker Flat radar in Alaska (location 65.120 N, 147.430 W) (Ecklund and Balsley, 1981; Balsley et al., 1983).

We have investigated the behavior of polar Mesospheric summer echoes (PMSE) during solar proton event (SPE) including dusty plasma effects for the first time. The observational data recorded using the VHF (224 MHz) radar at the European Incoherent SCATter Scientific Association (EISCAT) on July 10 and 11, 2012 will be presented. The observed radar echoes show correlation and anti-correlation with the elevated background electron density variation. The experimental observations are compared with the numerical simulations of the temporal evolution of PMSE with different background dusty plasma parameters during SPE. Specifically, the effect of dust radius, dust density, and electron density on the behavior of PMSE layer and the associated dust charging process in the course of electron precipitation events is studied. It has been indicated that the ratio of electron density fluctuation amplitude ne to the plasma density (ne), dust density

and dust radius, recombination/photoionization rates play a critical role in appearance (and disappearance) of the layer. Possibilities of ice particles charging by mesospheric electrons will be discussed. The condensation of nuclei of the ice particles such as proton hydrate clusters (H+(H2O)n) or meteoric smoke particles (MSP) can be determined by employing microphysical simulations. This can resolve the discrepancy in the description of the observed phenomena. The possibilities of combining the Virginia Tech dusty plasma model with NCAR WACCM/CARMA (Whole Atmosphere Community Climate Model/ Community Aerosol and Radiation Model) to develop a large aperture radar simulator for the dusty space plasma in the near-Earth space environment will be discussed.

C5.2-0005-18 METEORIC DUST, ICE NUCLEATION AND NOCTILUCENT CLOUD GROWTH

Linda Megner, linda@misu.su.se Stockholm University, Stockholm, Sweden

Meteoroids entering the atmosphere ablate, whereupon the resulting material is believed to re-condense as smoke particles. These particles are thought to play a major role in mesospheric processes, effecting charge and radiation balance, ice nucleation and chemistry. In particular, they have long been considered the favorite candidate as a condensation nucleus for noctilucent clouds (NLC). There was, however, a puzzle; the atmospheric circulation efficiently transports the meteoric smoke away from the summer mesopause where NLC form, and ice growth models showed that the particles were transported away before they grow large enough to efficiently act as ice condensation nuclei. The ice growth models at that were used, were based on stationary conditions and thus drastically different from the vivid conditions that lidars and radars observe; temperature changes around 20 K per hour and winds of close to one meter per second that reverse direction sometimes several times per hour are not unusual. Here, the consequences of the choice of atmospheric conditions for ice growth and cloud characteristics are investigated. The results are compared to tomography observations from the OSIRIS instrument and it is found that inclusion of these rapid fluctuations is crucial to simulate clouds characteristics that correspond to observations. Moreover, the reduced number of meteoric ice condensation nuclei that is left in the summer mesopause is not a problem for ice formation once you include the rapid mesospheric fluctuations - in fact it leads to clouds that are better in agreement with observations.

C5.2-0006-18 METEORIC DUST EFFECTS ON THE ELECTRODYNAMICS OF LOW LATITUDE E-REGION PLASMA

Polinaya Muralikrishna, polinaya.muralikrishna@inpe.br

Instituto Nacional de Pesquisas Espaciais - INPE, São José Dos Campos, Brazil

Electrodynamic processes occurring in the E-region of the equatorial ionosphere can be affected by dust particles of meteoric origin. The dust particles can capture the ambient electrons and cause considerable increase in the loss rate of electrons thus affecting the growth rates and amplitudes of the plasma irregularities. The attachment of electrons on dust particles can increase the threshold velocities needed for the onset of two stream and gradient drift instability mechanisms responsible for the generation of Type I and Type II plasma irregularities respectively, observed in the equatorial E-region plasma. In situ rocket observations also indicate that, under similar ambient conditions, the amplitudes of Type II irregularities observed in the lower E-region are considerably smaller than those observed at higher altitudes. This probably is a direct evidence for the effect of dust particles that dominate the lower E-region altitudes practically all the time. Electric field changes in the low latitude E-Region are attributed to changing neutral winds and to remote causes like the mapping of storm time electric field changes or changes in the neutral winds caused by Sudden Stratospheric Warming (SSW). Variation of electrojet currents is a manifestation of changing electric fields and/or electrical conductivities. Changes in the conductivity parameters, especially in the lower E-region can also be caused by the ambient dust particles of meteoric origin. Statistical studies have shown that the monthly occurrence rate of reversals in the electrojet currents is highly correlated to the monthly mean of meteor showers. This high correlation is seen even during geomagnetically disturbed periods. The meteoric dust particles thus play a very important role in altering the local electrical conductivities in the lower E-region and in controlling the electrodynamic processes in this region.

C5.2-0007-18 LABORATORY OBSERVATIONS OF METEOROID DIFFERENTIAL ABLATION

Michael DeLuca, michael.deluca@colorado.edu

University of Colorado, Boulder, Colorado, United States Zoltan Sternovsky, zoltan.sternovsky@colorado.edu University of Colorado, Boulder, Colorado, United States

Experiments at the University of Colorado's 3 MV dust accelerator facility have simulated the ablation of micrometeoroids entering planetary atmospheres by shooting submicron-sized particles into an air chamber at high velocities. These experiments allow direct observation of the fundamental physical processes that govern meteoric ablation, which is relevant to the study of meteoric entry in planetary atmospheres and the study of meteoroids in the Solar System. Current models of meteor ablation depend on an accurate specification of the drag and heating that meteors undergo when they enter a gaseous medium. In one set of experiments, aluminum particles were shot into a variety of gases at speeds of 1-10 km/s and their slowdown was measured using precise timing measurements at the beginning and end of the air chamber. The drag coefficient of the particles was calculated from the slowdown measurements and found to be around 1.3 regardless of gas type, which is somewhat higher than expected. In another set of experiments, magnesite and olivine particles were shot into an air chamber at speeds of 10-30 km/s. The charge production by the particles was spatially resolved inside the chamber, and multiple peaks were observed in the charge production profiles. The multi-peak observations are believed to correspond to the differential ablation of different constituents of the particle as the particle heats up during its passage through the chamber. The differential ablation charge production profiles enable the heating coefficient to be estimated. In this presentation, these experimental results are summarized and used to give us a more complete understanding of the ablation process through a better understanding of meteoric drag and heating.

We present results of in situ measurements of the MLT-dusty plasma conducted during the WADIS-2 sounding rocket campaign. These measurements included densities of electrons, positive ions, charged aerosols and neutrals. For the first time all plasma and neutral densities were measured with high spatial resolution in a true common volume. A new approach combining all measurements allows for a reliable derivation of mean sizes and a size distribution function for the charged meteor smoke particles (MSPs).

In addition a simple charging model is adapted to reproduce the in situ measured densities. We discuss the size distributions from the model and the in situ measurements.

C5.2-0009-18 THE FIRST DIRECT DETECTION OF SATURN'S MAIN RING MATERIAL - CASSINI COSMIC DUST ANALYSER GRAND FINALE RESULTS

Hsiang Wen Hsu, sean.hsu@lasp.colorado.edu

University of Colorado, Boulder, Colorado, United States CDA Grand Finale Science

Ralf Srama, Sascha Kempf, Frank Postberg, Georg Moragas-Klostermeyer, Marcia Burton, Frank Spahn, Martin Seiss, Juergen Schmidt, Holger Hoffmann, ShengYi Ye, William S. Kurth, Mihaly Horanyi, Nozair Khawaja, Daniel Schirdewahn, James O'Donoghue, Luke Moore, Jeff Cuzzi, Geraint H. Jones

The Cosmic Dust Analyzer observations during the Cassini Grand Finale Orbits were designed for the in situ characterization of Saturn's rings' composition and to study their interactions with the host planet. It is found that the 2,000 km wide corridor between the inner most D ring and Saturn's cloud tops is lacking of larger, micron-sized dust grains but rich in nanodust particles (radius smaller than 50 nm) that only become detectable by CDA because of the high spacecraft speed of 30 km/s.

Regarding the grain composition, while the majority of CDA mass spectra recorded during this phase are too faint to be individually calibrated, two types of mass spectra has been identified - water ice and silicate types. While water ice type dominates, the observed silicateto-ice grain ratio is much higher than that of Saturn's main rings, implying a differential erosion that preferably removes the more refractory constituents from the rings in the form of nanograins. As for the dynamics, the observation confirms the electromagnetic transport of charged nanodust from the main rings along magnetic field lines to the planet, previously proposed to be responsible for the observed "Ring Rain" effect. The estimated ring mass loss rate is sufficient to support the required H3+ chemistry of the ring rain effect. The derived erosion rate also indicates a relatively young ring age, consistent with results from ring-moon system dynamics and other recent observational constraints.

JHU/APL, Laurel, Maryland, United States

Classically, the discriminator between asteroids and comets is that the latter group is surrounded by a dust coma while the former group is not. Observations over the last decade or so, however, have found a class of “active asteroids” that have a comet-like coma but are otherwise like typical asteroids in physical and orbital properties. These observations have been accompanied by identification of processes that liberate dust from asteroidal surfaces, from the constant stream of ejecta from micrometeorite impacts to sudden, large-scale events that can lead to satellite formation. The presence of asteroidal dust leads to new opportunities for in situ compositional measurements that do not require surface descents or sample handling. We will discuss these topics, including how modern, capable dust analysis instruments could answer important questions in asteroid science.

University of Colorado, Boulder, Boulder, Colorado, United States

Wave instruments onboard spacecraft are designed to detect radio and plasma waves in space. However, when spacecraft encounter dust at tens of kilometers per second, the plasma clouds released by energetic dust impacts can couple to the antennas of wave instruments and cause either voltage pulses in waveforms or broadband noise in the spectra recorded by the receivers. The impact signals have been simulated in the lab by shooting dust particles onto a spacecraft model with electric field antennas. During the Cassini and Juno mission, such signals have been detected by the onboard wave instruments in the solar wind and different regions of planetary magnetospheres. Given the particle velocity and impact charge yield function, the size and density of the particles can be estimated from the measured signals. We will compare the dust observations made by the two spacecraft and discuss the possible effects of background plasma density and magnetic field on the waveforms of the dust impact signals.

C5.2-0012-18 ELECTRIC FIELD INSTRUMENTS AS DUST DETECTORS, SIGNAL INTERPRETATION

Jakub Vaverka, jakubvaverka@gmail.com

Charles University, Faculty of Mathematics and Physics, Prague, Czech Republic Jiri Pavlu, jiri.pavlu@mff.cuni.cz

Umeå University, Umea, Sweden

Electric field instruments are able to detect hypervelocity dust impacts on the spacecraft body as transient pulses in the measured electric field. This method is frequently used for dust detection in various parts of our solar system. In spite of intensive ongoing studies, signatures generated by dust impacts are not completely understood and explained. A very important issue is a reliable identification of dust impacts in obtained waveforms. Solitary waves and pulses generated by instrumental effects can be similar to pulses triggered by dust impacts. This fact can result in false dust detection. We present a study of a possible source of signal misinterpretation based on Cluster and MMS data. We show that the identification of dust impacts especially by a single electric field antenna is a very challenging issue and that it is necessary to be aware of that not all pulses in the electric field data are triggered by dust impacts.

C5.2-0013-18 LASER ORBITAL DEBRIS REMOVAL

David Neely, david.neely@stfc.ac.uk

STFC Rutherford Appleton Laboratory, DIDCOT, United Kingdom

Laser orbital debris removal

David Neely Central Laser Facility, STFC, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon, OX11 0QX, UK Department of Physics, SUPA, University of Strathclyde, Glasgow, G4 0NG, UK david.neely@stfc.ac.uk

The efficiency with which a laser pulse energy couples into a target object and can generate momentum [1] is of critical importance for applications such as orbital debris removal. The selection of a suitable laser for deorbiting debris will strongly depend on the wavelength, pulse length, duty cycle and average power which can be delivered, with currrent estimates indicating that a 20-100 KW average power class laser driver is required. Over the last 30 years there has been a significant reduction in the pulse lengths from ns to fs's which can be routinely delivered. Although shorter pulses can more readily ionise a material for a given pulse energy, the absortpion efficiency can play a dominent role in the interaction. Recent studies have shown absorptions ranging from 4 - 97%, for ps pulses[3]. The absorption is strongly dependent on the plasma scale length and studies will be presented and reviewed considering the implications for the choice of ideal pulse length and energy density to optimise laser plasma coupling for orbital debris removal. The potential to now build such a system will be examined and studies looking at the atomic and particle debris will also be presented.

Keywords: Lunar Dust, Lunar exosphere, Moon, Plasma, Dust

Introduction:

The scientific payload of the "Luna-Glob" lander includes PmL instrument. This instrument is designed to study the dust component, its dynamics in the near-surface exosphere of the Moon, the registration of micro-meteorites and secondary particles of the lunar regolith, impact by micrometeorites and the measurement of their physical characteristics. The device directly measures momentum, velocity, mass and charge of the particles. For the purpose of conducting physical experiments on modeling of the dusty environment conditions in the surface layer was created an experimental setup. This experimental set-up had been designed for carrying out functional tests, adjustments and calibrations of the instrument. The installation is carried out testing of the methodology of space experiment. It is planned to hold correction of the coefficients of relative sensitivity and verification of the scientific data obtained during the mission.

Experimental set-up: The experimental set-up is realized on the base of the vacuum chamber and includes a system of supply and control of vacuum, the injector (generator) of charged particles. The setup includes the control system for measuring the speed of the charge of particles and the system to measuring and control electrical signals and instrument parameters. Vacuum system provides vacuum with a residual pressure sufficient to operate the injector of the dust particles and simulate the conditions of the dust of the atmosphere. Injector (generator) of dust, charged particles produces a stream of metallic, charged particles with dimensions from units to hundreds of microns with flow rates from units to tens of meters per second with a charge of not less than 1000 electrons per the particle. The measuring system for the control of the speed and charge of particles consists of the induction sensor and charge sensitive amplifiers that allow to display and measure the signal. Method of measuring charge is based on the measurement of the induced mirror charge from the moving particles in the metallic electrode of the induction sensor. The geometry data of the placement of the induction sensors is used to measure the speed of particles by time delays of signals. The voltage applied to the injector governs the speed and charge of the injected particles. In the experiments are used different in size and mass of particles loaded into the injector. Since the process of injection and the detection of particles are random, the statistical methods to handle the large volume of accumulated data are used. Another source of charged dust particles possibly can be created from the UV-irradiation system inside experimental set-up which leads us to dust particles levitation inside the chamber.

Results:

The set-up made it possible to realize the streams of charged particles with velocities in the range of 2 to 60 m/s for the metalized particles with sizes from 10 μm to 200 μm. On the installation was carried out calibration of the engineering sample PML device, had allowed to determine the sensitivity of the sensors of the device. Threshold sensitivity for the charge is amounted to 2 000 the charge of the electron. The threshold sensitivity of the momentum is amounted to the value of 3*10−12 N*s.

Acknowledgements:

The research was carried out using funds of the Russian science foundation (project №17-12- 01458).

C5.2-0015-18 CREATING ASTROPHYSICALLY RELEVANT WATER-ICE DUSTY PLASMA IN THE LABORATORY

Ryan Marshall, rmarshal@caltech.edu

California Institute of Technology, Pasadena, California, United States Kil-Byoung Chai, kbchai@kaeri.re.kr

Korea Atomic Energy Research Institute, Daejeon, Korea Paul Bellan, pbellan@caltech.edu

California Institute of Technology, Pasadena, California, United States

Water-ice dusty plasmas occur terrestrially in polar mesospheric clouds, extraterrestrially in Saturn's E, F, and G rings, and throughout the universe in protoplanetary disks and molecular clouds [1-3]. The Caltech Water-Ice Dusty Plasma Experiment creates similar plasma in the laboratory. Background gas on the order of 100s of mTorr enters into a small vacuum chamber where it is ionized into plasma by 1-3 W of 13.56MHz RF across two parallel circular electrodes. These electrodes are cryogenically cooled with liquid nitrogen to 150K which causes water vapor to spontaneously freeze into ice grains in the plasma. The length and aspect ratio of the grains depend on the background plasma gas, the background gas pressure, and the applied magnetic field. Large grains (500 microns in length) are created in hydrogen plasma with low gas pressure (200 mTorr) and no external magnetic field. Increasing the background gas pressure, increasing the atomic mass of the plasma species, or introducing external magnetic field all make the ice grains smaller [4]. The growth of the water-ice grains in helium plasma was studied using a long distance microscope lens and an ultra-high speed video camera. Accretion likely dominates the growth because the grains have a large negative charge resulting in strong mutual repulsion to prevent agglomeration, even in the presence of observed waves (believed to be Dust Acoustic Waves) [5]. A Laser Induced Fluorescence diagnostic is under development for the Caltech Water-Ice Dusty Plasma Experiment. This diagnostic uses a diode laser, a photomultiplier tube, and a lock-in amplifier. Preliminary measurements without cryogenic cooling show that the temperature of the neutrals is close to room temperature. Indication of a flow velocity is also observed. When completed at Caltech, this project will be transported to Germany to measure temperatures and flow velocities on the ground-based PK4 replica.

C5.2-0016-18 ION-ACOUSTIC SHOCK WAVES IN A SIX COMPONENT COMETARY PLASMA

Manesh Michael, maneshmichael@gmail.com St. Albert's College, Ernakulam, Kerala, India Plasma Physics: M.G. University

Sijo Sebastian Anu Varghese Sreekala G Chandu Venugopal

We investigate the propagation characteristics of Ion-Acoustic Shock waves in a six component cometary plasma composed of two hot and one colder electron component, hot lighter ions, and pair ions. The colder and one hotter component of electrons together with the lighter hydrogen ions are modelled by kappa distribution. The other hotter electron is described by q-nonextensive distribution. The KdVB equation is derived for the system and its solution plotted for different kappa values, oxygen ion densities, kinematic viscosities as well as the temperature ratios of ions. It is found that, in afore said composition shock wave shows a transition to soliton. The basic features of the Ion-Acoustic Shock waves such as amplitude, width, and phase speed have been extensively studied by a numerical analysis of the KdVB equation. The amplitudes of the Shock waves seem to be well correlated to the presence of water molecules in a cometary plasma and the associated photo-ionisation processes.

C5.2-0017-18 CYLINDRICAL SHOCK WAVE IN A SELF-GRAVITATING ROTATIONAL AXISYMMETRIC DUSTY GAS WITH DENSITY VARYING EXPONENTIALLY

Gorakh Nath, gn_chaurasia_univgkp@yahoo.in National Institute of Technology, Allahabad, India

The propagation of a strong cylindrical shock wave in a self-gravitating and rotational axisymmetric dusty gas, having variable azimuthal and axial fluid velocities is work out in the case of isothermal and adiabatic flows. The dusty gas is assumed to be a mixture of small solid particles and perfect gas. The equilibrium flow conditions are assumed to be maintained, and the density of the mixture and the fluid velocities in the ambient medium are assumed to be varying and obeying an exponential law. The shock wave moves with variable velocity and the total energy of the wave is non-constant. Non-similarity solutions are obtained and the effects of variations of the mass concentration of solid particles in the mixture and the ratio of the density of solid particles to the initial density of the gas, and the presence of self-gravitational field and rotating medium on the flow variables are investigated at given times. The shock waves in self-gravitating rotational dusty gas can be important for description of star formation and shocks in stellar explosion, shocks in supernova explosions, in the study of central part of star burst galaxies, nuclear explosion, in industry, rupture of a pressurized vessel and explosion in the ionosphere. Other potential applications of this study include analysis of data from exploding wire experiments and cylindrically symmetric hypersonic flow problems associated with meteors or re-entry of vehicles and the measurements carried out by spacecraft in the solar wind and in neighborhood of the Earth's surface etc. A comparison is made between the solutions obtained in the case of rotating gravitating and the non-rotating gravitating or non-gravitating rotating or non-rotating non-gravitating. The obtained solutions are applicable for arbitrary values of time.

C5.2-0018-18 EFFECT OF DISCRETE CHARGE FLUCTUATIONS ON AGGREGATE GRAIN GROWTH

Center for Astrophysics, Space Physics, and Engineering Research (CASPER), Baylor University, Waco, Texas, United States

The earliest stages of protoplanetary development are characterized by the coagulation of micron-sized dust grains. Aggregate growth due to collisions between grains is highly dependent on the local environment, including the dust and gas densities, turbulence, and grain charging mechanisms, as well as the physical characteristics of the aggregates themselves. In many regions of a protoplanetary disk, the gas is weakly ionized. Dust particles immersed in a plasma environment become charged through the collection of electrons and ions at random times, causing the dust charge to fluctuate about an equilibrium value. Sub-micron sized grains or grains in a tenuous plasma environment are sensitive to single additions of electrons or ions. These charge fluctuations occur on timescales which are relevant for dynamics of aggregate growth. Here we present a numerical model that allows examination of discrete stochastic charge fluctuations on the surface of aggregate grains and determine the effect of these fluctuations on the dynamics of grain aggregation. Coupled dynamics and charging models show that charge fluctuations tend to produce aggregates which are much more linear or filamentary than aggregates formed in an environment where the charge is stationary.

C5.2-0019-18 NEW INSIGHT INTO EM RADIATION FROM SPINNING DUST AND ITS INFLUENCE ON THE COSMIC MICROWAVE BACKGROUND

Jose Tito Mendonca, titomend@tecnico.ulisboa.pt Universidade de Lisboa, Lisboa, Portugal

Dust is ubiquitous in the Universe and its influence on the observed Electromagnetic (EM) radiation needs to be correctly addressed. In recent years it became clear that scattering of EM radiation from interstellar dust grains could change the local properties of the observed Cosmic Microwave Background (CMB) radiation. Here we summarize some new results concerning the relevant processes of emission and scattering of EM radiation from spinning dust particles, and discuss their possible influence on the CMB. In particular, we show that scattered radiation can establish a correlation between different spectral components of galactic dipolar emission. This could explain the observed correlation between the CMB and the 100-micron thermal emission form interstellar dust. Another important property of CMB is related with its polarization anisotropies, and the observation of a cosmological B-mode. We show that scattering of CMB radiation from dust grains in the presence of a static magnetic field could indeed create a Bmode spectral component, which is very similar to that due to primordial gravitational waves. This can be described by a kind of Cotton-Mutton effect on the CMB radiation. Finally, we review the low frequency spectrum of dusty plasma instabilities and their possible signature on the polarization and spectral correlations of the observed microwave radiation.

C5.2-0020-18 EVOLUTION OF TWISTED WAVES CARRYING ORBITAL ANGULAR MOMENTUM: APPLICATION TO THE LORENTZIAN (KAPPA) DISTRIBUTED NON-GYROTROPIC PLASMAS.

Kashif Arshad, kashif.arshad.butt@gmail.com

Centre for Plasma Astrophysics, KU Leuven, Leuven, Belgium Marian Lazar, mlazar@tp4.rub.de

Ruhr-Universität Bochum, Bochum, Germany Stefaan Poedts, stefaan.poedts@wis.kuleuven.be

Centre for Plasma Astrophysics - KU Leuven, Leuven, Belgium

Twisted waves are usually characterized as waves carrying orbital angular momentum (OAM), related to the helicity of the wave front, i.e. vortices. It is demonstrated experimentally with laser beams having OAM, that light and matter can interact and exchange angular momentum. About 10-15 years ago, the OAM (a macroscopic property of light) was rediscovered that can be also transferred from the light to a gas or plasma, which opens the door to new experiments and theoretical studies. The appearance of an azimuthal component is the new parameter, as compared to non-twisted plasmas, due to the presence of helical electric field perturbation in the plasma. The propagation of twisted waves in plasmas is predominantly prescribed by the longitudinal and azimuthal wave numbers. The longitudinal wave number reflects the variation in the spatial symmetry while the varying phase of nonplanar helical wave fronts is described by the azimuthal wave number.

The study of twisted waves is influenced by the many recent investigations of orbital angular momentum and its relevance for the Alfvénic and magnetic tornadoes, the High Frequency Active Auroral Research Program (HAARP) ionospheric radar facility and program to study plasma turbulence in the ionosphere of the Earth, twisted gravitational waves, ultra intense twisted laser beams, and quantum entanglement of twisted photons, neutrino physics, and astrophysics in the radio frequency range. In the optical frequency range, the variety of potential applications such as ultra-fast optical communication, quantum computing, microscopy and imaging are already well known. The observed morphologies of twisted modes are spiral, ringlike or helical, and may describe many phenomena in astrophysical and terrestrial environments like spiral galaxies, gravitational waves around rotating black holes, tornados in the solar corona, cometary tails, etc.

The first kinetic studies of twisted waves were performed for Maxwellian distributed (thermal) plasmas. It is, however, evident that most of the space plasmas are not in (local) thermal equilibrium, especially due to presence of superthermal particles in the tails of the distribution. The velocity (or energy) distributions of these plasmas are well reproduced by the generalized Lorentzian or Kappa distribution function. At present, we have investigated properties of the twisted waves in unmagnetized plasmas. Therefore, twisted Langmuir and ion acoustic waves are studied for plasma of Kappa distributed electrons and Maxwellian distributed protons (ions), as reported by the observations in various space plasma environments (e.g., the solar corona, planetary magnetospheres, etc.). The study of twisted waves is then further extended for the dusty plasmas, as dust is ubiquitous in astrophysical environment, planetary rings and interplanetary media, comets, interstellar medium, the Eagle nebula, supernova remnants, Jupiter's dusty rings and Earths mesosphere. These studies lead to the prediction of instabilities (growth rates and instability windows) for twisted waves of different types, e.g. the dust ion acoustic (DIA), and dust acoustic (DA) twisted waves.

Mathematically, twisted modes are well described by the Laguerre-Gaussian (LG) mode function in cylindrical coordinates, which decomposes the helical electric field and the perturbed distribution function into planar and non-planar components described by the longitudinal and azimuthal wave numbers. The characteristic system of Vlasov-Poisson equations is derived and solved to obtain the dielectric function for the twisted waves in the presence of a helical electric field. The approximative analytical and 'exact' numerical solutions are derived and analyzed to study the dependence of Landau damping or growth rates on various parameters like the wave numbers, drift velocities, temperature ratios, dust charging parameters, spectral indices, etc. The results are physically interpreted and their relevance for various applications is discussed.

C5.2-0021-18 ANISOTROPIC DUST COULOMB STRUCTURES IN CRYOGENIC AND MICROGRAVITY ENVIRONMENT: THE BRIDGE FROM CHAOS TO THE SELFORGANIZED MATTER

Oleg Petrov, ofpetrov@ihed.ras.ru

Joint Institute for High Temperatures of the Russian Academy of Sciences, Moscow, Russia Mikhail Vasiliev, mixxy@mail.ru

Joint Institute for High Temperatures of the Russian Academy of Sciences, Moscow, Russia

The dust Coulomb systems are the ensembles of macroparticles carrying a charge and experiencing the mutual Coulomb interaction. Here we present the results of our studies the evolution of strongly coupled Coulomb systems of charged dust particles at cryogenic temperatures (temperatures of liquid helium and nitrogen) and microgravity conditions. The dust particles were trapped in dc glow discharge. In this case the active dust particles of micron-sized polydisperse CeO2 particles in He dc glow discharge at temperatures 5-10 K and 77 K were obtained. We present experimental evidence that cryogenic temperatures result in a non-equilibrium phase transition from random motion (chaos) of dust particles to formation of flow-aligned strings, due to the attractive downstream wake field, and then to collective rotational motions with non-zero mean velocities. The transition is continuous during discharge parameters change tending to align the direction of motion of particles. In our observations the dust particles in active motion state exist as one of two components in binary-like dust structure where other component consists of the same particles ordered in dust chains. The effect of a dc electric field on strongly non-ideal Coulomb systems consisting of a large number (104) of charged diamagnetic dust particles in a cusp magnetic trap are carried out aboard the Russian segment of the International Space Station (ISS) within the Coulomb Crystal experiment. Graphite particles of 100-400 mum in size are used in the experiments. The formation of threadlike chains of particles from graphite particles with diameter of 300 mum in a magnetic trap are observed experimentally under the illumination by the electroluminescent panel in the lower part of the experimental cell. The processes are simulated by the molecular dynamics (MD) method.

C5.2-0022-18 COMPLEX PLASMA EXPERIMENTS WITH PK-4 ON PARABOLIC FLIGHT CAMPAIGN DLR #31

Michael Kretschmer, michael.kretschmer@exp1.physik.uni-giessen.de Justus-Liebig-Universität Gießen, Giessen, Germany

Markus Thoma, markus.h.thoma@exp1.physik.uni-giessen.de Justus-Liebig-Universität Gießen, Giessen, Germany Christopher Dietz, christopher.dietz@physik.uni-giessen.de Justus-Liebig-Universität Gießen, Giessen, Germany

Benjamin Steinmüller, benjamin.steinmueller@physik.uni-giessen.de Justus-Liebig-Universität Gießen, Giessen, Germany

The Plasmakristall-4 (PK-4) plasma facility employs a dc discharge in a low-pressure noble gas inside a glass tube to study complex (dusty) plasmas under various gravity conditions. Micron-sized spherical particles injected into the plasma collect several thousands of electrons and interact with each other by a screened Debye-Hueckel (Yukawa) potential, forming a multiparticle system drifting along the tube towards the anode. The flowing particle cloud – illuminated by an expanded laser beam – resembles a fluid wherein the individual particles can by observed with a video camera. The particles in the videos are tracked providing full dynamic information.

A flight model of PK-4 is installed inside the Columbus module of the International Space Station ISS since November 2014. Another model is situated at the University of Giessen, Germany, which is used for experiments on ground and on parabolic flights to compare with and extend the experiments performed in space.

The results of a recent parabolic flight campaign are presented: Investigation of electrorheological effects in complex plasmas and a laser-induced shearflow to gain some material properties of the complex plasma fluid.

Acknowledgements: This work is supported by the German Aerospace Center (DLR) under grant number 50WM1742.

C5.2-0023-18 PK-4 - COMPLEX PLASMA RESEARCH ON THE INTERNATIONAL SPACE STATION

The PK-4 facility in the Columbus module of the International Space Station ISS allows longterm investigations of complex plasmas under microgravity conditions. “Complex plasmas” are dusty plasmas specially “designed” for the study of classical condensed matter physics. Due to the heavy component in the complex plasma - the microparticles - research under microgravity conditions is necessary to complement the knowledge gained from 2-dimensional and stressed 3- dimensional systems on the ground. Although phenomena in classical condensed matter physics are at the forefront of complex plasma research the basic know-how gained from experiments, theory and numerical simulations can be of importance for the understanding of naturally occurring dusty plasmas in space. In this presentation we will present recent work on complex plasmas from the PK-4 facility onboard the International Space Station ISS. This includes basic topics like charge and ion drag force on the microparticles, but also more dedicated research on shear induced melting, wave propagation, and electrorheology.

Complex plasmas are a versatile analog for studying systems where global behavior is determined by the combined effect of the particles' low temperature / kinetic energy, interparticle interactions, and global and local confinement. In general, the dust particles are small enough to act as probes of the local plasma conditions since their perturbations to the background plasma are small. However, when embedded in a plasma with directed ion flow the dust grains affect the ion trajectories, creating a focused ion region downstream. To date, most systems of charged dust particles and streaming ions have been examined under the presence of gravity, making the fundamental physics behind such correlation driven effects difficult to determine. Data from a recently funded (NASA / NSF) project proposing examination of field-aligned dust chains formed in the Plasma Kristall-4 (PK-4) onboard the International Space Station (ISS) will be discussed. The possibility that thermally excited waves propagating along and perpendicular to such chains can provide details of the resulting interparticle / interchain potential allowing study of the relationship between this potential, the ion wakefield and the controlling DC bias will be presented and the robustness of this conjecture discussed.

Ekoplasma is a joint German-Russian project, developing the future multi-purpose laboratory for the investigation of complex plasmas under microgravity conditions on the International Space Station (ISS). Complex plasmas are low-temperature plasmas, consisting of neutral gas atoms, ions, electrons and micro-meter sized particles as an additional component. The particles become charged in the plasma and as a result of their mutual repulsion form an optically thin cloud that can be studied in its full spatial and dynamical complexity on the granularity scale of each individual particle by optical cameras. Therefore, complex plasma allow fundamental investigations down to the kinetic level of individual particles also for a wide field of interdisciplinary topics in classical condensed matter physics.

The experimental apparatus of Ekoplasma features a newly developed large, cylindrical plasma chamber (the Zyflex chamber) with an adaptive internal geometry and 4 rf-driven electrodes for plasma generation. With the implemented technology, the accessible experimental parameter range will be extended by magnitudes (e.g. particle charge, neutral gas pressure range) and it will allow an independent control of plasma parameters. Further, particle dynamics will be investigated by a 3D optical diagnostic system, giving new insights into physical phenomena by adding the information of the 3rd dimension, which is usually lost when observing a 2D cross-section of the observation volume.

Ekoplasma will launch to the ISS after 2022, covering a wide range of research topics such as solidification and melting, phase separation in binary systems, the transition to turbulence, active matter or electrorheology. The experimental setup of Ekoplasma will be presented, as well as recent results of experiments performed on parabolic flights and in the ground laboratory, demonstrating the scientific possibilities of this new laboratory.

This work and some of the authors are funded by DLR/BMWi (FKZ 50WM1441), and by NASA/NSF (JPL-RSA-1571699/NSF-PHY-1740784).

Keywords: Lunar Dust, Lunar exosphere, Moon, PiC, Numerical Simulation, Plasma

Introduction: One of the complicating factors of the future robotic and human lunar land- ing missions is the influence of the dust. Meteorites bombardment has accompanied by shockexplosive phenomena, disintegration and mix of the lunar soil in depth and on area simultaneously. As a consequence, the lunar soil has undergone melting, physical and chemical transformations. Recently we have the some reemergence for interest of Moon investigation. The prospects in current century declare USA, China, India, and European Union. In Russia also prepare two missions: Luna-Glob and Luna-Resource. Not last part of investigation of Moon surface is reviewing the dust condition near the ground of landers. Studying the properties of lunar dust is important both for scientific purposes to investigation the lunar exosphere component and for the technical safety of lunar robotic and manned missions. The absence of an atmosphere on the Moon's surface is leading to greater compaction and sintering. Proper-ties of regolith and dust particles (density, temperature, composition, etc.) as well as near-surface lunar exo-sphere depend on solar activity, lunar local time and position of the Moon relative to the Earth's magneto tail. Upper layers of regolith are an insulator, which is charging as a result of solar UV radiation and the constant bombardment of charged particles, creates a charge distribution on the surface of the moon: positive on the illuminated side and negative on the night side. Charge distribution depends on the local lunar time, latitude and the electrical properties of the regolith (the presence of water in the regolith can influence the local distribution of charge). On the day side of Moon near surface layer there exists possibility formation dusty plasma system. Altitude of levitation is depending from size of dust particle and Moon latitude. The distribution dust particle by size and altitude has estimated with taking into account photoelectrons, electrons and ions of solar wind, solar emission. Dust analyzer instrument PmL for future Russian lender missions intends for investigation the dynamics of dusty plasma near lunar surface. PmL consists of three parts: Impact Sensor and two Electric Field Sensors. One of the tools, which allows to simulate the dust emission from the Moon and asteroids, its transport, deposition and its interaction with a lander, is the SPISDUST (Spacecraft Plasma Interaction Software) code which based on Particle-in-Cell (PiC) method. This paper presents results of SPIS-DUST modelling of the interaction between the lunar plasma environment, regolith and a lander. The model takes into account the geometry of the Luna-Glob lander, the electric properties of materials used on the lander surface, as well as Luna-Glob landing place. Initial conditions were chosen based on the current theoretical models of formation of dusty plasma exosphere and levitating charged dust particles.

Acknowledgements:

The research was carried out using funds of the Russian science foundation (project №17-12- 01458).

C5.2-0027-18 EFFECTS OF ELECTROSTATIC ENVIRONMENT ON CHARGED DUST DYNAMICS NEAR LUNAR HOLES

Yohei Miyake, y-miyake@eagle.kobe-u.ac.jp Kobe University, Kobe, Japan

Masaki N. Nishino, mnishino@isee.nagoya-u.ac.jp Nagoya University, Nagoya, Japan

The Moon has neither dense atmosphere nor intrinsic magnetic field, and solar wind interactions with lunar surfaces are one of major plasma processes. The near-surface, dayside electrostatic environment is governed mainly by volume charges of solar wind plasma and photoelectrons as well as charged lunar surfaces. In fact, the electric environment strongly depends on surface topologies, as it will produce a shaded region, the electric environment of which can be very different from that in a sunlit condition. As one of high-profile terrains on the Moon, we have been focusing on the lunar vertical holes (or lunar pits), identified by the KAGUYA satellite and the Lunar Reconnaissance Orbiter. In order to model the distinctive electric and dust environments near the holes, we have started three-dimensional particle simulation analysis [1].

The particle-in-cell simulations address the plasma environment of a lunar hole that is accompanied with a subsurface cavern, and provide electric and plasma current fields in 3- dimensional space. We subsequently applied the obtained data to the study on the dynamics of submicron-sized charged dust grains around the distinctive landscape. We particularly focus on an effect of dynamic and stochastic charging processes of such small dust grains. Because of their small surface areas, the dusts will get/ lose one elementary charge infrequently, and thus charge amount owned by each dust should be a stochastic variable unlike a typical spacecraft charging. We develop a numerical model of such a charging process, which will be embedded into the test particle analysis of the dust dynamics. We report some results from our simulations on the dust charging process and dynamics around the lunar hole.

Elke Pilat-Lohinger, elke.pilat-lohinger@univie.ac.at University of Vienna, Vienna, Austria

We investigate the role of regular and chaotic motions of plasma and dust particles in the regime of magnetic reconnection of the Earth magnetotail on plasma processes. Our study is based on numerical simulations of particle orbits in plasma simulations. We analyze the variational system of equations together with the evolution and characteristics of the short time Local Lyapunov Indicators. We find regular and chaotic motions of (dust) particle orbits in phase space and link our results to open problems of plasma physics.

Electric field sensors or solar wind detectors based on Faraday cups are sensitive to impacts of high velocity dust particles. Despite a number of missions/instruments capable to detect dust particles, details of the detection mechanisms remain not fully understood. In order to study the properties of dust impacts, we conducted laboratory investigations of two principally different instruments: (1) antennas and (2) Faraday cups. Submicron-size iron dust particles within a velocity range of 1-40 km/s were generated by the dust accelerator facility operated at the University of Colorado. A scaled-down model of the Cassini spacecraft and three antennas of the RPWS (Radio Plasma Wave Science) instrument in dipole and monopole configurations have been used to study the response of antennas to dust impacts. Faraday cups were represented by an engineering prototype of the BMSW (Bright Monitor of the Solar Wind) instrument, operating onboard Spektr-R. Both instruments registered dust impact events with the recorded signals that resembling those detected in the space. We discuss the similarities and differences in physical processes leading to observed responses of detectors and corresponding electronics.

C5.2-0030-18 CURRENT-MODULATION-INDUCED VERTICAL DUST OSCILLATION IN A STRATIFIED GLOW DISCHARGE.

The dust particle forced oscillation excited by square wave low-frequency current modulation are investigated. Amplitude-frequency response (AFR) of the single dust particle oscillation is obtained in the range of pressures p=0.06-0.66 torr. Resonance peaks at frequency, which is close to the eigenfrequency of the dusty plasma system, are observed at lowest pressures. Max-ima at multiple of the resonant frequencies are also observed. The eigenfrequency is determined by two independent methods. AFR for the different shapes of modulating signal is measured. The calculation of the phase-frequency characteristic is made. The resonance curves are used to obtain the vibrational characteristics of the dusty plasma system such as resonance amplitude, damping coefficient, eigenfrequency, Q-factor. The calculation of the single dust particle with help of the measured eigenfrequency is made.

C5.2-0031-18 TRANSPARENT DUST UNDER ELECTRON BOMBARDMENT: SURFACE ALTERATION AND HEATING

Different kinds of transparent dust are widely spread across the solar system, besides silica or glass-like dust there exists a number of ices. Since the grains are exposed to space plasma and radiation environments, charging properties of such materials appear important. On the other hand, transparent grains can be easily overheated by particle impacts, since they cannot radiate in certain wavelength range. We have observed that electron bombardment could significantly alter the surface properties and also lead to the intense mass reduction. Further impacts include (a) intense sputtering when complemented with the electron bombardment and thus destruction of the grain, (b) fast production of neutrals and pick-up ions, (c) changes in grains albedo and its surface conductivity, etc. This paper presents a series of laboratory observations on spherical glass grains that are levitated in the quadrupole trap and exposed to the particle beam. An evolution of the grain is recorded and changes in grain mass and emission properties are estimated. Particular characteristics are compared with theoretical and numerical models. Suggestions are made towards ices in the solar system.

C5.2-0032-18 INTERACTION OF TWO DUST ION ACOUSTIC SHOCK WAVES IN A WEAKLY RELATIVISTIC MULTICOMPONENT NONEXTENSIVE PLASMA

Papihra Sethi, papihra.sethi@gmail.com

Guru Nanak Dev University, Amritsar, India, Ropar, India Nimardeep Kaur, nimarphy@gmail.com

Complex dusty plasmas have been under intense scrutiny by plasma physicists for understanding various nonlinear phenomena in space and astrophysical environments. Dust is witnessed as an ubiquitous component in many environments such as magnetosphere of Earth, planetary rings, comets, ionosphere, interstellar molecular clouds and circumstellar disks. Shocks waves are characterized as an abrupt change in properties of the medium such as density, pressure etc. that propagate with supersonic speed. High-speed and energetic streaming ions with energies of 0.1-100 MeV are frequently observed in astrophysical and space environments. The relativistic effects cannot be ignored when particles have the streaming velocity in the order of the velocity of light. Tsallis statistics have been based on the usual Boltzmann-Gibbs statistics by introducing an additional parameter q measuring the strength of nonextensivity which has been successfully applied to a number of plasma systems such as Earth's magnetosphere, Mercury, Saturn and Solar wind. One of the interesting and important nonlinear phenomenon in the modern plasmas researches is interaction or collision between two waves. Keeping in view, the importance of dust, relativistic particles and nonextensivity, interaction of dust ion acoustic shock waves containing nonextensive electrons and positrons in a weakly relativistic plasma is studied. Employing extended Poincare-Lighthill-Kuo method with suitable asymptotic expansion, two Korteweg-deVries Burgers equations in a weakly relativistic plasma are derived for the study of phase shifts and time evolution of two shock waves after a head-on collision while travelling in opposite directions. Various physical parameters such as relativistic factor, nonextensivity, viscosity and dust etc. have paramount influence on the phase shifts and potential pulse profile of dust ion acoustic shock waves. The results may be helpful in understanding the head on collision between two dust ion acoustic shock waves in astrophysical and laboratory plasmas.

C5.2-0033-18 DUST MAGNETOSONIC BREATHERS AND FREAK WAVES IN A MAGNETIZED PLASMA

Nimardeep Kaur, nimarphy@gmail.com

Guru Nanak Dev University, Amritsar, India, AMRITSAR, India Nareshpal Singh Saini, nssaini@yahoo.com

Guru Nanak Dev University, Amritsar, India, Amritsar, India

Dust particles in motion generate new wave modes for shear Alfven, magnetosonic and whistler waves. During the last one decade, magnetosonic waves in dusty plasma have received an increased attention in major areas of basic research due to their important role in scattering energetic electrons in the magnetosphere through Landau resonance interaction. In the present study, a theoretical investigation of dust magnetosonic breathers and freak waves is presented in an electron-ion-dust magnetized plasma composed of cold dust fluid with inertialess electrons and ions. Nonlinear Schrödinger equation (NLSE) has been derived under the low frequency limit and admits spatially and/or temporally localized structures often called as breather solutions. Recently, there has been a great interest in these localized structures in many diverse fields, e.g., fiber optics, hydrodynamics, plasmas, etc. Kuznetsov-Ma breathers/solitons (spatially localized patterns oscillating in time) and Akhmediev breathers (spatially periodic structures localized in time) are two important classes of breather solutions. In present investigation, the exact analytical solutions of the NLSE for breather waves in the form of Akhmediev breathers, Kuznetsov-Ma (KM) solitons and freak waves (first and second order) are obtained. The results are also examined numerically using the observed data in space/astrophysical environments particularly in Earth's inner magnetosphere. The characteristics of different breather structures are significantly influenced by the relevant physical parameters of the observed data. The results obtained in the present investigation may be helpful in explaining the formation and dynamics of nonlinear excitations in different regions of space/astrophysical environments viz., Earth's magnetosphere, solar wind, Saturn's magnetosphere etc., where the existence of energetic electrons, ions and dust have been confirmed by various satellite observations. The present investigation can also be extended to investigate the characteristics of nonlinear excitations in super dense astrophysical regimes.

C5.2-0034-18 EFFECT OF POLARIZATION FORCE ON DUST ACOUSTIC ROGUE WAVES IN SUPERTHERMAL DUSTY PLASMA

Kuldeep Singh, singh.kdeep07@gmail.com

Guru Nanak Dev University, Amritsar, India, AMRITSAR, India Nimardeep Kaur, nimarphy@gmail.com

Guru Nanak Dev University, Amritsar, India, AMRITSAR, India Nareshpal Singh Saini, nssaini@yahoo.com

Guru Nanak Dev University, Amritsar, India, Amritsar, India

Dust is an ubiquitous component of space and astrophysical environments and has a wide ranging applications in the different fields as well as in the study of astrophysical and space environments. Most of the space and astrophysical observations revealed the presence of superthermal particles in different plasmas. The deformation in the Debye sheath formed by ions around the negatively charged dust grains is termed as polarization force, which is an important frontline area of research in dusty plasma from last few decades. The polarization force is eloquently modified due to the presence of superthermal ions and thus produces the drastic changes in dust-acoustic waves (DAWs). In this investigation, the modulational instability (MI) of dust acoustic waves under the influence of polarization force, which is induced by superthermal ions, are examined. Using the reductive perturbation method, the nonlinear Schrödinger equation that governs the MI of the DAWs is obtained. It is found that the effect of the polarization term R is to narrow the wave number domain for the onset of instability. The amplitude of the wave envelope decreases as R increases, meaning that the polarization force effects render weaker the associated DA rogue waves. The DA rogue wave profile is very sensitive to any change in the restoring force acting on the dust particles. The polarization force has emphatic influence on rogue waves profile. It is intensified that results of this investigation may be useful in understanding the nonlinear wave dynamics in the magnetospheres of planets, such as Jupiter and Saturn as observed by the Nozomi satellite.

C5.2-0035-18 SHOCK DYNAMICS IN MULTI-ION DUSTY PLASMAS: THEORY VERSUS SIMULATIONS

Ibrahem Elkamash, elkamashi@gmail.com

Queen's University Belfast, Belfast, United Kingdom Brian Reville, b.reville@qub.ac.uk

Queen's University Belfast, Belfast, United Kingdom Ioannis Kourakis, ioanniskourakissci@gmail.com Queen's University Belfast, Belfast, United Kingdom

We introduce an analytical model for shocks in dusty plasma mixtures, taking into account collisionality and kinematic viscosity. A multicomponent plasma configuration is considered, consisting of positive ions, negative ions, electrons and a massive charged component in the background (dust). The model relies on the derivation of a dissipative hybrid Korteweg de Vries/Burgers equation, whose analytical shock-type solutions are derived analytically and tested numerically.

A comprehensive series of numerical simulations based on a semi-spectral algorithm are undertaken to test our analytical predictions against arbitrary step-like functions used as initial conditions.

The dependence of the shock profile and dynamics on various relevant plasma configuration parameters, including the Havnes dust parameter, in addition to dissipation, is investigated.

C5.2-0036-18 ROLE OF VORTEX DISTRIBUTED ELECTRONS ON LARGE AMPLITUDE DUST ION ACOUSTIC WAVES

Barjinder Kaur, kaurbarjinder1@gmail.com

Guru Nanak Dev University, Amritsar, India, Amritsar, India Manpreet Singh, singhmanpreet185@gmail.com

Guru Nanak Dev University, Amritsar, India, Amritsar, India Yashika Ghai, yashu.gh92@gmail.com

Guru Nanak Dev University, Amritsar, India, Amritsar, India Nareshpal Singh Saini, nssaini@yahoo.com

Guru Nanak Dev University, Amritsar, India, Amritsar, India

Depending on plasma environments, dust particles can be positively or negatively charged and the presence of charged dust in a usual electron-ion plasma generates a new type of wave mode called dust ion-acoustic mode and the waves associated with this mode have speed larger than the usual ion-acoustic mode. Also, instead of Boltzmann distribution, electrons in plasma may follow other distributions such as vortex/trapped distribution due to wave particle interaction. The vortex-like distribution plays a vital role in modifying the basic features of nonlinear electrostatic structures in many laboratory and space plasma. In present investigation, propagation properties of dust ion acoustic solitary waves are investigated in plasma with cold fluid ions, stationery negatively charged dust and trapped/vortex distributed electrons. Sagdeev pseudopotential method has been used to derive energy balance equation and the existence conditions for the formation of solitary structures in terms of Mach number are determined. The Sagdeev pseudopotential expression is a function of various physical parameters such as dust concentration, trapping parameter for electrons etc. These parameters significantly influence the basic features of dust ion-acoustic solitary structures. The results of present investiga- tion shall be useful to understand the various nonlinear phenomena in space and astrophysical environments, where charged particles obeying vortex-like distribution have been observed.

C5.2-0037-18 EFFECT OF DENSITY GRADIENT ON NONLINEAR STRUCTURES IN A DUSTY PLASMA

Guru Nanak Dev University, Amritsar, India, Amritsar, India Nimardeep Kaur, nimarphy@gmail.com

Guru Nanak Dev University, Amritsar, India, AMRITSAR, India Nareshpal Singh Saini, nssaini@yahoo.com

Guru Nanak Dev University, Amritsar, India, Amritsar, India

Non-thermal particle distributions are ubiquitous in the solar-wind and near Earth space plasma, their presence having frequently been confirmed by interplanetary missions. Such distributions represent suprathermal deviations from the Maxwellian equilibrium and are expected to exist in any low-density plasma in the Universe, where binary collisions of charges are sufficiently rare. The suprathermal populations are well parameterized by the so-called Kappa () index. Moreover, inhomogeneity may arise in plasma from the equilibrium dust density gradient. Even if the dust density is kept uniform, the plasma density gradient can still significantly affect dust acoustic solitary waves (DASWs) through the equilibrium dust charge because the dust grain charge is self-consistently determined by plasma charging currents that depend on plasma densities. In this case, the equilibrium dust charge instead of density becomes spatially non-uniform. In such a case, inhomogeneity is generated by electron and ion density gradients in the plasma and the amplitude of DASWs is mainly affected by density inhomogeneity rather than the electrons' energy. We investigate dust acoustic nonlinear structures in unmagnetized, inhomogeneous dusty plasma containing superthermal electrons and ions. In this model, the electrons and ions are described by the kappa distribution function and dust-neutral collisions have been taken into account. Using the reductive perturbation method, Modified Burger's equation will be derived. Our study would be useful for understanding different nonlinear features of localized electrostatic disturbances in a number of astrophysical dusty plasma systems, namely, planetary rings, cometary environments, and the interstellar medium where density inhomogeneity of charged particles is prevalent.

C5.2-0038-18 LOW FREQUENCY NONLINEAR WAVES IN A PAIR-ION QUANTUM DUSTY PLASMA

Yashika Ghai, yashu.gh92@gmail.com

Barjinder Kaur, barjinder.kaur@yahoo.in

Guru Nanak Dev University, Amritsar, India, Amritsar, India
Manpreet Singh, singhmanpreet185@gmail.com

Guru Nanak Dev University, Amritsar, India, Amritsar, India
Nareshpal Singh Saini, nssaini@yahoo.com

Guru Nanak Dev University, Amritsar, India, Amritsar, India

Pair-ion plasmas consist of particles having equal mass and opposite charges, where the negative ions may occur naturally or may be injected from external sources. Moreover, dust being ubiquitous component in laboratory and space plasma environments, gets charged and influences the dynamics of nonlinear plasma waves. The in-situ observations of polar mesosphere have revealed positively charged nanoparticles, positive-negative ions and electrons where the number density of negative ions is considerably large. The possible applications of pair-ion plasmas in Earth's ionosphere, mesosphere, solar atmosphere and in the microelectronics plasma processing reactors have been proposed by different investigations. Quantum effects play an important role in dense astrophysical environments such as white dwarfs, neutron stars etc. However, dilute charged particle systems may also exhibit quantum features provided the dimensions of the system are comparable to the de Broglie wavelength of the charged particles. The Quantum hydrodynamic (QHD) model is considered for describing the linear and nonlinear properties of charged quantum particles. We use QHD model to investigate dust-ion aocustic nonlinear waves in a three-fluids quantum pair-ion dusty plasma using Sagdeev Pseudopotential method with a new approach to derive the energy-integral equation. The dust and pair-ion species are considered as inertial fluid whereas the inertialess electrons are assumed to show quantum effects. The influence of various physical parameters such as quantum parameter, Mach number etc. has been investigated on the properties of dust ion acoustic waves (DIAWs). The findings of this investigation may give physical insights on nonlinear phenomenon occurring in quantum dusty pair-ion plasmas in space and laboratory environments.

42ND ASSEMBLY | 60TH ANNIVERSARY

SPACE PLASMAS IN THE SOLAR SYSTEM, INCLUDING PLANETARY MAGNETOSPHERES (D)

OVERVIEW TALKS (D0.1)

D0.1-0001-18 CORONAL MASS EJECTIONS AND SPACE WEATHER EFFECTS

Manuela Temmer, manuela.temmer@uni-graz.at Institute of Physics, UNI Graz, Austria, Graz, Austria

Earth-directed coronal mass ejections (CMEs), with their embedded magnetic fields and shocks ahead, compress and reconnect with the Earth's magnetic field and are the main drivers of strong geomagnetic storms. The impact of strong events may endanger critical ground-based infrastructure like power grids or disrupt communication and navigation systems. Due to such Space Weather effects, CMEs and related phenomena are an area of intense research interest. Important scientific knowledge could be achieved by closely monitoring and investigating the Sun-to-Earth "chain of action" of solar activity (evolution of surface magnetic fields, flares and CMEs), measurements of near-Earth space (in-situ plasma and magnetic field, energetic particles) and geomagnetic activity (response of the magnetosphere and different atmospheric layers down to ground-induced currents). This overview talk covers and discusses our recent understanding of the physical processes about the initiation and propagation of CMEs, their interaction with the solar wind and other ejecta, and consequences for Space Weather.

D0.1-0003-18 MULTI-WAVELENGTH OBSERVATIONS OF ASTROSPHERES ACROSS THE HERTZSPRUNG-RUSSELL DIAGRAM

Dominik Bomans, bomans@astro.rub.de Ruhr-University Bochum, Bochum, Germany

During the last 20 years, observation of the circumstellar material around stars, and specially bow-shocks (and bow-waves) allowed the investigation of the mass loss properties and mass loss histories of very different stellar types. It also opened new avenues to determine the interaction mechanisms and properties of the surrounding circumstellar and interstellar medium, and their magnetic fields. In this talk I will review the current state of multi-wavelength observations of astrospheres / bow shock nebulae. While most observations of bow-shock nebulae concentrated on the MIR and FIR emission up to now, I will especially discuss the power of UV, optical, and NIR line emission to characterize circumstellar environments / astrospheres. Further, I discuss the observational properties for different temperature, mass loss properties, and evolutionary state of the stars, as well as the effects of different interstellar environments. Some recent observations imply that bow shock may be particle accelerators and modulators. I therefore will include a critical look at the current observational knowledge of non-thermal radio emission, as well as X-ray, and cosmic rays from astrospheres beyond our solar system.

D0.1-0005-18 MMS HIGHLIGHTS AFTER TWO YEARS OF OPERATIONS

James Burch, jburch@swri.edu

Southwest Research Institute, San Antonio, Texas, United States

The NASA Magnetospheric Multiscale (MMS) mission, launched in March 2015, uses four closely-spaced spacecraft to investigate magnetic reconnection in the boundary regions of the Earth's magnetosphere by measuring charged particles and electric and magnetic fields at the electron scale for the first time in space. The prime mission was conducted in two phases, the dayside magnetopause and the magnetotail, with four spacecraft in a tetrahedron formation with separations adjustable from 160 km down to 7 km in a lowinclination, highly elliptical orbit with apogee at 12 Earth radii on the day side and 25 Earth Radii in the tail. Reconnection at the dayside magnetopause is asymmetric with different plasma and magnetic conditions on either side of the current layer. As predicted by plasma simulation, the electron stagnation point is located Earthward of the reconnection X line. In the tail, magnetic fields and plasma densities are equal in both inflow regions, and the electron stagnation point and the X line are coincident. Another important difference is the much lower plasma density in the tail, which results in much higher magnetic energy per particle available for acceleration. Early results confirmed the prediction of agyrotropic crescent-shaped electron distribution functions at the stagnation point of dayside reconnection. These distributions carry the out-of-plane current and are accelerated by the reconnection electric field, which is mainly generated by divergence of the electron pressure. In this way, reconnection is driven by electron dynamics, which is initiated by acceleration of magnetosheath electrons through the X-line magnetic null by the well-known ambipolar normal electric field at the magnetopause. Conversion of magnetic energy to electron energy occurs mainly at the stagnation point for small guide fields but equally at the X line for large guide fields. The physics of reconnection in the tail is similar in that electron crescent distributions are observed in the electron diffusion region but different in that their source is electrons from the neutral sheet rather than from the inflow regions and in the fact that the tail crescents are multiple (double or triple) resulting from a longer residence time in the current layer where multiple acceleration by the reconnection electric field occurs along meandering orbits. MMS has also observed the unexpected occurrence of reconnection inside of flux transfer and Kelvin-Helmholtz events as well as in the magnetosheath where at the smallest scales it proceeds by electron dynamics only with no participation by ions. These and other findings of MMS during its prime mission are discussed in this paper.

D0.1-0007-18 FLUX TRANSFER EVENTS AT EARTH AND THE OTHER PLANETS

James Slavin, jaslavin@umich.edu

University of Michigan, Ann Arbor, Michigan, United States

Flux transfer events (FTEs) are twisted flux tubes created by multiple X-line reconnection in the magnetopause current sheet at Earth and the other magnetized planets. One end is anchored in the magnetosphere and maps to one of the magnetospheric cusps, while the other is connected to the interplanetary magnetic field. These structures are generally well-modeled as force-free flux ropes moving in response to the stress exerted by the end of the FTE embedded in magnetosheath flow. Spacecraft passing through the FTE observe a strong core magnetic field along its central axis surrounded by weaker helical fields. If the spacecraft remains outside of the FTE, then it encounters only the interplanetary or magnetospheric magnetic field that is draped and compressed about the FTE. This signature is referred to as a traveling compression region. This review compares and contrasts the FTEs observed at Mercury, Earth, Jupiter, and Saturn with special attention to their frequency of occurrence and magnetic flux content. The possible implications of these comparative FTE analyses for our understanding of magnetic reconnection at the different planets and the role of FTEs in driving magnetospheric dynamics will be considered and assessed. Finally, the new opportunities for progress in understanding FTE formation, evolution and dynamics presented by the Multiscale Magnetospheric mission and new global magnetohydrodynamic simulations with reconnection regions captured by embedded particle-in-cell codes will be briefly discussed.

D0.1-0008-18 PARKER SOLAR PROBE: A NASA MISSION TO TOUCH THE SUN

Klaus Scherer, kls@tp4.rub.de

Ruhr-Universität Bochum, Bochum, Germany Nicola Fox, nicola.fox@jhuapl.edu

Applied Physics Laboratory, Laurel, Maryland, United States

The newly renamed, Parker Solar Probe (PSP) mission will be the first mission to fly into the low solar corona, revealing how the corona is heated and the solar wind and energetic particles are accelerated, solving fundamental mysteries that have been top priority science goals since such a mission was first proposed in 1958. The scale and concept of such a mission has been revised at intervals since that time, yet the core has always been a close encounter with the Sun. The primary science goal of the Parker Solar Probe mission is to determine the structure and dynamics of the Sun's coronal magnetic field, understand how the solar corona and wind are heated and accelerated, and determine what mechanisms accelerate and transport energetic particles. PSP uses an innovative mission design, significant technology development and a risk-reducing engineering development to meet the science objectives. In this presentation, we provide an overview of the mission science and design, and an update on the progress of the Parker Solar Probe mission as we prepare for the July 2018 launch.

D1.1-0001-18 OBSERVATIONS OF WIDESPREAD SOLAR ENERGETIC ELECTRON EVENTS: WHAT CAN WE LEARN FROM ANISOTROPIES AND SPECTRA?

Nina Dresing, dresing@physik.uni-kiel.de University of Kiel, Kiel, Germany

Andreas Klassen, klassen@physik.uni-kiel.de University of Kiel, Kiel, Germany

Bernd Heber, heber@physik.uni-kiel.de

Christian-Albrechts-Universität zu Kiel, Kiel, Germany Raul Gomez-Herrero, raul.gomezh@uah.es

SRG. Universidad de Alcala, Spain

The two STEREO spacecraft in combination with close to Earth observatories have provided us with a wealth of multi-spacecraft solar energetic particle (SEP) observations. Among these, surprisingly wide longitudinal SEP distributions have been observed which still challenge the current acceleration, injection, and transport theories. An indispensable observation to disentangle different mechanisms and to shed some light on the specific scenarios is the anisotropy observed at different positions throughout the same event. We will present anisotropy observations which suggest that no overall scenario can explain every widespread event but that different types of events exist. We will also show spectra of near-relativistic electrons observed at multiple spacecraft during widespread events and discuss if different source populations might be present at the same time.

D1.1-0002-18 MODELLING OF NON-DIFFUSIVE TRANSPORT OF SOLAR ENERGETIC PARTICLES

Timo Laitinen, tlmlaitinen@uclan.ac.uk

University of Central Lancashire, Preston, United Kingdom

Solar Energetic Particles (SEPs), accelerated during solar eruptions, are typically observed with in situ instruments in the interplanetary space. They propagate in the interplanetary medium permeated by turbulent magnetic field, and their transport is typically modelled with a Fokker-Planck (FP) equation as diffusive propagation along and across the mean magnetic field. Cross-field diffusion is often considered small or negligible, as transport theory gives small values for cross-field diffusion coefficient in the solar wind. However, recent multi-spacecraft SEP observations made with the STEREO, SOHO and ACE spacecraft have shown that SEPs have access to wide range of heliolongitudes, across the mean Parker field spiral field, with transport model fits of the observations implying much stronger cross-field diffusion than what the current transport theory allows. Our recent studies using full-orbit test particle simulations offer a possible explanation for the fast cross-field transport of SEPs as early non-diffusive propagation of SEPs. Our studies show that charged particles remain on their initial meandering field lines for considerable time, comparable to particle's mean parallel scattering time, τ. Within these timescales, particle propagation with respect to the mean field direction is nondiffusive, with the particles each propagating back and forth along their initial meandering field lines. Subsequently, particles begin to decouple from their initial field lines, and only after 10 τ their propagation propagation across the mean field can be described as diffusion. For 10 MeV protons in interplanetary turbulence environment, observed at 1 AU from their source location, this results in a wide extent of the SEPs already at the onset of an SEP event. Crossfield diffusion begins to dominate the particle distribution only after tens of hours. Using an extended FP model that accounts for the early non-diffusive propagation, we are able to explain the observed wide SEP events even with a narrow SEP source. We discuss the implications of our new model approach to SEP event modelling, and for improving our understanding of SEP origins.

D1.1-0003-18 HEAVY ION CHARACTERISTICS OF SOLAR ENERGETIC PARTICLE EVENTS RESULTING FROM FILAMENT ERUPTIONS

Christina Cohen, cohen@srl.caltech.edu

California Institute of Technology, Pasadena, California, United States Richard Mewaldt, rmewaldt@srl.caltech.edu

California Institute of Technology, Pasadena, California, United States George Ho, george.ho@jhuapl.edu

Catholic University of America, Washington, District of Columbia, United States

Solar energetic particles (SEPs) can be accelerated near the Sun both by flare-related reconnection processes and shocks driven by coronal mass ejections (CMEs). As the latter is believed to dominate in large SEP events, understanding the details of shock acceleration is critical to accurate space weather prediction and as well as directly impacting our understanding of the variability of SEP events. Unfortunately, it is often difficult to identify which SEP event characteristics are controlled by shock acceleration and which are a result of related flare processes as large flares and fast CMEs frequently occur together. SEP events associated with filament eruptions typically have no or weak soft X-ray flares and so provide the best opportunity to study shock acceleration near the Sun without the added complication of flare-associated acceleration. Recent studies of such events have found associated fast CMEs and type II radio bursts observed both near the Sun and in the interplanetary medium, indicating the presence of a strong and long-lasting shock able to accelerate particles. The formation of the shocks appears to occur significantly higher in the corona than is standard for typical SEP events and the resulting energetic proton spectra are substantially softer. We present the characteristics of heavy ion properties (e.g., spectra and composition) in ten such events and compare them to those typical for large SEP events.

D1.1-0004-18 ACE/EPAM ELECTRON EVENT CATALOG (1997-2017)

Susan Samwel, s_w_samwel@yahoo.com

National Research Institute of Astronomy and Geophysics (NRIAG), Helwan, Egypt Rositsa Miteva, rmiteva@space.bas.bg

Space Research and Technology Institute - Bulgarian Academy of Sciences, Sofia, Bulgaria

In the present study, a list of solar energetic electron events in solar cycle 23 and 24 in the energy range 103-315 keV is given. We collected and analyzed the observed in situ electron data from the Advanced Composition Explorer (ACE) spacecraft located near Earth using the Electron, Proton and Alpha Monitor (EPAM) instrument, and more specifically the deflected electron (DE) suite. This event list is considered as the first comprehensive catalog for electrons during the period 1997-2017. We identified the onset times, peak times and peak intensities of the electron events, and the characteristic quantities of the associated solar activity, namely solar flares and coronal mass ejection. We performed linear and partial correlation analysis of the properties of electron events and the associated eruptive solar phenomena in order to distinguish between the effects from the different particle accelerators. This catalog can be employed by the space weather community in studying the effect of the solar energetic particles on man-made systems and on climate changes. Correlation study is essential ingredient of models used to predict solar events. Thus, hazard effects of solar energetic particles can be mitigated.

D1.1-0005-18 ANOMALOUS TRANSPORT OF ENERGETIC ELECTRONS IN SOLAR FLARES.

Nicolas Bian, nbian@hotmail.com

Western Kentucky University, Bowling Green, Kentucky, United States

The transport of the energy contained in suprathermal electrons plays a key role in our understanding of many aspects of flare physics, from the spatial distribution of hard X-ray emission and energy deposition in the ambient atmosphere to global energetics. More generally, the study of energetic electrons during flares may prove very valuable to understand the genesis of anomalous transport in astrophysical plasmas. We will show that a satisfactory treatment of the diffusion of suprathermal electrons during flares require the consideration of non-local effects, so that the electron flux depends not just on the local gradient of the electron distribution function but on the value of this gradient within an extended region encompassing a significant fraction of the scattering mean free path. Our analysis applies to a variety of scattering mechanisms including turbulent scattering. We will show that the transport of energetic electrons along the magnetic field of a flaring loop can be modeled as a Continuous Time Random Walk with velocity-dependent distributions of jump sizes and occurrences, both of which can be expressed in terms of the scattering mean free path.

Recent studies of particle acceleration in the heliosphere have revealed a new mechanism that can energize particles up to several MeV/nuc locally in the solar wind. It has been found that stream-stream interactions as well as the heliospheric current sheet - stream interactions produce huge magnetic cavities, which resemble tokamaks in terms of solving the confinement problem. Such cavities are usually filled with dynamical small-scale magnetic islands (SMIs) with a typical width of 0.01 AU or less, which are produced by magnetic reconnection at strong current sheets representing the borders of magnetic cavities. SMIs experience compression and merging due to dynamics of the entire system, which leads to trapping and re-acceleration of energetic particles in the confined region according to predictions based on the theory describing stochastic particle energization in the supersonic solar wind via numerous dynamically interacting SMIs (Zank et al. ApJ, 2014, 2015; le Roux et al. ApJ, 2015, 2016). Since SMIs cannot escape, acceleration of energetic particles occurs in the most effective way. As a result, crossings of magnetic cavities are associated with unusual variations in the energetic particle flux up to 1-2 MeV/nuc near the Earth's orbit. These energetic particle flux enhancements called "atypical energetic particle events" (AEPEs) are observed at timescales from sim1/2 hour to several hours, sometimes, against the background of classical solar energetic particle events or before/after energetic particle enhancements associated with corotating interaction regions, but mostly in the relatively quiet solar wind (Khabarova et al. ApJ, 2015, 2016,

Khabarova Zank, ApJ, 2017). AEPEs possess energies that overlap SEP events and can be an important component in understanding space weather. Since both SMIs and current sheets of various origins are a manifestation of turbulence, the study of temporal and spatial evolution of these structures links dynamical processes in different plasmas and particle acceleration in the heliosphere. This work is partly supported by the International Space Science Institute (ISSI) in the framework of International Team 405 entitled "Current Sheets, Turbulence, Structures and Particle Acceleration in the Heliosphere.

D1.1-0007-18 PARTICLE ACCELERATION IN A RECONNECTING CURRENT SHEET: COALESCENT AND SQUASHING MAGNETIC ISLANDS

Valentina Zharkova, valentina.zharkova@northumbria.ac.uk University of Northumbria, Newcastle Upon Tyne, United Kingdom Qian Xia, q.xia@northumbria.ac.uk

Northumbria University - UK, Newcastle, United Kingdom

We investigate particle acceleration in 3D reconnecting current sheets (RCSs) containing multiple Oand X-nullpoints and different topologies: coalescent (moving towards each other) and squashed islands using a test particle and particle-in-cell (PIC) approach. The inclusion of multiple O-nullpoints, or magnetic islands, reveals that acceleration of protons and electrons in a current sheet with strong guiding field remains asymmetric towards the midplane, e.g. electrons and protons are ejected into the opposite directions from the midplane. Both types of particles (electrons and protons) mainly gain energy in a vicinity of X-nullpoints or inside O-nullpoints and, depending on their initial energy, these gains can reach relativistic energies in a single island. Accelerated particles with critical energies can escape O-nullpoints, or magnetic islands, only through neighbouring X-nullpoints escape along the midplane. As result, there are electron clouds formed between the magnetic islands while electrons gain the critical energy to break from an RCS. The energy gains in coalescent islands are much smaller than from the squashed ones. Electrons are shown to form clouds about X-nullpoints between the magnetic islands where they become ejected after gaining the critical energies required to break from the RCS magnetic topology. Particle acceleration in 3D RCSs with multiple Xand O-nullpoints is probed with some observational features in the solar corona and heliosphere. This research is funded by the US Airforce grant.

D1.1-0008-18 REGULARIZED KAPPA-DISTRIBUTIONS WITH NON-DIVERGING MOMENTS

Klaus Scherer, kls@tp4.rub.de

Ruhr-Universität Bochum, Bochum, Germany Horst Fichtner, hf@tp4.rub.de

Ruhr-Universität Bochum, Bochum, Germany Marian Lazar, mlazar@tp4.rub.de

Ruhr-Universität Bochum, Bochum, Germany

For various plasma systems the so-called κ-distribution is widely used to describe suprathermal (non-relativistic) particle components exhibiting a power-law behaviour in velocity or energy. Despite its success the concept of the standard κ-distribution remains disputable because the latter is defined only for κ > 3/2 and possesses only a finite number of velocity moments vl (with the integer l defining the l-th moment), some of which, i.e., l > 2κ1, are diverging. In order to resolve these limitations we introduce the regularized κ-distribution. After a discussion of its properties and its relation to the standard κas well as to the Maxwellian distribution, we provide a general analytical expression that enables to calculate all of its moments, and illustrate that only fluid results, that critically depend on these moments will change, but not those obtained within the framework of kinetic theory.

D1.1-0009-18 NON-LINEAR DIFFUSIVE SHOCK ACCELERATION: THEORY AND OBSERVATIONS

Elena Amato, amato@arcetri.astro.it

INAF-Osservatorio Astrofisico di Arcetri, Firenze, Italy

The process of diffusive shock acceleration is likely the most commonly invoked particle acceleration mechanism in Astrophysics. It is thought to operate in several other environments, with very different physical properties, such as the Earth bow shock, interplanetary shocks, extragalactic radio sources, galactic and intergalactic shock waves and more. Diffusive acceleration at the shock waves produced by Supernova explosions is thought to be responsible for the energization of the bulk of cosmic rays in the Galaxy. In this particular environment the efficiency of the process has long been implied to be of order 10-15%, high enough to force the scientific community working on the subject to take into account non-linear effects, namely the back reaction of the accelerated particles on the accelerating system.

In this talk I will summarize our current knowledge of non-linear diffusive shock acceleration. I will discuss all the elements that go into the state-of-the-art description of this process, such as dynamical and thermodynamical effects on the ambient plasma, magnetic field amplification and implications for the spectrum and maximum energy achievable by the accelerated particles. I will then discuss how theory compares with observations of Cosmic Rays and Supernova Remnant shocks, and what the current challenges are, finally mentioning the possible extension of this kind of modeling to the heliospheric environment.

D1.1-0010-18 ANISOTROPY OF TEV COSMIC RAYS

Ming Zhang, mzhang@fit.edu

Florida Institute of Technology, Melbourne, Florida, United States
Nikolai Pogorelov, np0002@uah.edu

University of Alabama in Huntsville, Huntsville, Alabama, United States

A number of experiments have conclusively determined a low level of 0.1% anisotropy in the angular variations of TeV cosmic ray intensities. Although there is an overall dipole component, the anisotropy pattern contains a significant amount of fluctuations on smaller angular scales, making it appear to be quite complicated. One source of the observed anisotropy is the heliosphere because TeV cosmic rays are significantly deflected by the nonuniformity of the magnetic field and suffer energy changes by the electric field of plasma flows. We have developed a method of using the Liouville theorem to map out particle distribution function to Earth from the local interstellar medium. In this paper, selected results of our calculations with the mapping technique will be presented. Based on the Tibet ASγ measurements, we are able to determine the truly pristine cosmic ray anisotropy in the local interstellar medium. It turns out the interstellar anisotropy pattern of TeV cosmic rays is much simpler than it is observed. We can also determine the amount of distortion caused by the heliosphere. We can locate the anisotropy features that are associated with the plane perpendicular to the interstellar magnetic field, hydrogen deflection plane, heliotail, and solar corona. The distortion may account for some of the observed small-scale anisotropies.

D1.1-0011-18 THE EFFECT OF MAGNETIC TURBULENCE ON PITCH-ANGLE ANISOTROPIES OF INTERSTELLAR PICKUP IONS ACCELERATED BY THE SOLAR WIND TERMINATION SHOCK

Jakobus Le Roux, jar0013@uah.edu

University of Alabama in Huntsville, Huntsville, Alabama, United States

It will be discussed how time variations in the turbulent magnetic field affect the solar wind frame pitch-angle distribution of interstellar pickup ions accelerated by the nearly perpendicular solar wind termination shock. For this purpose, fluctuations in the magnetic spiral angle, modeled as a q-Gaussian distribution, and fluctuations in the magnetic field strength, simulated as a log-normal distribution, were introduced as a time series in a focused transport model of pickup ion acceleration by the termination shock. The results show that varying the standard deviation of the spiral angle distribution and of the field strength distribution can significantly affect pitch-angle distributions of pickup ions both upstream and downstream of the termination shock. In the simulations, pitch-angle distributions upstream varied from beam-like to pancake distributions whereas downstream distributions were altered from nearly isotropic distributions to pancake distributions.

D1.1-0012-18 LOW-ENERGY ELECTRONS IN THE VERY LOCAL INTERSTELLAR MEDIUM

Marius Potgieter, marius.potgieter@nwu.ac.za North-West University, Potchefstroom, South Africa Donald Ngobeni, donald.ngobeni@nwu.ac.za

North-West University, Mafikeng Campus, Mmabatho, South Africa

Voyager 1 has been observing electrons down to 4 MeV, from ahead of the position of the termination shock (TS), through the inner heliosheath, up to the heliopause (HP) and beyond. As predicted, this very local interstellar spectrum (or heliopause spectrum) exhibits a power-law down to the mentioned energy. The behaviour of these electrons are investigated further with a numerical, shock-acceleration model from the TS up to the HP, focussing on the question that comes up about what the Galactic electron spectrum is below 4 MeV and how it may differ from the HP spectrum.

D1.1-0013-18 ENERGETIC PARTICLE TRANSPORT AND ACCELERATION AT INTERPLANETARY SHOCKS

Joe Giacalone, giacalon@lpl.arizona.edu

University of Arizona, Tucson, Arizona, United States

Interplanetary (IP) shocks, especially those with high Mach numbers, are associated with significant enhancements in high-energy charged particles. The observed variation of energetic particle intensities, energy spectra, and composition near these shocks, along with observations of the solar wind and magnetic field, provide important constraints on theories of possible acceleration mechanisms and particle transport in irregular magnetic fields. In this talk, I will give an overview of our current theoretical understanding of the acceleration and propagation of energetic particles near IP shocks. I will also present some new observations of the evolution of the ion energy spectrum (with energies below the thermal peak to the high-energy tail) from a few hours before the shock until after its passage with a resolution of 12 minutes. On the one hand, these new observations solve some previously unanswered questions; but, on the other hand, they also presents new puzzles.

D1.1-0014-18 PROLONGED ACCELERATION OF NON-THERMAL ELECTRONS IN A HIGH MACH NUMBER SHOCK TRANSITION REGION

Takanobu Amano, amano@eps.s.u-tokyo.ac.jp University of Tokyo, Tokyo, Japan

Yosuke Matsumoto, ymatumot@chiba-u.jp Chiba University, Chiba, Japan

Takuma Katou, t.kato@eps.s.u-tokyo.ac.jp The University of Tokyo, Tokyo, Japan

Masahiro Hoshino, hoshino@eps.s.u-tokyo.ac.jp University of Tokyo, Tokyo, Japan

We discuss recent three-dimensional (3D) particle-in-cell simulation results for high Mach number quasi-perpendicular shocks. At very high Mach numbers relevant to supernova remnant shocks, we show that the shock internal structure is filled with large-amplitude magnetic turbulence generated by the Weibel instability driven unstable by the reflected ion beam. At the same time, however, clear coherent electrostatic waves are also found at the leading edge of the shock. We demonstrate that the both of them contribute to the production of non-thermal electrons. We find that upstream low-energy particles entering into the shock transition region are first accelerated through the interaction with the coherent electrostatic waves, and then suffer a further energization in the Weibel-generated turbulent region in a deeper shock transition region. The former may be understood as the shock-surfing mechanism, which thus has finally proved to be effective in 3D for the first time. We consider the latter mechanism as a shock drift acceleration (SDA) but modified by the Weibel-generated turbulence. We show that, in contrast to the classical adiabatic SDA for small-gyroradius particles, stochastic pitch-angle scatterings during the acceleration process efficiently confine the particles in the acceleration region. As a result, a power-law energy spectrum is formed with its index independent of detailed properties of the scattering. The same mechanism, which we call a stochastic SDA, may be applicable to moderate Mach number shocks where, instead of the Weibel turbulence, high-frequency whistler waves may play the role of pitch-angle scattering. We also discuss implication for recent high temporal resolution in-situ measurements of the Earth's bow shock by the Magnetospheric Multiscale (MMS) spacecraft.

D1.1-0015-18 ION ACCELERATION IN NON-RELATIVISTIC QUASI-PARALLEL SHOCKS USING FULLY KINETIC SIMULATIONS

Cedric Schreiner, mail@cschreiner.de

Max Planck Institute for Solar System Research, Göttingen, Germany Patrick Kilian, mail@petschge.de

North-West University, Potchefstroom, Potchefstroom, South Africa Felix Spanier, felix@fspanier.de

North-West University, Potchefstroom, South Africa Patricio A. Patricio Muñoz, munozp@mps.mpg.de

Max Planck Institut für Sonnensystemforschung, Göttingen, Germany

Shocks in collision-less space plasma are now widely studied using hybrid and kinetic simulations. Their formation and dynamics are mostly understood and there have been advances in the understanding of particle acceleration by these shock fronts. From observation we know however that not only electrons and protons – the most abundant species in the solar wind – are strongly affected by the shock but that also rare, heavier species, such as different helium isotopes, are scattered and accelerated. We therefore used fully kinetic particle-in-cell simulations to model non-relativistic quasi-parallel shocks in a collision-less plasma that contains a small fraction of heavier ions species to study their energy spectra. A fraction of the heavier ions is reflected at the shock front and is able to modify the upstream plasma before it actually reaches the shock itself.

D1.1-0016-18 LOW-ENERGY IONS INJECTION AND ACCELERATION AT INTERPLANETARY SHOCKS WITH FOCUSED TRANSPORT MODEL

Pingbing Zuo, pbzuo@hit.edu.cn

HIT Institute of Space Science and Applied Technology, Shenzhen, China Ming Zhang, mzhang@fit.edu

Florida Institute of Technology, Melbourne, Florida, United States Xueshang Feng, fengx@spaceweather.ac.cn

National Space Science Center, Chinese Academy of Sciences, Beijing, China

There are strong evidences that a small portion of suprathermal particles from hot coronal material or remnants of previous solar energetic particle (SEP) events serve as the source of large SEP events. Here we present a test particle simulation on the injection and acceleration of lowenergy suprathermal particles by Laminar nonrelativistic oblique shocks in the framework of the focused transport theory, which is proved to contain all necessary physics of shock acceleration, but avoid the limitation of diffusive shock acceleration (DSA). We first characterize the role of cross-shock potential (CSP) on pickup ions (PUIs) acceleration. The CSP can affect the shape of the spectrum segment at lower energies, but it does not change the spectral index of the final power-law spectrum at high energies. It is found that a stronger CSP jump results in a dramatically improved injection efficiency. Our simulation results also show that the injection efficiency of PUIs is mass dependent, which is lower for species with a higher mass. The injection efficiency as the function of Mach number, obliquity, injection speed, and shock strength is also calculated. It can be proved that the focused transport theory is an extension of DSA theory with the capability of predicting the efficiency of source particle injection.

D1.1-0017-18 A STOCHASTIC SHOCK DRIFT ACCELERATION OF ELECTRONS IN THE SHOCK TRANSITION REGION

Takuma Katou, t.kato@eps.s.u-tokyo.ac.jp The University of Tokyo, Tokyo, Japan Takanobu Amano, amano@eps.s.u-tokyo.ac.jp University of Tokyo, Tokyo, Japan

The acceleration of non-thermal particles is one of the most important problems in astrophysics. Galactic cosmic rays with energies below 1015eV are believed to be accelerated by the Diffusive Shock Acceleration (DSA) at supernova remnant (SNR) shocks. However, it is well known that the DSA is not efficient for non-relativistic electrons. Radio and X-ray observations of SNR shocks implies that there exists an efficient pre-acceleration mechanism that injects thermal electrons to relativistic energies. The shock accelerated non-thermal electrons have also been observed at the planetary bow shocks. A statistical analysis of in-situ satellite observations of the Earth's bow shock showed that the whistler critical Mach number of the shock regulates the acceleration efficiency of energetic electrons (Oka et.al., 2006). This may be understood as the condition required for the self-generation of whistler waves by energetic electrons (Amano and Hoshino 2010). These results indicate that whistler waves play a role for the acceleration of sub-relativistic electrons.

We here propose a new acceleration mechanism that takes into account the effect of stochastic pitch-angle scatterings by whistler waves during the course of the Shock Drift Accelerations (SDA), which is an adiabatic acceleration process for small-gyroradius particles at a quasiperpendicular shock. To simplify the analysis, we focus only on spatially integrated spectra and employ a box model in which only the dependence on the energy and pitch-angle of the distribution function is considered. We theoretically analyzed the energy spectrum of electrons in the limit of strong scattering. In this case, the pitch-angle distribution is isotropic and the energy spectrum becomes a power-law. We show that the spectral index is independent of the strength of pitch-angle scatterings, and is roughly consistent with those measured in the bow shock. We also discuss Monte-Carlo simulation results for the proposed model to take into account the effect of an anisotropy in the pitch-angle distribution which should appear in general, in particular at around the maximum energy cutoff. We demonstrate that the simulation results agree quite well with the theoretical prediction in the strong scattering limit. We find that the maximum energy attainable through the proposed mechanism scales linearly with the pitch-angle diffusion coefficient.

D1.1-0018-18 TIME-DEPENDENT PERPENDICULAR TRANSPORT OF ENERGETIC PARTICLES

Andreas Shalchi, andreasm4@yahoo.com University of Manitoba, Winnipeg, Canada

The motion of energetic particles in magnetic turbulence across a mean magnetic field can be explored analytically. The approach presented in this talk allows for a full time-dependent description of the transport, including compound sub-diffusion. For the first time it is shown systematically that as soon as there is transverse structure of the turbulence, diffusion is restored even if no Coulomb collisions are invoked. Compared to other non-linear theories the new approach has the advantage that a diffusion approximation is no longer part of that theory. Criteria for sub-diffusion and normal Markovian diffusion are discussed as well. A comparison with test-particle simulations is also shown.

D1.1-0019-18 SUPERDIFFUSION OF ENERGETIC PARTICLES IN MHD TURBULENCE: EFFECTS ON PROPAGATION AND ACCELERATION

Alex Lazarian, lazarian@astro.wisc.edu

University of Wisconsin - Madison, Madison, Wisconsin, United States

Turbulent magnetic field lines exhibit superdiffusive behavior at the scales less than the turbulent injection scale. As a result, first of all, the subdiffusive propagation of energetic particles gets essentially impossible. More importantly, the processes of propagation cannot be described by the diffusion equation on the scales smaller than the injection scale. This entails important consequences for the particle acceleration. I shall discuss how the diffusive shock acceleration and the acceleration in magnetic reconnectin sites changes in the presence of the superdiffusion at hand.

D1.1-0020-18 FROM BALLISTIC TO DIFFUSIVE PROPAGATION OF ENERGETIC PARTICLES USING AN EXACT SOLUTION OF FOKKER-PLANCK EQUATION

Mikhail Malkov, mmalkov@ucsd.edu

University of California, San Diego, La Jolla, California, United States

Propagation of energetic particles through magnetized turbulent media is reconsidered using an exact solution to the Fokker-Planck equation. It strictly applies to isotropic scattering but it captures all relevant propagation regimes, from ballistic to diffusive, for arbitrary spaceand time-scales relative to the particle mean free path and collision time. It is found that an intermediate (transdiffusive) propagation regime lasts for a (surprisingly) long time, about five particle collision times while starting as early as at a one-half of that. Since the particle scattering strongly depends on its energy, there always are particles that propagate neither ballistically nor diffusively. Their treatment should utilize the exact solution of Fokker-Planck equation. Problems with the application of often used approaches based on the telegraph equation and fractional diffusion are also briefly discussed.

D1.1-0021-18 ENERGETIC PARTICLE TRANSPORT IN THE PRESENCE OF MAGNETIC TURBULENCE: INFLUENCE OF SPECTRAL EXTENSION AND INTERMITTENCY

Francesco Valentini, francesco.valentini@fis.unical.it Università della Calabria, Arcavacata Di Rende, Italy

The transport of energetic particles in the presence of magnetic turbulence is an important but unsolved problem of space physics and astrophysics. Here we aim at advancing the understanding of energetic particle transport by means of a new numerical model of magnetic turbulence, which allows to reproduce an isotropic turbulence spectrum with large spectral extension at a reasonable computational cost. The synthetic turbulence model, that consist in a superposition of wavelet-like functions at different scales, allows for the first time to reproduce a spectrum longer than four decades and to change the level of intermittency, implemented through a pmodel. Considering simulation parameters close to those of the solar wind at 1 AU, we inject 1 MeV protons in the turbulence realization and compute the parallel and perpendicular diffusion coefficients as a function of spectral extension, turbulence level, and intermittency level. While a number of previous results are recovered in the appropriate limits, including anomalous transport regimes for low turbulence levels, we find that long spectral extensions tend to reduce the value of the diffusion coefficients. Further, we find that intermittency has an influence on parallel transport but not on perpendicular transport, with the parallel diffusion coefficient increasing with the level of intermittency. We also obtain the distribution of particle inversion times for parallel velocity, which is found to be a power law for more than one decade, and compare it with the pitch angle scattering times observed in the solar wind.

D1.1-0022-18 ANOMALOUS AND GALACTIC COSMIC RAY INTENSITY VARIATIONS AT 1 AU THROUGHOUT THE SOLAR CYCLE

Richard Leske, ral@srl.caltech.edu

A. C. Cummings, ace@srl.caltech.edu

California Institute of Technology, Pasadena, California, United States Richard Mewaldt, rmewaldt@srl.caltech.edu

California Institute of Technology, Pasadena, California, United States

E. C. Stone, ecs@srl.caltech.edu

California Institute of Technology, Pasadena, California, United States Christina Cohen, cohen@srl.caltech.edu

California Institute of Technology, Pasadena, California, United States Mark Wiedenbeck, mark.e.wiedenbeck@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Anomalous cosmic rays (ACRs) and galactic cosmic rays (GCRs) probe energetic particle transport conditions throughout the heliosphere. At 1 AU, measured ACR intensities generally track GCR intensities but with differences between solar polarity cycles: at high rigidities, GCRs reach higher peak intensities during A<0 cycles, while ACRs have been higher at A>0 solar minima. During the present approach to an A>0 solar minimum, ACR oxygen above 8 MeV/nucleon as measured by the Advanced Composition Explorer (ACE) is still 40% below the levels seen in 1997 during the last A>0 minimum (but has already reached the peak intensities seen during the 2009 A<0 solar minimum). Conversely, the GCR iron intensity at 300 MeV/nucleon is presently slightly greater than that in 1997 (but remains 10% below its record-setting 2009 value). Drift effects play an important role in the modulation of both ACRs and GCRs. Positively charged ions drift inward along the heliospheric current sheet (HCS) during A<0 cycles and their intensities are thus sensitive to the HCS tilt angle, which remained high for much of the last solar cycle. We have previously shown that both ACR and GCR intensities were significantly higher for a given HCS tilt angle during the 2000-2012 A<0 cycle than they were during the prior (1980-1990) A<0 cycle, and this trend appears to be continuing into the new A>0 cycle. But while GCR intensities in 2009 reached the highest levels recorded during the last 50 years, ACR intensities were only similar to those in the 1980's A<0 minimum. This observation, along with the higher GCR intensities but lower ACR intensities at present compared with 1997, indicate that 1-AU ACR intensities are being suppressed relative to GCRs in recent solar minima, despite the overall reduction in heliospheric

modulation. Contributing factors may include greater sensitivity of the ACRs to the HCS tilt angle due to their source distribution in latitude, a reduction in the acceleration efficiency of ACRs, or a drop in abundance of ACR seed material (pick-up ions) resulting from weaker solar activity.

We present more than 20 years of ACR and GCR intensity data acquired by ACE throughout two complete solar cycles, with emphasis on the recent observations, and discuss possible reasons for the differences in the relative behavior of ACRs and GCRs in the different solar cycles.

D1.1-0023-18 SOLENOIDAL IMPROVEMENTS FOR THE JF12 GALACTIC MAGNETIC FIELD

Jens Kleimann, jk@tp4.rub.de

Ruhr-Universität Bochum, Bochum, Germany

Timo Schorlepp, timo.schorlepp@ruhr-uni-bochum.de Ruhr-Universität Bochum, Bochum, Germany

Lukas Merten, mertelx3@ruhr-uni-bochum.de Ruhr-Universität Bochum, Bochum, Germany Julia Becker Tjus, julia@tp4.rub.de

Ruhr-Universität Bochum, Bochum, Germany

The popular JF12 (Jansson & Farrar 2012) analytic model provides a quantitative description of the Galaxy's large-scale magnetic field that is widely used in various astrophysical applications. However, both the poloidal X-type component and the spiral disk component of JF12 exhibit regions in which the magnetic divergence constraint is severely violated. We first propose a cure for this problem, resulting in a truly solenoidal large-scale field. Second, the otherwise straight field lines of the X-type component exhibit kinks in the Galactic plane that, while not unphysical, may pose difficulties for, e.g., numerical tracing of cosmic-ray particles. We propose and discuss two possible strategies to mitigate this problem. All corrections are kept as minimal as possible in order not to destroy the agreement to observational data that the unmodified JF12 field was based on. Furthermore, the performance of our improved version of the field model is quantitatively assessed by test simulation using the CRpropa Galactic cosmic-ray propagation code.

D1.1-0024-18 PITCH ANGLE RESOLVED DIFFUSION COEFFICIENTS FROM MHD SIMULATIONS

Alex Ivascenko, 24790052@nwu.ac.za

North-West University, Potchefstroom, South Africa Felix Spanier, felix@fspanier.de

North-West University, Potchefstroom, South Africa

A crucial part of understanding particle events is an understanding of the particle transport processes that shape the measured spectra. Since charged particles are of primary interest, a description of the magnetic field structure and development in the heliosphere coupled with an adequate depiction of the resonant wave-particle interaction processes play a vital role.

The correct interpretation of anisotropic particle distributions measured by satellite experiments requires a resolution in pitch angle of at least the essential transport parameters. Under the assumption that (re-)acceleration of particles occurs only in specific magnetic field configurations, particle diffusion becomes crucial, with the change of the particle pitch angle μ as the predominant effect of particle scattering on magnetic irregularities.

This work extends the numerical methods introduced in Ivascenko et al. 2016 to the calculation of pitch angle dependent spacial perpendicular diffusion coefficients $D_\perp(\mu)$ (as opposed to the angle-averaged coefficient $\kappa_\perp$ widely used in QLT) and applies these methods to test-particle data from simulations of heliospheric conditions with our spectral MHD code GISMO. We present the μ-resolved perpendicular coefficients for multiple particle energies in heliospheric MHD conditions from these self-consistent turbulence simulations.

D1.1-0025-18 TEN MILLISECOND MEASUREMENTS OF THE FULL 3-D VDF WITH THE FAST IMAGING SOLAR WIND ION COMPOSITION SPECTROMETER (FISWICS)

George Gloeckler, gglo@umich.edu

University of Michigan, Mitchellville, Maryland, United States

L. A. Fisk, lafisk@umich.edu

University of Michigan, Ann Arbor, Michigan, United States

We describe an instrument (FI-SWICS) that will measure the full 3-D velocity distribution function (VDF) of solar wind protons and solar wind alpha particles as fast as every 10 milliseconds. FI-SWICS combines the SWICS ion identification system with a novel, highly symmetric Concentric Spheres Electro-Static Deflection Analyzer (CONSESA) driven by a rapidly swept (or stepped) deflection voltage, Vdef <5 kV between the outer mechanical collimator (OMC) at ground and the inner mechanical collimator (IMC) at -Vdef. Each collimator is an assembly of n wedges of angular width $\Delta\phi=2\pi/n$. Each of the n identical wedges has m tunnels with specified look direction, ϑm, and desired angular width, $\Delta\vartheta m$. Position sensing detectors are used to identify the specific tunnel and wedge through which a positively charged particle has entered, and thus the entrance direction of the particle. With dimensional changes only, larger versions of this instrument will also measure the full 3-D VDF of suprathermal, pickup and tail ions of protons, 4He++, 3He++, 4He+ and an additional 70 heavy ion species with different mass-(mass/charge), such as O+6, Fe+10, etc. every few seconds to minutes. Three such FISWICS instruments of different dimensions on a spacecraft similar to ACE would provide data that would resolve many outstanding problems concerning local particle acceleration by shocks and turbulence at 1 AU.

D1.1-0026-18 INVESTIGATION OF ANISOTROPY OF SOLAR WIND AND ENERGETIC PARTICLES USING ASPEX MEASUREMENTS ONBOARD ADITYA-L1

S. K. Goyal, goyal@prl.res.in

Physical Research Laboratory, Ahmedabad, India Presenting author: D. Chakrabarty, dipu@prl.res.in Physical Research Laboratory, Ahmedabad, India Aditya Solar wind & Particle EXperiment (ASPEX)

Many aspects of the origin, acceleration and anisotropy of solar wind and energetic particles in the interplanetary medium are poorly understood till date. These particles (energy ranging from few keVs to MeVs) are originated during solar flares, during the passage of interplanetary coronal mass ejections (ICME) or corotation interaction regions (CIR) through the heliosphere and produced by the terrestrial bow shock. As a consequence, these particles can arrive at the first Lagrangian point (L1) of the Sun-Earth system from a number of directions. Further, thermal anisotropy of the solar wind particles along and across the Parker spiral direction is also reported in the past. In order to understand the origin, acceleration and anisotropy of the solar wind energetic particles, it is, therefore, essential to have multi-directional measurements of both low and high energetic particles. The measurements of He++ and H+ fluxes can be used to test the efficacy of the alpha-proton ratio in the solar wind as a possible precursor for the arrival of ICME, CIR at the earth's orbit. Keeping these aspects in mind, Aditya Solar wind Particle EXperiment (ASPEX) experiment has been selected to fly onboard Aditya-L1 mission, the first Indian mission for the study of the Sun from the Sun-Earth L1 point. ASPEX will make the in-situ, multidirectional measurements of the slow fast solar wind, supra-thermal particles and solar energetic particles in the energy range of 100 eV to 20 MeV/n using its two sub-systems: Solar Wind Ion Spectrometer (SWIS) and the Supra Thermal Energetic Particle Spectrometer (STEPS). SWIS instrument is a low energy ion spectrometer consisting of hemispherical electrostatic analyzer and magnetic mass analyzer for the identification of the He++ and H+ and energy measurement in the range of 100 eV to 20 keV. While the STEPS uses customized Si-PIN detector and plastic scintillator in the delta E-E configuration mode for energy measurement and identification of the species (H+ and He++) in the energy range of 20 keV/n to 20 MeV/n. To have multidirectional measurements, SWIS has two units THA-1 and THA-2 looking in and across the ecliptic planes respectively. While STEPS has six directional measurements which include radial (towards the Sun), Parker (along the Parker

Spiral), intermediate (between radial and Parker), Earthward (from Earth side) and across the ecliptic plane in the northward and southward directions. In this talk, overall configuration of the ASPEX instrument and its salient features will be discussed. Developmental status of the engineering model and its preliminary results will also be presented.

D1.1-0027-18 FORBUSH DECREASE MECHANISM IN A MAGNETIC CLOUD

Yu.G. Shafer Institute of Cosmophysical Research and Aeronomy of SB RAS, Yakutsk, Russia Ivan Petukhov, i_van@ikfia.ysn.ru

Institute of Cosmophysical Research and Aeronomy SB RAS, Yakutsk, Russia

Using back tracing we research galactic cosmic ray propagation in a moving magnetic cloud having the shape of magnetic loop. It is obtained that the inductive electric field of an extended magnetic cloud decreases particle energy. Both energy losses and long particle trapping by a magnetic loop produce Forbush decrease. The calculation results of particle density and the components of uniand bidirectional anisotropies are shown. The calculation results generally agree with measurements.

D1.1-0028-18 EXPLORATION OF THE EDGE OF HELIOSPHERE THROUGH STRATEGICALLY PLACED SOLAR-SAIL PROPELLED STATELLITES

University of Petroleum & Energy Studies, Dehradun, India

For over five decades, the shape and interaction of the heliosphere with the neighborhood interstellar medium have been discussed concerning two contending models: magnetospheric and symmetric bubble. Voyagers 1 and 2 crossed the termination shock, north and south of the ecliptic plane at 94 AU and 84 AU in 2004 and 2007, respectively, and discovered the reservoir of ions and electrons that constitute the heliosheath, while Cassini remotely imaged the heliosphere for the first time in 2003. This paper presents a much faster way to reach the interactive layer of the heliosphere, as compared to the time taken by the Voyagers 1 and 2, using a dynamic inter-planetary constellation of satellites that shall propel two Solar Sails using a controllable push-type propulsion by LASER. Besides previous missions, a more extensive study of the heliosphere will test the mankind's drive for deep space exploration, as exotic means of travel are needed. This paper will take a futuristic case study of the event and various possibilities of space travel will be discussed in detail. Comprehensive tables and graphs will be given, which will depict the amount of time that will pass at each stage of the mission and more importantly some idea on the cost in terms of energy, as well as money, will be discussed within today's context. Even though the possibility of such a mission is probably nonexistent for this decade, it is essential to do these exercises in order to unfold the mysteries of the universe. In addition, this paper hopes to establish some general guidelines for such exploring missions.

D1.1-0030-18 THEORETICAL MODELING OF THE DIURNAL ANISOTROPY IN PERIODS MINIMA AND NEAR MINIMA OF SOLAR ACTIVITY (CYCLES: 23 - 24)

Marek Siluszyk, marek.siluszyk@uph.edu.pl Siedlce University, Siedlce, Poland

Witold Wozniak, witek.wozniak81@gmail.com Polish Gas Company, Warszawa, Poland Krzysztof Iskra, k.iskra@wsosp.pl

Siedlce University, Siedlce, Poland Pawel Wolinski, pawxx@poczta.onet.pl

Warsaw University of Technology, Poland, Warszawa, Poland

We study behavior of diurnal anisotropy in period's minima and near minima of solar activity (SA) for two cycle 23 and 24. Parker's transport equation is numerically solved in order to obtain three components Ar, $A\vartheta$ and $A\phi$ of the anisotropy vector. We used in mathematical model with few physical parameters corresponding to the given minimum of SA as, tilt angle δ of the Heliospheric Neutral Sheet (HNS), module B of the Heliospheric Magnetic Field (HMF) and changing the sign of the global magnetic field of the Sun (A>0) (positive polarity magnetic field lines are directed away from the Sun's northern hemisphere, 23 cycle); (A<0) (negative polarity magnetic field lines are directed towards the Sun's northern hemisphere, 24 cycle). The results of the theoretical modeling were compared with the changes of the diurnal anisotropy based on hourly data of galactic cosmic rays (GCR) intensity from the global network of neutron monitors using harmonic analysis. We received a satisfactory agreement of the theoretical results with the experiment.

D1.1-0031-18 CHARGED PARTICLES SURFATRON ACCELERATION AT SIMULTANEOUS INTERACTIONS WITH TWO ELECTROMAGNETIC WAVES IN SPACE PLASMA

Resonant wave-particle simultaneous interactions with two electromagnetic waves in space plasmas at the presence of weak constant magnetic field are studied. Special attention is paid to the electrons surfatron acceleration interactions with two electromagnetic waves in space plasmas. The theory of this phenomenon, basic differential equations and their transformations are presented in a separate section of this work. Particles relativistic equations of motion are analyzed for this type of interactions. The final form of second order nonlinear, nonstationary equation for the wave phase at the particle's trajectory, describing interactions with two electromagnetic waves is outlined and presented. In the next stage the task is reduced to the exact numerical solution of equations for different sets of initial particles' and waves parameters. The particles are assumed as weakly relativistic electrons acting simultaneously with two electromagnetic waves with a low phase velocity. Based on large number calculations for different initial waves' phases, the probability of the electron trapping by the waves is estimated. The influence of the variations in differences between two waves phase velocities on the particle capturing process is examined. Numerical experiments demonstrate that no particle trapping occurs in the cases when two modes phase velocities are too close to each other. For every numerical experiment the capture probability results are presented in tables. Particles maximal energy gained through the acceleration process is assessed. Additional calculation results as particle relativistic factor, phase plane structure of the captured particle and particle's velocity components are graphically presented. Conclusions about charged particles surfatron acceleration at interactions with two electromagnetic waves are made.

D1.1-0032-18 STUDY OF PARTICLE ACCELERATION IN KH DRIVEN TURBULENCE IN SOLAR CORONAL LOOP TOPS VIA COUPLED MHD-PIC SIMULATIONS

Kirit Makwana, kirit.makwana@gmail.com KU Leuven, Leuven, Belgium

Rony Keppens, rony.keppens@kuleuven.be KU Leuven, Leuven, Belgium

Giovanni Lapenta, giovanni.lapenta@wis.kuleuven.be

KU Leuven, Leuven, Belgium

Solar coronal loops are heated at their foot-points by particles accelerated in solar flares. This heat deposition causes strong upflows that meet and interact at the coronal loop tops. As these are sheared flows, they lead to Kelvin Helmholtz (KH) instabilities which produce turbulence. This can lead to turbulent acceleration of particles at these sites. We study this process by using a coupled MHD-PIC simulation. The global coronal loop is simulated with a fluid magnetohydrodynamics (MHD) code, while the loop top where the turbulence occurs is simulated with a kinetic, particle-in-cell (PIC) code, in 2.5 dimensions. The embedded PIC domain receives its initial and boundary conditions from the MHD simulation. We will present and compare the turbulent spectrum from the MHD and PIC regions. The particle energy spectrum will also be presented with a focus on the particle acceleration mechanisms. This is relevant for explaining hard X-rays observed near the coronal loop tops after solar flares.

D1.1-0033-18 A NUMERICAL SIMULATION OF THE SPATIAL PROFILES OF ENERGETIC PARTICLES UPSTREAM AND DOWNSTREAM OF INTERPLANETARY SHOCKS

Giuseppe Prete, giupyprete@gmail.com University of Calabria, Rende, Italy

Gaetano Zimbardo, gaetano.zimbardo@fis.unical.it University of Calabria, Rende, Italy

Silvia Perri, silvia.perri@fis.unical.it University of Calabria, Rende, Italy

The spatial distribution of energetic particle accelerated at shocks depends on the transport properties of those particles. In the case of standard diffusion, it can be easily shown that an exponetial decay for the energetic particle intensity is obtained upstream of the shock, and a constant profile downstream. However, these kind of profiles are rarely observed by spacecraft at interplanetary shocks. We set up a numerical simulation to compute the energetic particle profile both upstream and downstream of the shock: particles are injected at the shock and then propagate according to a Gaussian random walk in the case of normal diffusion and according to a Levy random walk in the case of superdiffusion. The latter is characterized by a nonlinear growth of the mean square displacement of particles and by a power law distribution of free path lengths. A Langevin type equation is solved numerically, and energetic particle spatial profiles are obtained by means of a further integration over time. A number of solutions are obtained while varying the exponent of superdiffusion, and it is found that power law upstream profiles and nonconstant downstream profiles are obtained. These results are compared with previous analytical and numerical studies, and with interplanetary shock observations by the ACE spacecraft.

D1.1-0034-18 ON THE FRACTIONAL PARKER EQUATION FOR THE TRANSPORT OF COSMIC RAYS: STEADY-STATE SOLUTIONS

Gaetano Zimbardo, gaetano.zimbardo@fis.unical.it University of Calabria, Rende, Italy

Silvia Perri, silvia.perri@fis.unical.it University of Calabria, Rende, Italy Frederic Effenberger, feffen@gfz-potsdam.de

German Research Centre for Geosciences, Potsdam, Germany Horst Fichtner, hf@tp4.rub.de

Ruhr-Universität Bochum, Bochum, Germany

The acceleration and transport of energetic particles in astrophysical plasmas can be described by the so-called Parker equation, which is a kinetic equation comprising diffusion terms both in coordinate space and in momentum space. In the past years, it has been found that energetic particle transport in space can be anomalous, for instance, superdiffusive rather than normal diffusive. This requires a revision of the basic transport equation for such circumstances. Here, we extend the Parker equation to the case of anomalous diffusion by means of fractional derivatives that generalize the usual second-order spatial diffusion operator. We introduce the left and right Caputo fractional derivatives in space. These derivatives are one of the tools used to describe anomalous transport. We consider the case of steady-state solutions upstream and downstream of a planar shock. An analytical solution of the steady-state fractional Parker equation is given by the Mittag-Leffler functions, which correspond to a power-law profile for the energetic particle intensity far upstream of the shock, in agreement with the results obtained from a probabilistic approach to superdiffusion. These functions also correspond to a stretched exponential close upstream of the shock. These results can help to model more precisely the measured fluxes of energetic particles that are accelerated at both interplanetary shocks and supernova remnant shocks.

D1.1-0035-18 STRUCTURE OF INTERSTELLAR CLOUDS INCLUDING THE EFFECTS OF COSMIC RAYS AND WAVES

Chung-Ming Ko, cmko@astro.ncu.edu.tw

National Central University, Taiwan, Taoyuan, Taiwan, China Dmitry Chernyshov, dmit.mipt@gmail.com

Lebedev Physical Institute of Russian Academy of Sciences, Moscow, Russia Bilal Ramzan, d1049601@astro.ncu.edu.tw

National Central University Taiwan, Taoyuan, Taiwan, China

The energy densities of thermal gas, magnetic field and cosmic ray in the Milky Way are comparable. Cosmic ray would exert significant influence on the structure of thermal gas clouds. The interaction of cosmic ray with thermal plasma is facilitated through hydromagnetic fluctuations or waves embedded in the plasma. We adopt a hydrodynamical model to study the dynamical effect or feedback of cosmic ray on the thermal plasma. The model comprises four fluids, thermal plasma, cosmic rays and two oppositely propagating self-excited Alfven waves. We examine the ways that cosmic rays and waves affect the structure and properties of the cloud.

D1.1-0036-18 UNIFYING THE MULTIPLE-FIELD-LINE-ADVECTION MODEL FOR PARTICLE ACCELERATION WITH ALFVEN WAVE TURBULENCE

Zhenguang Huang, zghuang@umich.edu University of Michigan, Ann Arbor, United States Igor Sokolov, igorsok@umich.edu

University of Michigan, Ann Arbor, Michigan, United States Dmitry Borovikov, dborovik@umich.edu

University of Michigan, Ann Arbor, Michigan, United States Tamas Gombosi, tamas@umich.edu

University of Michigan, Ann Arbor, Michigan, United States

A study of Solar Energy Particle (SEP) events is an important topic in space physics. Extreme events are not only dangerous to instruments onboard spacecraft in deep space, but they are also very harmful to astronauts, because SEPs can easily penetrate spacesuits and high radiation doses can even kill astronauts. It is important to predict the arrival time of SEP events so that we can better prepare and mitigate the hazards brought by such events.

The Multiple-Field-Line-Advection Model for Particle Acceleration (M-FLAMPA) within the Space Weather Modeling Framework (SWMF), which solves the kinetic equation for SEPs along a multitude of interplanetary magnetic field lines, has been proven to be a powerful tool for the predication. However, there are some certain limitations of the current M-FLAMPA, for example, the code currently uses a physics-based but phenomenological pitch angle scattering coefficient.

In this study, we plan to introduce a more realistic and quantitative pitch angle scattering coefficient, which is calculated from the amplitudes of Alfven waves obtained from the AlfvenWave-driven Solar Model (AWSoM) as well as the Outer Heliosphere (OH) model, all being the parts of the SWMF. With such an improvement, M-FLAMPA should be able to better describe the SEP transport and predict their arrival time.

D1.2-0001-18 ASTROSPHERES AND STELLAR BOWSHOCKS

Allard Jan Van Marle, ajvanmarle@gmail.com UNIST, Ulsan, Korea

Like our sun, each star (or binary system) has a surrounding region in which all physical processes are dominated by the central star(s). This area is known as the astrosphere.

Astrospheres are fascinating objects. Because they are formed through the interaction between the stellar feedback (wind and radiation) and the interstellar gas, they can tell us a great deal about both. Furthermore, because they are shaped over time they provide us with a window into the past. This is of particular interest for the study of stellar evolution, because the astrosphere reflects changes in the properties of the stellar wind, which relate directly to the properties of the star. A special sub-class of astrospheres, the stellar bow shocks, occur when the progenitor star moves through the surrounding medium at supersonic speed. Because the properties of the bow shock relate directly to both the stellar wind and the interstellar medium, the shape and size of the bow shock can be used to determine the current state of the stellar wind, rather than its history.

Beyond the study of astrospheres themselves, their influence is also felt when investigating certain high energy phenomena, such as core-collapse supernovae and long gamma-ray bursts which occur at the end of the evolution of massive stars. Because they originate within the astrosphere any study of these objects will have to involve an understanding of the characteristics of the astrosphere.

Using state of the art numerical codes it is possible to simulate the interaction between the stellar wind and radiation and the interstellar medium. These results can then be compared to observations. They can also be used to predict the type of observations that are best suited to study these objects. In this fashion, computational and observational astronomy can support each other in their efforts to gain a better understanding of stars and their environment.

D1.2-0002-18 THE INTERSTELLAR MAGNETIC FIELD FROM GALACTIC SCALES DOWN TO THE HELIOSPHERE

Marta Alves, m.alves@astro.ru.nl

Radboud Universiteit Nijmegen, Nijmegen, Netherlands Katia Ferriere, katia.ferriere@irap.omp.eu

Institut de recherche en Astrophysique et Planétologie, Toulouse, France

I will review the observational properties (strength, direction, and spatial distribution) of the interstellar magnetic field of our Galaxy, starting from the large Galactic scales and gradually zooming in towards the Sun. I will show that the large-scale magnetic field in the Galaxy disk has a strength of a few microGauss and a predominantly azimuthal direction. While the magnetic field appears to maintain a microGauss strength in to the edge of the heliosphere, its azimuthal direction is completely lost in the perturbed small-scale interstellar surroundings of the Sun. I will discuss these perturbations, introduced by nearby bubbles, the Local Bubble, and the very local clouds within the Local Bubble.

D1.2-0003-18 THE SUN'S DUSTY INTERSTELLAR ENVIRONMENT

Veerle Sterken, veerle.sterken@aiub.unibe.ch

Astronomical Institute, University of Bern, Bern, Switzerland

The Sun and the heliosphere are embedded in the Local Interstellar Cloud that consists of partially ionised gas, and for about 0.5-1% of its mass is in interstellar dust (ISD). Because of the relative motion of the solar system with respect to this cloud, at speeds of ca. 26 km/s, many of the dust particles enter the heliosphere and can be measured in situ, using spacecraft dust detectors.

In 1993, such ISD particles were for the first time detected using the Ulysses cosmic dust detector. The mission provided a total of 16 years of ISD data and thus covered almost one Hale cycle. The Hale cycle is important for understanding the dust data, since the interstellar dust trajectories are shaped not only by solar radiation pressure force and gravity, but also by Lorentz forces as a result of the (charged) interstellar particles that move through the heliosphere's magnetic fields. Also, the heliosphere boundary regions play a large role in the measured dust size distributions in the solar system.

By using Monte Carlo computer simulations of dust trajectories, the interpretation of these spacecraft data allows us to constrain the particle properties, and it teaches us about the role of the heliosphere for dust transport.

In this talk, we review the latest developments in the study of "local" interstellar dust, with astronomical, in-situ, and sample return techniques. We explain the dynamics of the ISD as it moves through the heliosphere, and finally, we elaborate on how we can use computer simulations and spacecraft data for constraining the ISD properties and for studying the heliosphere.

D1.2-0004-18 WHAT ARE COSMIC RAYS TELLING US ABOUT THE FAR OUTER STRUCTURES OF THE HELIOSPHERE?

Marius Potgieter, marius.potgieter@nwu.ac.za North-West University, Potchefstroom, South Africa Xi Luo, xluo@spaceweather.ac.cn

National Space Science Center, Chinese Academy of Sciences, Beijing, China

The behaviour of cosmic rays (CRs), as very energetic charged particles, reflects local heliospheric conditions of where they are observed, and global conditions which they had experienced during their propagation up to the place of observation. A testimony for this is the set of CR observations made by the two Voyager spacecraft since their launch 40 years ago, from the Earth, along their different trajectories to the solar wind termination shock, into the heliosheath, and for Voyager 1 beyond the heliopause. Using a variety of CR transport models, together with appropriate MHD models, a parameter set is tuned to reproduce observations from the Earth, over large radial distances, up to the heliopause. The computed CR flux can be used to make conclusions about the far outer structures of the heliosphere, e.g. a well-defined and large flux-jump could be the signature of the spacecraft crossing the HP. They also indicate that the outer heliosheath must be included in modulation models to accurately describe CR transport near and across the HP.

D1.2-0005-18 AN INVESTIGATION INTO A GENERALIZED FISK-TYPE HELIOSPHERIC MAGNETIC FIELD

Petrus Johannes Steyn, 25261630@nwu.ac.za

North-West University, Potchefstroom, Potchefstroom, South Africa Renier Burger, adri.burger@nwu.ac.za

North-West University, Potchefstroom, South Africa

The existence of a Fisk-type heliospheric magnetic field (HMF) has been questioned since it was proposed by Fisk more than two decades ago. Fisk-type fields are believed to occur when polar coronal holes are well developed, and are the result of photospheric differential rotation, superradial expansion of the solar magnetic field, and rigid rotation of polar coronal holes at the equatorial rotation rate. Theoretically the net result is that the footpoint of magnetic field lines that form the HMF, move in circles about an axis that is offset from both the solar rotation and the solar magnetic field axis. This circular motion leads to a meridional field component, and combined with the rotation of the Sun, leads to notable differences between Fisk-type fields and Parker-type fields. We present a generalized Fisk-type HMF that retains information about the solar differential rotation rate where the field line originates on the photosphere, in contrast to the average value used in other models. It differs from the Fisk-Parker hybrid field approach of Burger and co-workers since it does not assume a combination of Fiskand Parker fields at different heliographic latitudes. Open-field line origination in polar coronal holes is Fisk-type while others are Parker-type. By using the statistical approach developed by Forsyth and co-workers, we show that this newly-developed HMF is significantly better at explaining the magnetic field winding angles observed by the Ulysses spacecraft during its first solar orbit (1992 - 1998) than the traditional Parker field. We also show that the signature of a Fisk-type field may well be present in 26-day recurrent cosmic-ray variations seen in neutron monitor data from the global network.

D1.2-0006-18 SOLAR MAGNETIC FIELD STRENGTH AND THE COSMIC-RAY SUN SHADOW OBSERVED BY THE TIBET AIR SHOWER ARRAY

Yoshiaki Nakamura, 15st303c@shinshu-u.ac.jp Shinshu University, Matumoto-City, Japan the Tibet ASgamma Collaboration

X. L. Qian, X. B. Qu, T. Saito, T. Y. Saito, M. Sakata, T. K. Sako, J. Shao, M. Shibata, A. Shiomi, T. Shirai, H. Sugimoto, M. Takita, Y. H. Tan, N. Tateyama, S. Torii, H. Tsuchiya, S. Udo, H. Wang, H. R. Wu, L. Xue, Y. Yamamoto, K. Yamauchi, Z. Yang, S. A. F. Yuan, T. Yuda, L. M. Zhai, H. M. Zhang, J. L. Zhang, X. Y. Zhang, Y. Zhang, Yi Zhang, Ying Zhang, Zhaxisangzhu, X. X. Zhou,

We analyze the displacement of the Sun shadow observed in 5 240 TeV cosmic-ray intensity with the Tibet air shower array during 10 years between 2000 and 2009, and compare with the MC simulations based on the coronal magnetic field model and Parker's spiral interplanetary magnetic field model. We find that the observed North-South displacement is significantly larger than the prediction of the simulations. This result uniquely suggests the underestimation of the average field strength between the Sun and the Earth in our model. In order to identify the source of this underestimations, we investigate the influence of the coronal and interplanetary magnetic fields separately on the Sun shadow. In this presentation, we will discuss the results by changing independently each strength in the interplanetary and coronal magnetic fields.

D1.2-0007-18 MAPPING MAGNETIC FIELD LINES FOR AN ACCELERATING SOLAR WIND

Samira Tasnim, samira.tasnim@sydney.edu.au University of Sydney, Sydney, Australia

Iver Cairns, iver.carins@sydney.edu.au The University of Sydney, 2006, Australia

M. S. Wheatland, michael.wheatland@sydney.edu.au Australia

Bo Li, bo.li@sydney.edu.au

The University of Sydney, 2006, Australia

A new accelerating solar wind [Tasnim et al., 2018] is developed that includes conservation of angular momentum, deviations from corotation, and non-radial intrinsic velocity and magnetic field components from an inner boundary to beyond 1 AU. We fit the model to near-Earth observations of the Wind spacecraft for the solar rotation period between 19 April to 15 May 1995 (CR 1895). Later, we employ this accelerating solar wind to predict the magnetic field vectors and map the magnetic field lines. Note that magnetic field line mapping is important to trace the paths of solar energetic particles and electron beams in type III radio burst since superthermal beams move along the field lines from the Sun towards the Earth and even beyond. We map the magnetic field lines from the source surface towards 1 AU using the field line mapping algorithm developed by Li et al. [JGR,2016]. We compare these magnetic field lines with the field lines predicted by Li et al. [JGR,2016] using Schulte in den Baumen et al. [JGR,2012]'s model. The maps for accelerating and constant speed models are very similar. However, close comparisons show that the magnetic field lines for the radial speed model move further out than the accelerating wind model. The obvious interpretation is that the accelerating solar wind is slower at small heliocentric distance (r) and so travels less far outward than the constant speed solar wind.

D1.2-0008-18 IBEX (INTERSTELLAR BOUNDARY EXPLORER) OBSERVATIONS OF OUR EVOLVING HELIOSPHERE

David McComas, dmccomas@princeton.edu

Princeton University, Princeton, New Jersey, United States IBEX Team, dmccomas@princeton.edu

Princeton University, Princeton, United States

The Interstellar Boundary Explorer (IBEX) has made nearly continuous observations of Energetic Neutral Atoms (ENAs) coming in from the outer heliosphere over the past decade. These observations have reshaped our fundamental understanding of the outer heliosphere and its interaction with the local interstellar medium. In this talk we summarize some the IBEX discoveries and examine how the ENAs have evolved over time. For most of this time there has been an overall reduction in the ENA fluxes at all energies, reflecting a generally deflating heliosphere. The Ribbon, which is likely generated beyond the heliopause, in the outer heliosheath, has evolved differently from the globally distributed flux (GDF), which is primarily produced in the inner heliosheath, between the termination shock and heliopause. Most recently, IBEX has observed the initial response of the heliosphere to a persistent increase in the solar wind dynamic pressure that was observed at 1 AU in the second half of 2014. This enhanced pressure has arrived at the outer heliosphere as indicated by a strong enhancement in the ENAs returning from the closest regions of the inner heliosheath, and is re-expanding our heliosphere, with the termination shock and heliopause already driven outward in their locations closest to the sun.

D1.2-0009-18 MODELING THE TIME EVOLUTION OF THE IBEX RIBBON OVER THE SOLAR CYCLE

Paweł Swaczyna, pswaczyna@cbk.waw.pl

Space Research Centre of the Polish Academy of Sciences, Warsaw, Poland Maciej Bzowski, bzowski@cbk.waw.pl

Space Research Centre of the Polish Academy of Sciences, Warsaw, Poland Justyna M. Sokol, jsokol@cbk.waw.pl

Space Research Centre of the Polish Academy of Sciences, Warsaw, Poland

The IBEX ribbon is an arc-like enhancement of the Energetic Neutral Atom (ENA) fluxes in the sky, discovered by IBEX. Among many potential sources proposed to explain the ribbon, the secondary ENA mechanism has been shown to explain most of the observed features of the ribbon. In this mechanism, the ribbon originates in the outer heliosheath where the lines of the local interstellar magnetic field are almost perpendicular to the line-of-sight. The main component of the primary ENA flux, which is an input to the secondary ENA mechanism, is the neutralized supersonic solar wind. The IBEX ribbon reveals energy-dependent structure in the relative intensity along its circumference. It has been shown that the ribbon's position in the sky can be approximated by circles or ellipses in the sky, and the centers of these figures show a monotonic trend with a shift of 10° between the lowest and highest energy observed by IBEX-Hi. We have recently shown that this finding can be explained by the helio-latitudinal structure of the supersonic solar wind.

In this contribution, we model the IBEX ribbon fluxes using a semi-analytic model of the secondary ENA mechanism. We adopt a timeand latitude-dependent model of the speed and density of the supersonic solar wind based on observations, and we account for the time-delay between the solar wind emission and the observation of the secondary ENAs. Next, we fit circles to the modeled position of the IBEX ribbon. The positions of the circle's centers show a time-dependence related to the evolution of the solar wind during the solar cycle. The smallest changes with time in the position of the ribbon center are expected for the energy step of 1.7

keV. For higher and lower energies, the modeled solar cycle amplitudes of the positions of the ribbon's centers are up to ~2°.

D1.2-0010-18 TRANSPORT OF SUPRATHERMAL PROTONS IN THE INNER HELIOSHEATH

Adama Sylla, asy@tp4.rub.de

Institut für Theoretische Physik IV, Bochum, Germany Horst Fichtner, hf@tp4.rub.de

Ruhr-Universität Bochum, Bochum, Germany Klaus Scherer, kls@tp4.rub.de

Ruhr-Universität Bochum, Bochum, Germany Hans Joerg Fahr, hfahr@astro.uni-bonn.de

Argelander Institute for Astronomy of University of Bonn, Bonn, Germany

A quantitative understanding of the phase-space transport of suprathermal protons in the inner heliosheath is highly desirable, as it represents the basis for the modelling of so-called energetic neutral atoms (ENAs) observed with the Interstellar Boundary Explore (IBEX). A consistent modelling of all-sky maps of ENA fluxes at different energies will provide insight into the large-scale structure of the outer heliosphere, which is a welcome supplement to the in-situ measurements made with the Voyager spacecraft. Numerical solutions of the transport equation of supratherml protons will be presented. These solutions allow to compute the ENA production rate in the inner heliosheath and, subsequently, the resulting energy-dependent flux from a given direction.

D1.2-0011-18 THE LOCAL INTERSTELLAR MEDIUM REVEALED BY IBEX OBSERVATIONS OF INTERSTELLAR NEUTRAL ATOMS

Maciej Bzowski, bzowski@cbk.waw.pl

Space Research Centre of the Polish Academy of Sciences, Warsaw, Poland Paweł Swaczyna, pswaczyna@cbk.waw.pl

Space Research Centre of the Polish Academy of Sciences, Warsaw, Poland

Interstellar neutral (ISN) atoms penetrate the heliosphere and allow for remote sensing of plasma in the local interstellar medium (LISM) in the vicinity of the Sun. The charge-exchange processes between the ionized and neutral components provide that both components have similar bulk flow and temperatures. For hydrogen and helium, charge exchange reactions between the ions and atoms of the same chemical element dominate (H + H+ and He + He+, respectively). Consequently, protons and hydrogen atoms equilibrate at scales of several hundred of astronomical units, whereas helium ions and atoms at scales of a few thousand of astronomical units. The flow of the plasma is significantly disturbed around the heliosphere at scales smaller than necessary to obtain the equilibrium. Therefore, the ensemble of ISN atoms are considered as a sum of (1) the primary ISN population from the undisturbed LISM and (2) the secondary ISN population created in the outer heliosheath.

IBEX-Lo observes ISN atoms in the Earth's orbit. These observations allowed to identify the primary ISN He population and an additional population of ISN He atoms, called the Warm Breeze. In the earlier studies, we modeled these populations, assuming two separate MaxwellBoltzmann distributions that are propagated from the heliopause into the inner heliosphere to the observing spacecraft. We found that the inflow directions of the two populations are co-planar with the center of the IBEX ribbon, which, in the meantime, has been shown to be most likely due to the secondary ENA emission mechanism. In this mechanism, the center of the ribbon is close to the direction of the unperturbed interstellar magnetic field (ISMF), which is the main factor distorting the heliosphere from axial symmetry. This result suggested that the Warm Breeze is the secondary ISN He population. This supposition was later confirmed by combining MHD modeling of the plasma flow in the outer heliosheath with solutions of the charge-exchange production and loss balance equation along the trajectories of these helium atoms.

In this contribution, we show results of the modeling the ISN He signal using the MHD heliosphere simulation precisely conforming with those used to establish the direction and strength of the ISMF from the observations of the IBEX ribbon. We find that the resulting signal is sensitive to the ionization degree of the interstellar helium. We compare the IBEX-Lo observations with the modeled signal and determine the relative abundance of helium ions and atoms in the outer heliosheath. We conclude that most

likely, the ionization degree of interstellar helium in the LISM is significantly lower than previously thought. Moreover, we model the ISN He using various directions and strengths of the ISMF, complementing the interpretation of the IBEX ribbon and Voyager observations.

D1.2-0012-18 VOYAGER: THE OUTER HELIOSPHERE AND VERY LOCAL INTERSTELLAR MEDIUM

E. C. Stone, ecs@srl.caltech.edu

California Institute of Technology, Pasadena, California, United States

Now approaching six years beyond the heliopause and 143 AU from the sun, Voyager 1 has been observing the intensity gradient and pitch-angle anisotropy of galactic cosmic rays and the associated perturbations in the local interstellar medium. Now at 118 AU, Voyager 2 continues to observe plasma pressure pulses from merged interaction regions, laminar flow of the solar wind parallel to the heliopause, and modulation of galactic cosmic rays in the heliosheath. The increasing intensity of galactic cosmic ray electrons suggests that Voyager 2 may reach the heliopause in several years. An overview and update of recent observations and interpretations will be presented.

D1.2-0013-18 PLASMA AND MAGNETIC FIELD INTERACTIONS IN THE HELIOSHEATH

John Belcher, jwb@space.mit.edu Massachusetts, United States

Karabo Mdluli, 684164@students.wits.ac.za

Universty of Witwetersrand, Johannesburg, South Africa John Richardson, jdr@space.mit.edu

MIT, Cambridge, Massachusetts, United States Leonard Burlaga, lburlagahsp@verizon.net NASA/GSFC, Greenbelt, United States

Voyager 2 have been in the heliosheath for almost 11 years providing the first plasma data from this region. This region shows time variation on scales from tens of minutes up to the 11-year solar cycle. This paper concentrates on the relationship between changes in the plasma and magnetic field; an initial investigation of MHD waves covered only data from 2007 and early 2008 (Gutynska et al., ApJ 722, L228). We use data the most recent data available, to at least 2015. The 48-sec magnetic field data will be compared with 192-sec plasma data on varying time scales and the resulting correlations will be discussed.

D1.2-0014-18 VOYAGER PLASMA OBSERVATIONS IN THE HELIOSHEATH

John Richardson, jdr@space.mit.edu

MIT, Cambridge, Massachusetts, United States

Voyager 2 is now 34 AU beyond the termination shock and still in the heliosheath; the width of the heliosheath in the Voyager 1 direction was 27 AU. We present recent observations, compare with observations from Voyager 1, and compare with model predictions. The speed of the flows observed by Voyager 2 in the heliosheath have been, on average, remarkably constant at 150 km/s. The flow angle rotated to about 60circ from radial but has not changed for the past 15 AU; more of the turning occurred in the RT than RN planes. Recent data have been dominated by pressure pulses correlated with increases in the temperature and energetic particle fluxes. These pulses may drive shocks such as those observed by V1 through the interstellar medium.

D1.2-0015-18 SURVEY OF COMPRESSIONS AFTER TERMINATION SHOCK AT VOYAGER (IN SHEATH & LISM)

Daniel Berdichevsky, dbberdi@yahoo.com Maryland, United States

Examples of the plasma compression as it is observed in the solar wind at 1 AU with the suite of instruments in the SC Wind, and after the termination shock with both Voyager SC, as well as with Voyager 1 in the local interstellar medium (LISM) are presented. The work will focus on similarities and differences in the observations at the different locations. At priory is fair to mention that the 4 regions differ in several aspects. At 1 AU the solar wind (SW) flow is mostly alfvenic. In the sheath after the termination shock the possibly subsonic solar wind is mostly compressional but fluctuation modes in scales of one hour are much less observed at Voyager 1 than at Voyager 2 path. Finally Burlaga and Ness1 documented the nature of the compressional flow in the 'depletion' layer at the start of the LISM as well later in this medium, showing the low plasma-beta character of this LISM region in Voyager 1 path. 1Burlaga L.F., and N. Ness, ApJ, 784, 146 (14pp), 2014.

D1.2-0016-18 SHOCKS AND TURBULENCE IN THE VERY LOCAL INTERSTELLAR MEDIUM

Vladimir Florinski, vaf0001@uah.edu

University of Alabama in Huntsville, Huntsville, Alabama, United States Leonard Burlaga, lburlagahsp@verizon.net

NASA/GSFC, Greenbelt, United States Gary Zank, garyp.zank@gmail.com

University of Alabama in Huntsville, Huntsville, United States

The influence of the solar wind does not stop at the heliopause, but continues into the surrounding very local interstellar medium (VLISM). The motion of the heliopause in response to incident coherent structures, such as merged interaction regions, as well as weaker random ensembles of waves injects waves and fluctuations into the VLISM where they continue to propagate through the subsonic partially ionized plasma in the direction of the bow wave. It is thought that the abrupt increases and subsequent gradual decreases in magnetic field strength measured by Voyager 1 are produced by pressure waves incident on the heliopause that transform into a triangular pulse with a shock at the leading edge. However, these shock like structures are far broader than the characteristic width of subcritical resistive shocks. The weak Kolmogorov turbulence measured in the VLISM during the first two years of observations was primarily compressive, with the maximum variance direction aligned with the mean magnetic field. Two years later, however, the fluctuations became primarily transverse, similar to those in the solar wind. We discuss collisionless and collisional dissipative processes that could be responsible for broadening of the shock waves and the decay of the compressive magnetic fluctuations.

D1.2-0017-18 THEORY AND TRANSPORT OF NEARLY INCOMPRESSIBLE MAGNETOHYDRODYNAMICS TURBULENCE. III. EVOLUTION OF POWER ANISOTROPY IN MAGNETIC FIELD FLUCTUATIONS THROUGHOUT THE HELIOSPHERE

A theoretical model that describes the evolution of the power anisotropy in the energy-containing and inertial ranges throughout the heliosphere is developed for three possibilities: (i) no in situ sources of turbulence; (ii) stream-shear sources of 2D and slab turbulence; and (iii) a fully driven turbulence model that includes both streamshear driving and a pickup ion source of slab turbulence. At the inner boundary (1 au), we assume that the ratios of the 2D to slab fluctuating magnetic energy variances in the energy-containing range are 80:20, 70:30, 60:40, and 55:45. For case (i), <B2D > / < b2lab > intheenergy−containing range increases monotonically throughout the heliospher containing range ratio increases initially and then remains approximately constant and ordered beyond 2au, ac 20 case increases with heliocentric distance, whereas for the 70: 30, 60: 40, and 55: 45 cases, the rations incr 20au, and then generally decrease at larger heliocentric distances. For case (iii), the energy−containing and in

The Sun's motion relative to the surrounding interstellar medium leads to an interstellar neutral (ISN) wind through the heliosphere. This wind is moderately depleted by ionization and can be analyzed in-situ with pickup ions and direct neutral atom imaging. Since 2009, observations of the ISN wind at 1 AU with the Interstellar Boundary Explorer (IBEX) have returned a very precise 4-dimensional parameter tube for the flow vector (speed it VISN, longitude it lambdaISN, and latitude it betaISN) and temperature it TISN of interstellar He in the local cloud, which organizes it VISN, it betaISN, and it TISN as a function of it lambdaISN, and the local flow Mach number (it VThISN /it VISN). Typically, the uncertainties along this functional dependence are larger than across it. Here we present important refinements of the determination of this parameter tube by analyzing the spin-integrated ISN flux for its maximum as a function of ecliptic longitude for each year through 2018. We include a weak energy dependence of the sensor efficiency by comparing the response in all four energy steps that record the ISN He flow. In particular, we make use of an operational extension, with which we let the spin axis pointing of IBEX drift to the maximum offset west of the Sun, which we used for the first time during the entire ISN observation season in 2018. This expansion of the IBEX viewing results in an additional constraint that helps breaking the degeneracy of the ISN parameters along the 4D tube. This constraint is part of the complement of drivers effective in the full Chi-square-minimization to obtain the ISN parameters by comparison with a detailed model of the ISN flow. It is also complementary to an independent determination of ISN using the longitude dependence of the He+ pickup ion cut-off speed with STEREO PLASTIC and ACE

SWICS.

Here, we present our work automating the identification of shocks/waves, and Interplanetary Coronal Mass Ejections (ICMEs) in the Solar Wind Around Pluto on the New Horizons between 20 and 40 AU. New Horizons is a planetary mission designed to study the Pluto system and the Kuiper Belt; therefore, the prime instruments are geared towards optical observations. The spacecraft does not have a magnetometer so many standard techniques for finding shocks and ICMEs cannot be performed. We developed a simple algorithm to find all the steep rises in the speed, and we check for coincident changes in the solar wind density, temperature, and pressure. We have already found that beyond 20 AU most of the shocks/waves have only small jumps in speed. This likely reflects the lower activity level for this solar cycle, and that the solar wind is highly processed prior to reaching 20 AU owing to faster and slower wind parcels interacting with one another en route. The SWAP instrument is a top hat electrostatic analyzer and measures count rates as a function of energy per charge. In the outer heliosphere the solar wind proton and alpha peaks are often well separated since the temperature is lower. While acquiring solar wind observations, SWAP is in a mode where a coarse energy sweep is performed over the full energy range followed by a fine sweep centered on the energy step where the peak counts were observed in the coarse sweep. The fine sweep provides excellent energy coverage for the solar wind protons, but does not provide this level of coverage at higher energies where the alphas occur. Consequently, we only have coarse sweep measurements for the alphas. Here, we test estimating the alpha to proton density ratio (na/np) using a normalized ratio of the count rates for the proton and alpha peaks. We identify times when this na/np ratio is high and determine if those are associated with shocks or any anomalously low temperature intervals because high na/np, shocks, and low temperature are often associated with ICMEs. Being able to estimate na/np is very useful since this ratio should not evolve significantly as the solar wind propagates outward. Without a magnetometer our next best ICME indicator is anomalously low temperatures; however, as solar wind structures merge and are worn down this method of identifying ICMEs will likely break down.

D1.2-0020-18 TIME-VARYING PROCESSES IN THE OUTER HELIOSPHERE

University of Alabama in Huntsville, Huntsville, United States Haruichi Washimi, hw0002

University of Alabama in Huntsville, Alabama, United States Parisa Mostafavi, psm0011@uah.edu

University of Alabama in Huntsville, Huntsville, Alabama, United States

For the purposes of definition, we will assume that the outer heliosphere in this presentation is the region at and beyond the heliospheric termination shock (HTS), extending into the very local interstellar medium (VLISM). We will focus on two aspects of the temporal heliosphere. 1) The response of the outer heliosphere to interplanetary disturbances and long-term variability: we will describe theoretically, using large-scale models, and observationally the temporal structure of the HTS and inner heliosheath in response to interplanetary shocks; we will analyze the response of the heliopause (HP) to disturbances that impinge on it from the inner heliosheath, including the transmission of shocks into the VLISM, and we will discuss the location of the HP as deduced from global models that incorporate a temporal solar wind ram pressure during solar minimum and solar maximum, incorporating the periodic presence of global merged interaction regions. 2) Shock waves observed in the VLISM appear to be far broader than their interplanetary medium counterparts. Until recently, no theoretical explanation had been provided to explain the observed structure. We will discuss the model developed by Mostafavi et al. 2018 that shows that the VLISM is collisional and thermal collisional heat conduction and viscosity are responsible for determining the structure of VLISM shocks. The characteristic shock thickness is determined by the heat conduction length scale.

D1.2-0021-18 HELIOSHEATH ENA IMAGES BY CASSINI/INCA AND IN-SITU HOT PLASMA ION MEASUREMENTS BY VOYAGERS SUGGEST A BUBBLE SHAPE FOR THE HELIOSPHERE

The advent of Energetic Neutral Atom (ENA) imaging, (the result of charge-exchange with energetic ions), has revealed the global nature of the heliosheath (HS) at both high (> 5 keV, Cassini from 10 AU) and low (< 6 keV, IBEX from 1 AU) energies. Voyager 1 (V1) entered the HS in December 2004 at 94 AU and crossed the heliopause (HP) in August 2012 at 121.6 AU, while Voyager 2 (V2) has been in the HS since August 2007. Thus, the properties of the HS along the V1, V2 trajectories are now well-established. Portions of the global HS have been imaged by the Cassini/ INCA (Ion and Neutral CAmera) since 2003 with a full image available since 2009, when IBEX global imaging observations also became available. The presence of the two Voyagers measuring ions locally in the HS contemporaneously with INCA global imaging through ENA in overlapping energy bands provides a powerful tool for examining the spatial, temporal, and spectral evolution of the source hot plasma ions and the global variability of the neutral component. Some of the key findings from the Voyagers and INCA measurements are as follows: (a) The HS contains a hot plasma population that carries a substantial part (30-50 %) of the total pressure at E > 5 keV, the rest residing below that range, resulting in a beta (particle/magnetic pressure) always > 1, typically >10. (b) The width of the HS in the direction of V1 is 27 AU, but is > 33 AU in the southern ecliptic where V2 currently travels.

The ENA intensities at E > 5 keV exhibit a correlation with the solar cycle (SC) over the period 2003 to 2017, with minimum intensities in the anti-nose direction observed 2.5 years after solar minimum followed by a recovery thereafter, and (d) The in-situ ion measurements at V2 within the HS also show a similar SC dependence. The totality of the observations, together with the near-contemporaneous variability in intensities of ions in situ in the HS and ENA in the inner heliosphere shows that the source of such emissions at E > 5 keV is in the HS. These observations

constrain the shape of the HS and suggest a Parker "bubble" configuration rather than the heretofore assumed comet-like tail (Dialynas et al. 2017, Nature Astronomy, 1, 0115).

D1.2-0022-18 THE EFFECTS OF PICK-UP IONS ON THE SHAPE OF THE HELIOSPHERE

Merav Opher, mopher@bu.edu

Boston University, Boston, Massachusetts, United States Abraham Loeb, aloeb@cfa.harvard.edu

Harvard University, Cambridge, Massachusetts, United States Gabor Toth, gtoth@umich.edu

University of Michigan, Ann Arbor, Michigan, United States

As the Sun moves through the surrounding partially-ionized medium, neutrals hydrogen atom penetrate the heliosphere and through charge-exchange with the supersonic solar wind create a population of hot pick-up ions (PUIs). With the crossing of the termination shock by Voyager 2 it became clear that the heliosheath pressure is dominated by the PUIs while the bulk thermal solar wind is much colder. Recently the shape of the Heliosphere is being challenged by theoretical and observation work (Opher et al. 2015; Diyalinas et al. 2017). Previously we had explored the effects of PUIs in the termination shock crossing (Zieger et al. 2015). In this work, we explore the effects of PUIs on the shape of the heliosphere. We present global magnetohydrodynamic simulations that treats the PUIs a separate fluid. Most global models treat the PUI and thermal component as a single fluid. We comment on the effect of the global structure as well as the properties of the heliosheath.

D1.2-0023-18 KINETIC-MHD MODELS OF THE GLOBAL HELIOSPHERE

Vladislav Izmodenov, vlad.izmodenov@gmail.com Lomonosov Moscow State University, Moscow, Russia

Current state of art in the kinetic-MHD modeling of the solar/stellar wind interaction with the local interstellar medium (LISM) will be reviewed. New model results will be presented as well as compared with currently available observations from both Voyagers and Interstellar Boundary Explorer (IBEX). Differences between model and observations will be discussed. Especial discussion will be on the recently suggested two-jet structure of the heliosphere.

The heliosphere is formed due to interaction between the solar wind (SW) and local interstellar medium (LISM). The interplay between the asymmetrizing effect of the interstellar magnetic field and charge exchange between ions and neutral atoms plays an important role in the SWLISM interaction. By performing 3-D, MHD plasma / kinetic neutral atom simulations, we describe the structure of the outer heliosheath (OHS) - the LISM plasma region affected by the presence of the heliosphere - and analyze quantitatively the distributions in front of the heliopause. It is shown that charge exchange modifies the LISM plasma to such extent that the contribution of a shock transition to the total variation of plasma parameters becomes small even if the LISM velocity exceeds the fast magnetosonic speed in the unperturbed medium. By performing adaptive mesh refinement simulations, we show that a distinct boundary layer of decreased plasma density and enhanced magnetic field should be observed on the interstellar side of the heliopause. We show that this behavior is in agreement with the plasma oscillations of increasing frequency observed by Voyager 1. Numerical results are presented that reproduce shocks that pass by Voyager 1 in the OHS. We demonstrate that Voyager observations in the inner heliosheath between the heliospheric termination shock and the heliopause are consistent with dissipation of the heliospheric magnetic field. The effect of pickup ions is discussed in the context of in situ measurements. MHD instabilities and magnetic reconnection at the heliopause are analyzed. We also show that TeV cosmic ray anisotropy can serve as an imager of the heliosphere. The choice of LISM parameters in this analysis is based on the simulations that fit observations of energetic neutral atoms performed by IBEX. The effect of pickup ions born in the outer heliosheath on the IBEX ribbon is discussed.

D1.2-0025-18 MAGNETIC RECONNECTION AT THE HELIOPAUSE: PREDICTED ELECTRON AND ION BULK HEATING EFFECTS IN THE PLASMA DEPLETION LAYER AND OUTER HELIOSHEATH

Iver Cairns, i.cairns@physics.usyd.edu.au University of Sydney, Sydney, Australia Stephen Fuselier, sfuselier@swri.edu

Southwest Research Institute, San Antonio, United States

Magnetic reconnection is a well-known source of electron and ion bulk heating, as well as energetic particles, in the solar system. Examples include solar flares and reconnection at Earth's magnetopause and in Earth's magnetotail. Several authors have suggested that reconnection occurs at the heliopause. The primary focus of this paper is to predict the amount of electron and ion bulk heating for heliopause reconnection, using the empirical relations of T. Phan and colleagues between the changes in electron and ion temperature and an Alfven speed VA,R,A. This Alfven speed depends on the strengths of the reconnecting magnetic fields and includes asymmetries in the magnetic fields and densities on the two inflowing sides of the reconnection region. For the undisturbed interstellar flow the predicted VA,R,A 25 km/s and the pre- dicted changes in electron and ion temperature are ΔTe 1000 K and ΔTi 6000 K. These changes are relatively small and not important for the dynamics at the heliopause. However, a plasma depletion layer (PDL) is predicted beyond the heliopause, analogous to the PDLs observed sunwards of the magnetopauses of Earth, Mercury, Jupiter, and Saturn. In the PDL, the interstellar (ISM) magnetic field lines drape over the heliopause. Plasma ions and electrons with relatively large parallel temperatures escape along the field, increasing the field strength, decreasing the plasma density, and increasing the Alfven speed. In the region of the PDL where these effects are strong, the expected field and density changes are a factor of 4 and ¼, respectively, increasing VA,R,A by a factor close to 3 and the temperature changes by almost a factor of 10. Thus, heliopause reconnection in a strong PDL is predicted to increase the electron and ion temperatures by up to 104 K and 8 x 104 K, respectively, corresponding to changes by factors of order 1.5 and 11 compared to the predicted ISM temperature of 7 x 103 K. Thus, the effects of bulk heating in heliopause reconnection regions should only be important for plasma inside or magnetically connected to the strong region of the heliopause's PDL. The effects of this heating on electrons and ions accelerated by shocks beyond the heliopause and on associated Langmuir waves will also be discussed.

D1.2-0026-18 COMPARISON OF SOLAR CYCLE 23 AND 24: A DECLINE TREND IN SOLAR ACTIVITY

Ashok Singh, aksphys@gmail.com

Lucknow University Lucknow, Lucknow, India Asheesh Bhargawa, asheeshbhargawa@gmail.com Lucknow University Lucknow, Lucknow, India

Impetus to look into the nature of solar activity and variability has increased importance in recent years because of their terrestrial association. The variability in solar indices has played a key role in understanding of solar activities and their interpretations. In the present work we have compared some solar parameters observed during solar cycles 23 and 24. To that end, we have considered sunspot numbers, F10.7 cm solar flux, Lyman alpha index and Mg II index as input parameters. Sunspot numbers during solar cycle 23 was observed from 1.04 to 246.56 while during the solar cycle 24 it varied from 4.54 to 146.6. F10.7 cm solar flux was observed from 71.76 to 238.04 during the solar cycle 23 while it varied from 69.61 to 159.73 during the solar cycle 24. Similarly the Lyman solar index varied from 3.57 to 5.89 during the 23rd solar cycle while it varied from the value of 3.54 to 4.95 during the solar cycle 24 and the variations in Mg II index occurred from 0.2629 to 0.2886 for the solar cycle 23 while it varied from the value 0.2631 to 0.2836 for the present solar cycle. On the basis of above changes in various solar parameters we inferred about 40.54 % decline in maximum value of sunspot numbers, 32.89 % of decrement in F10.7 cm index, 0.15 % decrement in Lyman alpha index while in Mg II index decrement of 1.73 % was observed in cycle 24th as compared to cycle 23rd. By comparing above considered solar parameters we have concluded that the solar activity has declined during the cycle 24 as compared to cycle 23 and it may further decline during the next cycle 25.

D1.2-0027-18 INTERSTELLAR NEUTRAL OXYGEN IN THE HELIOSPHERE: ANALYSIS OF IBEX DATA ON THE BASIS OF THE KINETIC MODEL

Quantitative analysis of the interstellar heavy (oxygen and neon) atom fluxes obtained by Interstellar Boundary Explorer (IBEX) suggests the existence of the secondary interstellar oxygen component. This component is formed near the heliopause due to charge exchange of interstellar oxygen ions with hydrogen atoms as was predicted theoretically. A detailed quantitative analysis of the fluxes of interstellar heavy atoms is only possible with a model that takes into account both filtration of primary and production of secondary interstellar oxygen in the boundary region of the heliosphere as well as a detailed simulation of the motion of interstellar atoms inside the heliosphere. This simulation must take into account photoionization, charge exchange with the protons of the solar wind and solar gravitational attraction. We present the results of modelling interstellar oxygen and neon atoms through the heliospheric interface and inside the heliosphere based on a three-dimensional (3D) kinetic-MHD model of the solar wind interaction with the local interstellar medium and analysis of the IBEX data on the basis of the kinetic model.

D1.2-0028-18 RIGIDITY SPECTRUM OF THE LONG-TERM COSMIC RAY VARIATIONS DURING SOLAR ACTIVITY CYCLES 19-24

The monthly rigidity spectrum of cosmic ray (CR) variations in the 19-24 cycles of solar activity was obtained by the global survey method using the data of continuous ground and near-Earth monitoring of CRs, exempted from atmospheric and local effects. The changes of the spectrum, first obtained for such a long period, made it possible to reveal the features of large-scale effects in CR modulation, the presence of 22-year and 11-year CR variations in the spectrum, and confirm an abnormal spectrum change in the 70s. The paper assumes a rigidity spectrum of CRs, given in a three-parameter form. Analysis of the obtained long-term CR variations for particles with rigidity R = 10 GV shows that the amplitude of the 22-year wave in the CR intensity increases from cycle to cycle and reaches its maximum value at the minimum of 23/24th solar activity cycle. Gradual softening of the spectrum at the cycle minima has been revealed for the negative polarity of the solar magnetic field (A<0). The reasons for the abnormally high CR density at the minimum of the 24th cycle and the spectrum features in the 70s are discussed. The spectrum of long-term CR variations in the 19-24 solar activity cycles, determined from the experimental data, makes it possible to verify some conclusions of the theory of heliospheric CR modulation concerning the role of the magnetic drift of particles in cycles with the different polarity of the solar magnetic field. In particular, we propose the explanation for the observed R-2 spectrum of the variations in the minima of the negative solar activity cycles, related with the scattering of particles in the vicinity of the neutral current sheet.

D1.2-0029-18 CHARACTERIZING CORONAL STRUCTURE: CONTEXTUAL PREDICTIONS FOR PARKER SOLAR PROBE FROM GLOBAL MHD SIMULATIONS WITH DYNAMICAL TURBULENCE MODELING

Southwest Research Institute, Boulder, Colorado, United States

As the solar plasma flows out from the corona and transitions into the solar wind, it transforms from a magnetically structured, subsonic, and sub-Alfvénic regime into a supersonic and superAlfvénic flow dominated by hydrodynamics. Recent analysis of remote imaging observations in solar minimum conditions by DeForest et al. (2016) has described the early stages of this transition, which may also coincide with the onset of large-scale turbulence in the solar wind. Here we extend this analysis to global magnetohydrodynamic simulation of the corona and solar wind based on inner boundary conditions that emulate solar minimum, in anticipation of the first phase of Parker Solar Probe (PSP) observations, which are expected during solar minimum as well. Taken together with the imaging analysis, the simulation results provide more detailed expectations for locations of the Alfvén critical surface and the first plasma beta unity surface moving from the corona into the dynamically active solar wind. The turbulence parameters computed from the simulations also enable estimations of the characteristic scales at which in-situ turbulence may influence the dynamics of the solar wind. Estimations of relevant parameters along a simulated PSP trajectory are presented. Issues pertaining to the use of Taylor's frozen-in hypothesis with PSP perihelion data are discussed.

D1.2-0030-18 CHARACTERIZATION OF THE TURBULENCE AROUND COROTATING INTERACTION REGIONS FOR INVESTIGATING THE GALACTIC COSMIC RAYS MODULATION

Keyvan Ghanbari, keyvanghanbari@gmail.com

University of Alabama in Huntsville, Hutsville, Alabama, United States Vladimir Florinski, vaf0001@uah.edu

University of Alabama in Huntsville, Huntsville, Alabama, United States Xiaocheng Guo, xg0002(at)uah.edu

University of Alabama in Huntsville, 35899, Alabama, United States

Corotating interaction regions (CIRs) are large-scale structures that occur when the slow solar wind is overtaken by the fast wind. CIRs consist of a compression region ahead in the slow wind and a rarefaction region behind which are separated by a stream interface and are usually accompanied by a crossing of the heliospheric current sheet. It is well known that cosmic rays intensities are modulated around these structures. In this work, using WIND spacecraft plasma data, we have examined CIRs in the period from 2007 to 2009, near solar minimum activity. The spectral analysis of magnetic field turbulence is performed for intervals of 5 days before to 5 days after each CIR for 4-hour sub-intervals and then a superposed epoch analysis is applied over the results which report of a peak at the turbulence at the stream interface. We have linked our findings of the characteristics of the turbulence around CIRs to the galactic cosmic rays modulations from the data obtained from CRIS instrument of the ACE spacecraft with the purpose of investigating the cosmic ray diffusion transport. The results also compared with the MHD model simulations performed by Guo Florinski 2016.

Victor Yanke, yanke@izmiran.ru IZMIRAN, Moscow, Russia

In the proposed work with an annual resolution for the period 1950 2015 and the forecast to 2050 by the method of trajectory calculations, geomagnetic cutoff rigidities for vertical and inclined directions of the World Network of detectors were obtained. Geomagnetic cutoff rigidities were obtained using the International Geomagnetic Reference Field (IGRF 12) model. The results of the calculations indicate the manifestation of two World Anomalies: in the zone of one, the rigidity of the geomagnetic cutoff decreases, in the zone of the other - increases, but globally rigidity of the geomagnetic cutoff decreases by approximately 7% per century. For inclined directions, an irregular course is observed in the time dependence of the rigidity of geomagnetic cutoff: for northwest directions for detectors of the South Atlantic anomaly zone and directions south for the detectors of the zone of the North Atlantic anomaly. Such an irregular course is most likely due to the large variability of the penumbra zone for such inclined directions.

D1.2-0032-18 VOYAGER 1/UVS LYMAN-ALPHA MEASUREMENTS AT DISTANT HELIOSPHERE (90-130 AU): UNKNOWN SOURCE OF ADDITIONAL EMISSION

Olga Katushkina, okat@iki.rssi.ru

Space Research Institute (IKI), Russian Academy of Sciences, Moscow, Russia Eric Quemerais, eric.quemerais@latmos.ipsl.fr

University of Arizona, Tucson, United States

Voyager 1/UVS measurement of the Lyman α intensities at the distant heliosphere is a unique source of information on the interstellar hydrogen distribution at the heliospheric boundary. In 2003-2014 (at 90-130 AU from the Sun) Voyager 1 measured the Lyman α emission at an almost fixed direction close to the upwind (i.e. toward the interstellar flow). The data show an unexpected behavior in 2003-2009: the ratio of observed intensity to the solar Lyman α flux at Earth orbit is almost constant. We performed a numerical modeling of these data in the frame of a state-of-the-art self-consistent kinetic-MHD model of the heliospheric interface. The model results, for various interstellar parameters, predict a monotonic decrease of intensity not seen in the data. We propose two possible scenarios that explain the data qualitatively. The first is the formation of a dense layer of hydrogen atoms near the heliopause. Such a layer would provide an additional backscattered Doppler-shifted Lyman α emission, which is not absorbed inside the heliosphere and may be observed by Voyager. About 35 R of intensity from the layer is needed. The second scenario is an external nonheliospheric Lyman α component, which could have a galactic or extragalactic origin. Our parametric study shows that about 25 R of additional emission would be enough to provide a good qualitative agreement between the Voyager 1 data and the model results.

D1.2-0033-18 A FRESH LOOK AT THE GLOBAL HELIOSPHERE USING ANALYTICAL MHD MODELS

Jens Kleimann, jk@tp4.rub.de

Ruhr-Universität Bochum, Bochum, Germany

Christian Röken, christian.roeken@mathematik.uni-regensburg.de University of Regensburg, Regensburg, Germany

Horst Fichtner, hf@tp4.rub.de

Ruhr-Universität Bochum, Bochum, Germany

The analytical magnetohydrodynamic (MHD) model for the local interstellar magnetic field in the vicinity of the heliopause by Röken et al. (2015) is an exact solution of the induction equation of ideal MHD for an interstellar magnetic field being passively advected in a Rankine-type heliospheric flow. After a review of the model's basic properties, two recent generalizations are presented and discussed: First, the use of so-called distortion flows allows for the formerly circular heliotail to be deformed into a more realistic, ellipsoidal cross section while maintaining the exactness of this more involved, but still fully analytical MHD solution. Second, the generalization from incompressible to mildly compressible flow further improves the model's degree of realism by introducing an extended region of compressed magnetic field, as well as a pile-up of mass ahead of the heliopause, The usefulness of these still analytical solutions as approximations to self-consistent magnetic field configurations obtained numerically from the full set of MHD equations is illustrated by quantitative comparisons.

D1.2-0034-18 EXPERIMENTAL STUDY OF DELAY TIME PROBLEM IN GALACTIC COSMIC RAYS FLUX IN DIFFERENT EPOCHS OF SOLAR ACTIVITY: 1964-2008

Marek Siluszyk, marek.siluszyk@uph.edu.pl Siedlce University, Siedlce, Poland Krzysztof Iskra, k.iskra@wsosp.pl

Siedlce University, Siedlce, Poland

Witold Wozniak, witek.wozniak81@gmail.com Polish Gas Company, Warszawa, Poland

We analyzed long period changes in different epochs of Solar Activity (SA). A purpose of this paper is to carry on a study the delay time τ between changes of GCR intensity on the one hand, and various parameters characterizing conditions in heliosphere, on the other. We proof an existence of a varying delay time τ between changes of GCR intensity and various parameters characterizing conditions in heliosphere. Base on the experimental investigation we obtained delay times different for various solar cycles: 20, 21, 22 and 23. The analyses of solar cycles show different delay time in different epochs of SA. We concludes that observed delay time is very important factor to study of GCR transport in the heliosphere.

D1.2-0035-18 THEORETICAL INVESTIGATION OF DELAY TIME IN GALACTIC COSMIC RAYS FLUX IN DIFFERENT EPOCHS OF SOLAR ACTIVITY

B. Prus High School, Siedlce, Poland

Based on the Parker's Transport Equation (PTE) we expand three dimensional (3-D) time dependent model describing a propagation of the energetic astroparticles - Galactic Cosmic Rays (GCR) in heliosphere. The Parker's PTE contains a well-known four major processes: diffusion, convection, drift and adiabatic cooling responsible for modulation of the GCR flux in heliosphere. We analyzed long period changes in different epochs of Solar Activity. We study four last solar cycles: 20, 21, 22 and 23. We implement in numerical simulation of PTE few physical parameters as, tilt angle delta of the Heliospheric Neutral Sheet (HNS), module B of the Heliospheric Magnetic Field (HMF) and changes of drift effect of the GCR particles upon SA. The idea in present modelling is connected with the using for implementation of two independent parameters as the gamma and nu. The proxies gamma and nu are calculated from different sources, gamma - from neutron monitors (NMs) daily data, and nubased on the HMF's hourly data. The solutions of PTE obtained from numerical models are compared with the changes of the GCR flux measured by NMs. Base on the investigation we obtained delay times different for various solar cycles. We received a satisfactory agreement of the theoretical results with the experiment

The Interstellar Boundary Explorer (IBEX) is a NASA satellite in a highly elliptic Earth orbit. IBEX has been observing interstellar neutral matter entering the heliosphere and energetic neutral atoms (ENAs) from the heliosheath for almost one solar cycle, starting at the end of 2008.

In this presentation, we will give a short overview of IBEX observations starting from solar wind energies down to the lowest energies accessible with the IBEX-Lo sensor (1 keV - 10 eV). We will focus on heliospheric ENAs and interstellar neutral hydrogen. ENAs of this energy range originate from solar wind or pickup protons and mostly reveal processes in the inner heliosheath (the vast region of the heliosphere between the termination shock and the heliopause). The interstellar neutral hydrogen provides information on the interstellar matter, on the interaction between interstellar plasma and neutral gas in the outer heliosheath, and on losses inside the heliosphere due to ionization and deflection from Keplerian trajectories by radiation pressure.

Observations at these energies are challenging to interpret because the neutral atoms are very sensitive to ionization loss and radiation pressure, and compete with strong background sources. Nevertheless, these IBEX observations are very helpful to constrain the parameters of heliospheric models, such as the dimensions, the plasma pressure, the neutral density, the solar radiation pressure, and UV fluxes.

We present the first systematic analysis to determine pickup ion (PUI) cut-off speed variations, both during compression regions identified by their structure, and during times of highly variable solar wind (SW) speed or magnetic field strength. This study is motivated by the attempt to remove or correct these effects on the determination of the longitude of the interstellar neutral gas flow from the flow pattern related variation of the PUI cutoff with ecliptic longitude (Moebius et al. 2015 ApJ 815, 20). Using 2007-2014 STEREO A PLASTIC observations we identify compression regions in the solar wind and analyze the PUI velocity distribution function (VDF). Characterizing individual compression events programmatically and combining them in a superposed epoch analysis allows us to analyze the PUI population in similar interplanetary conditions and find the local cut-off shift with adequate statistics. This method yields positive cut-off shifts in compression regions whose values increase with the strength of solar wind speed gradients. Also, through sorting the entire set of PUI VDFs at high time resolution we obtain a noticeable correlation of the cut-off shift with the magnitude of gradients in the SW speed and interplanetary magnetic field strength. This effect may be understood in terms of motional electric fields in SW velocity gradients, similar to those produced at quasi-perpendicular shock fronts, causing PUI's to be accelerated along the plane of the compression. Alternatively, increases in the PUI cut-off in these compressions could be understood by invoking conservation of the first adiabatic invariant along with a transformation between the local frame where the electric field vanishes and the observer frame. Fundamentally, this study sheds light on the physical mechanisms that lead to energy transfer between the SW and the embedded PUI population, while providing criteria to select time periods when the PUI cut-off reflects most closely the interstellar flow velocity rather than SW related effects.

D1.3-0003-18 PICKUP IONS IN THE OUTER HELIOSPHERE

Nikolai Pogorelov, np0002@uah.edu

University of Alabama in Huntsville, Huntsville, Alabama, United States Tae Kim, tkk0023@uah.edu

Space Science Institute, Boulder, Colorado, United States Ming Zhang, mzhang@fit.edu

Florida Institute of Technology, Melbourne, Florida, United States

Pickup ions (PUIs) are created when a neutral atom in the heliosphere becomes ionized. It is then ionized and picked-up by the heliospheric magnetic field and swept outward. These ions are not in equilibrium with the solar wind (SW) ions and therefore are also called nonthermal. PUIs originate from the inner source neutral atoms and also from those of interstellar origin. PUIs are quickly isotropized and acquire the bulk velocity of the ambient SW. The distribution function of PUIs is unstable and produces turbulence that heats up SW ions. This effect becomes especially prominent when the thermal SW protons reach some minimum temperature at about 10 AU. Their temperature is further increasing until they reach the heliospheric termination shock. However, most of thermal energy carried by the SW plasma belongs to PUIs. Shock crossing is a kinetic process for PUIs and therefore it is hard to be modeled in global, data-driven, MHD simulations. In this talk we describe a few basic approaches to model PUIs in the turbulent SW. Numerical simulations are compared with New Horizons, Voyager, and Ulysses measurements. In addition, we show previously unpublished distributions of pickup protons observed by Ulysses. Numerical simulations are extended to Neptune, Pluto, and further towards the termination shock. The effect of PUIs on the latter is also discussed.

D1.3-0004-18 EVALUATION OF COMPETING DYNAMIC SMALL-SCALE FLUX-ROPE ACCELERATION SCENARIOS FOR ENERGETIC PROTONS NEAR EARTH

Jakobus Le Roux, jar0013@uah.edu

University of Alabama in Huntsville, Huntsville, Alabama, United States Gary Zank, garyp.zank@gmail.com

University of Alabama in Huntsville, Huntsville, United States Gary Webb, gmw0002@uah.edu

University of Alabama in Huntsville, Huntsville, Alabama, United States Olga Khabarova, olik3110@gmail.com

IZMIRAN, Moscow, Russia

Recent observations near 1 AU suggest that dynamic small-scale flux-rope structures are a much more common occurrence than previously thought (Zheng et al. 2018) and are linked to enhanced energetic particle fluxes (e.g., Zank et al. 2015; Khabarova and Zank 2017). In response we recently developed a system of coupled equations involving a kinetic focused transport equation with Fokker-Planck scattering coefficients for energetic charged particles coupled to a MHD turbulence transport equation for coherent, quasi-2D magnetic island structures based on NI MHD turbulence theory (Zank et al. 2017). The coupled equations can be used to model the self-consistent acceleration of suprathermal charged particles interacting with and traversing numerous dynamic (contracting and merging) quasi-2D small-scale flux ropes with cross-sectional sizes belonging to the inertial range. The particles are restricted to gyro radii smaller than flux-rope size (quasi-trapping of particles in these structures). Both coherent and stochastic energetic particle acceleration rate expressions were derived for four small-scale fluxrope acceleration scenarios present in focused transport theory: (1) Combined curvature drift and generalized betatron energization in small-scale flux ropes contracting and merging in the compressible limit (Zank et al. 2014; le Roux et al. 2015), (2) unified curvature drift energization and generalized betatron energy loss in small-scale flux ropes contracting and merging in the incompressible limit (e.g., Drake et al. 2006, 2013), (3) parallel guiding center motion energy gain and energy loss by the parallel reconnection electric field force generated in merging (reconnecting) flux ropes (e.g., Oka et al. 2010; Zank et al. 2014; Dahlin et al. 2016), and (4) parallel guiding center motion energy gain and energy loss produced by a non-inertial force associated with the acceleration of the plasma flow in dynamic small-scale flux ropes. Estimated test-particle suprathermal proton acceleration rates for the different flux-rope acceleration scenarios in the supersonic solar wind near 1 AU will be compared and discussed.

Dynamic flux-rope induced energetic particle pitch-angle scattering and stochastic acceleration rates will also be compared to the corresponding rates for parallel propagating Alfven waves.

D1.3-0005-18 PARTICLE ACCELERATION IN COALESCENT AND SQUASHING MAGNETIC ISLANDS: TP AND PIC APPROACH

Valentina Zharkova, valentina.zharkova@northumbria.ac.uk
University of Northumbria, Newcastle Upon Tyne, United Kingdom
Qian Xia, q.xia@northumbria.ac.uk

Northumbria University - UK, Newcastle, United Kingdom

We investigate particle acceleration in 3D reconnecting current sheets (RCSs) containing multiple Oand X-nullpoints and different topologies: coalescent (moving towards each other) and squashed islands using a test particle and particle-in-cell (PIC) approach. The inclusion of multiple O-nullpoints, or magnetic islands, reveals that acceleration of protons and electrons in a current sheet with strong guiding field remains asymmetric towards the midplane, e.g. electrons and protons are ejected into the opposite directions from the midplane. Both types of particles (electrons and protons) mainly gain energy in a vicinity of X-nullpoints or inside O-nullpoints and, depending on their initial energy, these gains can reach relativistic energies in a single island. Accelerated particles with critical energies can escape O-nullpoints, or magnetic islands, only through neighbouring X-nullpoints escape along the midplane. As result, there are electron clouds formed between the magnetic islands while electrons gain the critical energy to break from an RCS. The energy gains in coalescent islands are much smaller than from the squashed ones. Electrons are shown to form clouds about X-nullpoints between the magnetic islands where they become ejected after gaining the critical energies required to break from the RCS magnetic topology. Particle acceleration in 3D RCSs with multiple Xand O-nullpoints is probed with some observational features in the heliosphere. This research is funded by the US Airforce grant.

D1.3-0006-18 MODELLING THE INJECTION AND ACCELERATION OF ENERGETIC PARTICLES AT TRAVELLING SHOCKS

Phillip L Prinsloo, drageoprinsloo@gmail.com

North-West University, Potchefstroom, South Africa Du Toit Strauss, dutoit.strauss@nwu.ac.za

North-West University, Potchefstroom, South Africa

Propagating shocks are observed to form ahead of the solar material expelled into interplanetary space following coronal mass ejections (CMEs). During the passage of these CME-driven shocks, spacecraft often observe energetic particle enhancements commonly associated with particle acceleration. In this study, the acceleration of energetic particles at halo-CME-driven shocks is investigated, with a particular focus on the acceleration of particles from the suprathermal solar wind (SW). A set of stochastic differential equations, derived from the Parker transport equation and including the effects of diffusive shock acceleration, is solved numerically to model this process. The SW particle velocity distribution is described by a Kappa distribution in the solar wind frame and prescribed as a source function at the shock. The injection energy is calculated from first principles, but can also be changed to investigate the effect thereof on model solutions. With the further application of physically representative transport coefficients, the model results are presented and their accuracy evaluated against how well they reproduce observations of protons and heavier ions during selected shock passage events.

D1.3-0007-18 ALPHA PARTICLES SURFATRON ACCELERATION IN SPACE PLASMA

Rumen Shkevov, shkevov@space.bas.bg

Space Research Institute, Russian Academy of Sciences, Moscow, Russia Ludmila Mikhailovskaya, ludamikh@iki.rssi.ru

Space Research Institute, Russian Academy of Sciences, Moscow, Russia

A theoretical study on the alpha particles strong surfatron acceleration by an electromagnetic wave in space plasmas is performed. Based on numerical calculations for the wave phase on the particle trajectory we analyze the phenomenon of the interaction of the wave with the alpha particle when the wave propagates across weak constant magnetic field. The capture conditions of alpha particle and ultrarelativistic surfatron acceleration for different initial energies are studied. Wave phase dynamics on the trapped alpha particle trajectory, relativistic factor, energy growth rate and the final particle energy estimation are given. The phase plane structure and its different stages of the captured alpha particle are illustrated graphically. Particles velocity components dynamics during surfatron acceleration and their asymptotic values are also presented. Numerical simulations point that capture of the alpha particles by the wave in an effective potential well occurs immediately or after a relatively short period of time. The additional calculations results provided in tables and charts allow conclusions to be drawn about resonant interactions efficiency in space plasmas. The surfatron acceleration of alpha particles in space plasma can explain the appearance of a strong temporal and spectral feature in the experimental data.

D1.3-0008-18 ENERGETIC PARTICLES MEDIATED HELIOSPHERIC SHOCK WAVES

Parisa Mostafavi, psm0011@uah.edu

University of Alabama in Huntsville, Huntsville, Alabama, United States Gary Zank, garyp.zank@gmail.com

University of Alabama in Huntsville, Huntsville, United States Gary Webb, gmw0002@uah.edu

University of Alabama in Huntsville, Huntsville, Alabama, United States

The structure of heliospheric parallel, perpendicular, and oblique shocks is often determined by the mediation of energetic particles. Energetic particles (such as interstellar pickup ions (PUIs), solar energetic particles (SEPs), and cosmic rays) contribute significantly to the dissipative process that determines the structure of shock waves. The mediation effectively introduces a form of heat flux and viscosity (due to particle pitch angle scattering by magnetic field fluctuations), similar to those of classical fluid dynamics, but now appropriate to a collisionless magnetized plasma. Webb (1983) showed that in some Mach number regimes (even for a cold plasma), the energetic particle heat flux is insufficient to determine the shock structure, and a gas sub-shock needs to be added to ensure a shock transition. However, the presence of the energetic particle viscosity can further smooth a shock transition and ensures a complete smooth solution. We present a general theoretical model of parallel, perpendicular, and oblique shock mediation by energetic particles and we compare the theoretical results with observations. Russell et al. (2013) and Lario et al. (2015) showed that some interplanetary shocks within 1 AU can be dominated dynamically by energetic particles whose pressure exceeds that of the background thermal plasma and the magnetic field. Voyager 2 observations revealed that the heliospheric termination shock (HTS) is very broad and mediated by energetic particles (Richardson et al. (2008)). We show that the thermal gas remains cold through the HTS and does not provide the dissipation needed to account for the deceleration of the supersonic solar wind. Instead, PUIs are the primary dissipation mechanism and gain most of the solar wind kinetic energy through the HTS.

D1.3-0009-18 VOYAGER 1 OBSERVATIONS OF PITCH-ANGLE-DEPENDENT COSMIC RAY ANISOTROPY EVENTS IN THE LOCAL INTERSTELLAR MEDIUM

Unexpected decreases in the intensity of > 211 MeV galactic cosmic ray protons were revealed by Voyager 1's Low Energy Charged Particle instrument in 2013, upon crossing into the local interstellar medium (LISM). Decreases, lasting from 100 to 630 days have also been observed by Voyager 1's Cosmic Ray Subsystem (CRS) in its omnidirectional (20 MeV) and bi-directional

(70 MeV) proton intensities. Between late 2012 and early 2017, three durable episodes occurred, and are known to arise from a reduction of particles with pitch angles near 90°. However, there is no evidence of pitch angle anisotropy in cosmic ray electrons with energies of 5 to 105 MeV. Results from using a simple model to characterize the anisotropy are presented and an interpretation of the physical mechanism is discussed.

D1.3-0010-18 COSMIC RAY MODULATION IN THE OUTER HELIOSHEATH

Ming Zhang, mzhang@fit.edu

Florida Institute of Technology, Melbourne, Florida, United States Nikolai Pogorelov, np0002@uah.edu

University of Alabama in Huntsville, Huntsville, Alabama, United States Tae Kim, tkk0023@uah.edu

University of Alabama in Huntsville, Huntsville, United States

Voyager 1 observations show that the intensity of Galactic cosmic rays exhibits a peculiar pattern of variation and anisotropy at the heliopause and in the outer heliosphere. One of the most interesting features is the deficit of intensity near the 90° pitch angle to the magnetic field. The intensity of particles near the 90° pitch angle undergoes variations far stronger those at the small angles to the field. It is possibly caused CME shock waves passing through heliopause and continuing to propagate in the interstellar magnetic field of the outer heliosheath. In this paper, we present our model calculation results of cosmic ray modulation caused by the traveling waves and associated rarefaction region. We demonstrate how a combination of particle trapping and adiabatic cooling the rarefaction region affect the cosmic ray variations and anisotropies.

D1.3-0011-18 COSMIC RAYS IN THE VERY LOCAL INTERSTELLAR MEDIUM

University of Alabama in Huntsville, Huntsville, Alabama, United States Xiaocheng Guo, guogxc@gmail.com

National Space Science Center, Chinese Academy of Sciences, Beijing, China Keyvan Ghanbari, keyvanghanbari@gmail.com

University of Alabama in Huntsville, Hutsville, Alabama, United States

The behavior of energetic particles at the heliopause encountered by Voyager 1 in 2012 was by and large consistent with the expectations from theory and models. Namely, the low energy heliospheric ions have disappeared and the high energy galactic cosmic rays reached a steady plateau reflecting their ambient intensity in the local interstellar space. Nonetheless, a fraction of the heliospheric ions was evidently able to overcome the magnetic shear at the heliopause and escape into interstellar space. These ions' contribution to the overall pressure balance at the heliopause can be questioned, on account of the extremely large mean free path in the interstellar medium where the level of magnetic fluctuations is exceptionally low. Some possible effects of this pressure deficit on the structure of the heliosphere are examined. The second outstanding problem is the origin of the episodic depletions in the distributions of galactic cosmic rays at the 90 degree pitch angle. We discuss several physical processes that could account for the observed depletions, including drifts of trapped cosmic ray ions and shadowing by the heliopause.

D1.3-0012-18 GLOBAL MODULATION OF COSMIC RAYS IN A QUIET HELIOSPHERE

Marius Potgieter, marius.potgieter@nwu.ac.za North-West University, Potchefstroom, South Africa

In 2008 to 2009, cosmic ray intensities were at their highest levels since the beginning of the space exploration era. Since then solar activity has followed the 11-year cycle but with the Sun considerably quieter than before. This provides the opportunity to study and test modulation theory under such quiet heliospheric conditions, especially charge-sign-dependent modulation. This can be done from minimum to maximum solar activity, and over a solar magnetic field reversal from a so-called $A < 0$ polarity cycle to an $A > 0$ cycle. Drift theory predicts that the intensity of positively and negatively charged particles should show different behaviour in terms of responding rates during the solar cycle and during the magnetic field reversal period. This is now testes with the precise measurements made by the PAMELA and AMS-02 missions of electrons and positrons. The global features of cosmic ray modulation have been studied with comprehensive, three-dimensional, drift models and compared to PAMELA proton spectra from 2006 to 2014 to authenticate the modelling approach and subsequently to make predictions of how cosmic ray protons, electrons, and positrons are differently modulated down to 1 MeV. These solutions are based on new very local interstellar spectra.

D1.3-0013-18 COMBINED GLOBAL MODULATION OF JOVIAN AND GALACTIC ELECTRONS IN THE HELIOSPHERE

Rendani Rejoyce Nndanganeni, rnndanganeni@sansa.org.za
South Africa National Space Agency, Hermanus, South Africa
Marius Potgieter, marius.potgieter@nwu.ac.za

North-West University, Potchefstroom, South Africa

A three-dimensional, numerical model is used to study the total modulation of Jovian and Galactic electrons, from 1 MeV to 50 GeV and from the Earth into the heliosheath. For this purpose the Jovian electron source and the very local interstellar spectrum, or heliopause spectrum, are revisited. The latter can be computed with confidence since Voyager 1 already crossed the heliopause. Modeling results are compared with Voyager 1 observations in the outer heliosphere, including the heliosheath, as well as observations at or near the Earth, e.g. from ISSE3 and Ulysses for 1991 and 1992, and in particular the 2009 spectrum from the PAMELA space mission. Making use of the observations at Earth and a new source function for the Jovian electrons, the energy range over which the Jovian electrons dominate the Galactic electrons is determined so that the intensity of Galactic electrons at Earth below 100 MeV is calculated.

D1.3-0014-18 GALACTIC COSMIC RAY RATIO OF FREE PATHS NORMAL AND PARALLEL TO MEAN IMF AT HIGH RIGIDITIES

H.S. Ahluwalia, hsa@unm.edu

University of New Mexico, Albuquerque, New Mexico, United States

Data from the Nagoya Vertical muon telescope are used to compute the east-west and radial components of the solar diurnal anisotropy of galactic cosmic rays for 1970-2016, covering three sunspot cycles (21-23) and parts of the other two (19, 24). The ratio (alpha) of the diffusion coefficients perpendicular and parallel to the mean interplanetary magnetic field is computed and compared with corresponding values for the global network of the neutron monitors. Preliminary results for alpha, its rigidity dependence and correlation with solar activity for positive (p-) and negative (n-) intervals of solar polar field at 1 au are noted. The results challenge the validity of some old results and conceptual understanding of the modulation processes in the heliosphere.

D1.3-0015-18 TURBULENCE IN THE OUTER HELIOSPHERE AND VERY LOCAL INTERSTELLAR MEDIUM

University of Alabama in Huntsville, Huntsville, Alabama, United States

Low-frequency turbulence in the supersonic solar wind plays a key role in determining the propagation of anomalous and galactic cosmic rays into the heliosphere. It is also critical in determining the internal energy of the large-scale solar wind flow. In the distant heliosphere, the levels of turbulence and its subsequent dissipation is influenced strongly by the creation of pickup ions (PUIs) from interstellar neutral hydrogen that has crossed the heliospheric boundaries into the supersonic solar wind. In this regard, the physics of the solar wind is profoundly modified by interstellar processes. It also transpires that turbulence in the very local interstellar medium (VLISM) may be influenced by the nature of turbulence in the inner heliosheath i.e., by processes in the subsonic solar wind. In this presentation, we will review three aspects of the turbulence in the outer heliosheath and VLISM. 1) We will describe recent models that describe the transport of turbulence in the distant solar wind, identifying the contribution from the creation of PUIs, and the associated heating of the solar wind. 2) Based on the turbulence transport models, we will summarize their effect on cosmic ray modulation through the evaluation of the cosmic ray spatial diffusion tensor and the corresponding parallel, perpendicular, and drift mean free paths. 3) Finally, Voyager 1 observations of low-frequency turbulence in the VLISM close to the heliopause suggested that the dominant component was compressible. We will review these observations briefly and present a theoretical model that shows that fastmode waves are transmitted from the inner heliosheath into the VLISM, where they may be responsible for the observed compressible fluctuations.

D1.3-0016-18 TIME-DEPENDENT COSMIC RAY MODULATION IN THE HELIOSPHERE

Stefan Ferreira, stefan.ferreira@nwu.ac.za

North-West University, Potchefstroom, South Africa

Cosmic ray intensities are computed in the inner and outer heliosphere using a two-dimensional, time-dependent modulation model. Results are compared to IMP-8, Ulysses, Voyager 1 and Voyager 2 observations for compatibility. A time-dependence for the assumed transport parameters are constructed by incorporating recent theoretical advances. This approach gives results which compared well with the traditional compound approach of Ferreira and Potgieter (2004) and also to the observations along Voyager 1, Voyager 2 and at Earth on a global scale. However, for extreme solar maximum conditions the computed step-like modulation is not as pronounced as observed, indicating that some merging in the form of global interaction regions is needed.

D1.3-0017-18 A STUDY OF ELECTRON FORBUSH DECREASES WITH A 3D STOCHASTIC DIFFERENTIAL EQUATION (SDE) NUMERICAL MODEL

Xi Luo, xluo@spaceweather.ac.cn

National Space Science Center, Chinese Academy of Sciences, Beijing, China Marius Potgieter, marius.potgieter@nwu.ac.za

North-West University, Potchefstroom, South Africa Ming Zhang, mzhang@fit.edu

Florida Institute of Technology, Melbourne, Florida, United States Xueshang Feng, fengx@spaceweather.ac.cn

National Space Science Center, Chinese Academy of Sciences, Beijing, China

The precise measurements of the cosmic ray electron flux from PAMELA and AMS02 have made it possible to record electron Forbush decreases (Fds) for the first time. This is motivation to perform a numerical study of electron Fds, utilizing a three-dimensional (3D), time-dependent SDE model to simulate and study the main features of electron Fds. A newly developed electron Local Interstellar Spectrum is also included. The model is validated by first reproducing the observed PAMELA electron spectrum at the Earth over an energy range from 80 MeV to 100 GeV. In the process, all modulation parameters are refined. Subsequently, electron Fd profiles at different rigidity are simulated, first with particle drifts turned off. It was found that the magnitude of a Fd is determined by changes in the local values of the three main diffusion coefficients so that the observed magnitude of these Fds may shed light on the rigidity dependence of these diffusion coefficients. If these diffusion coefficients are to be almost constant at low kinetic energies (a few hundred MeV), as predicted by main stream diffusion theory, the magnitude of electron Fds should not change much over this energy range. Additionally, by solving the relevant transport equation including global particle drifts, electron Fd profiles during the two periods of different solar magnetic polarity have been simulated and compared to the profiles of proton Fds at the same rigidity. These studies indicate that drifts can cause a charge-sign dependence effect on the profiles of Fds, especially on their recovery times, even for these small scale phenomena.

D1.3-0018-18 THE TIME DEPENDENCE OF THE COSMIC RAY FLUXES MEASURED BY THE PAMELA EXPERIMENT.

It was the 15th of June of 2006 when the PAMELA satellite-borne experiment was launched from the Baikonur cosmodrome in Kazakstan. Then, for nearly ten years, PAMELA has been making high-precision measurements of the charged component of the cosmic radiation opening a new era of precision studies in cosmic rays and challenging our basic vision of the mechanisms of production, acceleration and propagation of cosmic rays in the galaxy and in the heliosphere. The study of the time dependence of the various components of the cosmic radiation from the unusual 23rd solar minimum through the maximum of solar cycle 24 clearly shows solar modulation effects as well as charge sign dependence. In this talk the solar modulation of the proton, helium and deuteron galactic cosmic ray component will be presented.

D1.3-0019-18 DATA-CONSISTENT MODEL OF THE FORBUSH DECREASE. APPLICATION OF THE APPROXIMATE BAYESIAN COMPUTATION TO ESTIMATE MODEL PARAMETERS.

Anna Wawrzynczak-Szaban, awawrzynczak@uph.edu.pl Siedlce University, Siedlce, Poland

Piotr Kopka, piotr.kopka@ncbj.gov.pl

National Centre for Nuclear Research, Swierk-Otwock, Poland

Accurate modeling of the complex phenomena as Forbush decrease of the galactic cosmic ray intensity is a quite challenging task. One aspect is a numerical solution of the Parker transport equation in five-dimensional space (three spatial variables, the time and particles energy). The second difficulty arises from a lack of detailed knowledge about the spatial and time profiles of the parameters responsible for the creation of the Forbush decrease. Among these parameters, the central role plays a diffusion coefficient. Assessment of the correctness of the proposed model can be done only by comparison of the model output with the experimental data of the galactic cosmic ray intensity. We present the method of evaluating the model of the Forbush decrease by assessing its capability of reproducing the neutron monitors data. To do so the set of model parameters is estimated with use of the Approximate Bayesian Computation (ABC) methodology. The ABC method is becoming increasing exploited for dynamic complex problems in which the likelihood function is costly to compute. The main idea of all ABC methods is to accept samples as an approximate posterior draw if its associate modeled data is close enough to the observed one. In this paper, we present application of the Sequential Monte Carlo Approximate Bayesian Computation algorithm scanning the space of the diffusion coefficient parameters in the vicinity of the space where the Forbush decrease is created. The proposed algorithm is adopted to create the model of the Forbush decrease observed by the neutron monitors at the Earth in November 2004. The model of the Forbush decrease is based on the stochastic approach to the solution of the Parker transport equation.

D1.3-0020-18 QUASI-PERIODIC CHANGES OF THREE DIMENSIONAL SOLAR ANISOTROPY OF GALACTIC COSMIC RAYS FOR 1965-2014

Renata Modzelewska, renatam@uph.edu.pl Siedlce University, Siedlce, Poland

Michael Alania, alania@uph.edu.pl Siedlce University, Siedlce, Poland

We study features of the three dimensional (3D) solar anisotropy of galactic cosmic rays (GCR) for 1965-2014 (almost 5 solar cycles 20-24). We analyze the 27-day variations of the two dimensional (2D) GCR anisotropy in the ecliptic plane, and the north-south anisotropy normal to the ecliptic plane. We study the dependence of the 27-day variation of the 3D GCR anisotropy on the solar cycle and solar magnetic cycle. We demonstrate that the 27-day variations of the GCR intensity and anisotropy can be used as an important tool to study solar wind, solar activity and heliosphere. We use the components Ar, Aϕ and At of the 3D GCR anisotropy found based on hourly data of neutron monitors (NMs) and muon telescopes (MTs) using the harmonic analyses and spectrographic methods. We correct 2D diurnal (24-hours) variation of the GCR intensity for the influence of the Earth magnetic field. We derive the north-south component of the GCR anisotropy based on the GG index calculated as the difference in GCR intensities of Nagoya multidirectional MTs. We show that behavior of the 27-variation of the 3D anisotropy verifies an existence of a stable long-lived active heliolongitudes on the sun. This finding illustrates usefulness of the 27-day variation of the GCR anisotropy as a unique proxy to study solar wind, solar activity and heliosphere. We distinguish a tendency of the 22-year changes of the amplitudes of the 27-day variation of the 2D anisotropy connected with the solar magnetic cycle. We demonstrate that the amplitudes of the 27-day variation of the north-south component of the anisotropy vary upon the 11 year solar cycle, however, a dependence of the solar magnetic polarity hardly can be recognized. We show that the 27-day recurrences of the GG index and At component are in a high positive correlation, and both are highly correlated with By component of the heliospheric magnetic field.

D1.3-0021-18 COMPARING THE RECURRENCE OF COSMIC RAY INTENSITY AT SOLAR ROTATION PERIOD IN SOLAR CYCLES 23 AND 24

Agnieszka Gil, gila@uph.edu.pl Siedlce University, Siedlce, Poland

Kalevi Mursula, kalevi.mursula@oulu.fi University of Oulu, Oulu, Finland

After the sunspot maximum and the solar polarity reversal in 2014, the Sun commenced the descending phase of cycle 24. Shortly after the polarity reversal, the galactic cosmic ray intensity, measured by neutron monitors at several latitudes, experienced a period of enhanced variability at the solar rotation period. It started in mid-2014 and continued until the beginning of March 2015. Some parameters of solar activity, like sunspot number and F10.7 radio flux, also experienced similar exceptional variation, which started slightly before than observed by neutron monitors. Several solar wind features also showed this variability, even though less steadily and during a shorter interval. We relate this strong periodicity in cosmic rays to the prompt development of an asymmetric southern polar coronal hole, which lead to a very asymmetric magnetic field configuration at midto highheliolatitudes.

We present here a detailed analysis of the above described period of recurrence and compare it with another similar period in 2007-2008, at the end of solar cycle 23, noting on differences and similarities. We show that in both periods a source of the recurrence was an asymmetric structure of a large coronal hole.

The radiation exposure due to galactic cosmic rays has been rising since early 2015 and is reaching some of the highest levels observed in the space age. This observation is not limited to the near-Earth space environment, but is also seen at Mars in measurements performed by the highly capable Radiation Assessment Detector (RAD) on NASA's Curiosity rover. We will discuss the increased radiation exposure at Mars and elsewhere, put into the larger heliospheric context and discuss implications for human exploration.

D1.3-0023-18 A STUDY OF THE COSMIC RAY PROTON FLUX LEVELS FOR A TRANSIT ORBIT TO MARS: A DATA-CONSTRAINED NUMERICAL APPROACH

National Space Science Center, Chinese Academy of Sciences, Beijing, China

Since the AMS02 cosmic ray detector began its operation in May, 2011, highly accurate proton fluxes have been observed at the Earth. These precise measurements provide an opportunity for a refinement of numerical models for the transport of cosmic rays in the heliosphere. In this study, we constructed a modulation model by numerically solving the relevant transport equation. The model contains all four major physical modulation processes: convection, diffusion, global particle drifts and adiabatic cooling. Current sheet drifts are incorporated by utilizing Parker's magnetic field model. Driven by a time-dependent current sheet tilt angle and interplanetary magnetic field magnitude, the measured monthly proton fluxes can be reproduced by adjusting the three main diffusion coefficients. After fine-tuning this numerical model, it has been applied to calculate the cosmic ray proton flux along the transit orbit to the planet Mars. Some initial results will be presented.

D1.3-0024-18 NEAR-EARTH COSMIC RAY DECREASES ASSOCIATED WITH REMOTE CORONAL MASS EJECTIONS

Simon Thomas, sthomas17@uclan.ac.uk

University of Central Lancashire, Preston, United Kingdom Mathew Owens, m.j.owens@reading.ac.uk

University of Reading, Reading, United Kingdom Mike Lockwood, m.lockwood@reading.ac.uk University of Reading, Reading, United Kingdom

Neutron monitor (NM) count rates are modulated by both particle drifts and diffusion associated with solar wind structures. Over time-scales of hours, drops of a few percent in NM count rates (Forbush decreases, FDs) are well known to be associated with the near-Earth passage of solar wind structures, such as corotating interaction regions or transient coronal mass ejections. We present observations of FDs seen at ground-based NMs which cannot be attributed to significant structures in the near-Earth solar wind. Three examples of such FDs are presented. The timing of these is such that STEREO in-situ and remote observations are available to examine the solar wind from three well-separated heliospheric locations. For each example, large CMEs passed the STEREOA spacecraft, which was behind the west limb of the Sun, approximately 2-3 days before the near-Earth FD was observed. Simulations from the solar wind model, ENLIL, suggest that the CMEs combined with pre-existing CIRs, enhancing the pre-existing barriers to GCR propagation. Our observations provide strong evidence for the modulation of GCR flux by remote solar wind structures.

D1.3-0025-18 ENERGY SPECTRA OF CARBON AND OXYGEN WITH HELIOS E6 - RADIAL GRADIENTS OF ANOMALOUS COSMIC RAY OXYGEN WITHIN 1 AU

Bernd Heber, heber@physik.uni-kiel.de

Christian-Albrechts-Universität zu Kiel, Kiel, Germany

HELIOS A and HELIOS B were launched on December 10, 1974 and January 15, 1976, respectively. The two almost identical space probes were sent into ecliptic orbits around the Sun. The Kiel experiment, E6 is one of three particle detectors aboard HELIOS that allows to study the flux of energetic particles in the energy range from 1.3 MeV/nucleon to above 1000 MeV/nucleon for ions and from 0.3 to 8 MeV for electrons. We present here the energy spectra of galactic cosmic ray (GCR) carbon and oxygen, as well as of ACR oxygen during solar quiet time periods between 1975 to 1977, utilizing both HELIOS spacecraft at distances between 0.3 and 1 AU. The radial gradient (Gr 50%/AU of 9-28.5 MeV ACR oxygen in the inner heliosphere is about three times larger than the one determined between 1 and 10 AU by utilizing the Pioneer 10 measurements.

D1.3-0026-18 DIFFERENCES IN THE SOLAR MODULATION OF PROTONS AND ANTIPROTONS

A comprehensive, three-dimensional drift model is used to study the solar modulation of cosmic ray protons and particularly for anti-protons. Spectra for protons and anti-protons from 1 MeV to 50 GeV are computed based on revisited local interstellar spectra for these cosmic ray particles. This is done for the prolonged period of minimum solar activity from 2006 to 2009, followed by the period afterwards until the recent period of maximum activity. Differences will be highlighted and comparison with observations will be made.

D1.3-0027-18 ISSUES PERTAINING TO THE POSITRON LOCAL INTERSTELLAR SPECTRUM AND ITS SOLAR MODULATION

Driaan Bisschoff, 20056950@nwu.ac.za

North-West University, Potchefstroom, South Africa Marius Potgieter, marius.potgieter@nwu.ac.za North-West University, Potchefstroom, South Africa

The uncertainty in the local interstellar spectra for protons and electrons has largely been solved by the addition of observations made below 100 MeV by the Voyager 1 spacecraft beyond the heliopause. For positrons such observations do not exist and the cosmic ray positron LIS has to be inferred by use of galactic propagation models, solar modulation models and observations at the Earth. By computing spectra simultaneously for galactic electrons, protons, Helium and Carbon, in order to reproduce the Voyager 1 spectra, the corresponding positron LIS is also calculated. This process has shown that while such a LIS can be produced with the GALPROP code, it differs from a positron LIS inferred from modulation studies and might not yet be conclusive. These LIS's and their modulated spectra, computed with a comprehensive three-dimensional solar modulation model, are shown and discussed.

D1.3-0028-18 COMPARISON BETWEEN STATISTICAL PROPERTIES OF FORBUSH DECREASES FROM TWO DIFFERENT TYPES OF SOLAR SOURCES

Anaid Melkumyan, amelkumyan6@gmail.com

Modulations of galactic cosmic rays (GCRs)intensity known as Forbush decrease (FD) have been recorded by network of neutron monitors (NMs)at Earth during the last six solar cycles. In this work, we perform a comparison between properties of FDs connected with two types of solar sources: coronal holes (CHs) and coronal mass ejections (CMEs). We investigate the relationship of FDs parameters (magnitude, decrease rate, anisotropy)with geomagnetic Ap index, solar wind (SW) velocity and interplanetary magnetic field intensity for each source group. The data from created in the Pushkov Institute of Terrestrial Magnetism, Ionosphere and Radio Wave Propagation (IZMIRAN) database of FDs and interplanetary disturbances (FEID)has been used. FEID database contains FDs parameters obtained by global survey method using the data from the worldwide network of NMs throughout the period from 1957 up to present as well as geomagnetic indices, the OMNI database and solar geophysical data. For each considered in this work FD (from 1997 to 2014) we identified its corresponding interplanetary mass ejection and the related causative CME (207 events, CME group) or corresponding corotating interaction region with the related CH (350 events, CH group). Statistical processing included a distribution analysis and a visual analysis of histograms, box plots and scatter plots as well as computing of descriptive statistics, correlations and multiple linear regression models. Regression analysis of events with similar SW disturbance' power reveals that: a) the CH group is significantly less effective in FDs creating; b) the geomagnetic activity and GCRs variations are statistically independent and their interrelation is determined only by a common source (the same SW disturbance). The CH group is characterized by increased geomagnetic activity, moderately powerful SW disturbances, relatively small FDs and significantly smaller equatorial component of anisotropy. The CME group is characterized by highly skewed FDs magnitude' distribution with the long tail of large values and generally corresponds to events with larger GCRs modulation at the same SW disturbance power.

D1.3-0029-18 NUMERICAL MODELING OF COSMIC RAY PROTON AND HELIUM OBSERVED BY AMS-02 DURING THE SOLAR MAXIMUM OF SOLAR CYCLE 24

Galactic cosmic rays (GCRs) are affected by solar modulation while they propagate throughout the heliosphere. The study of the time variation of the GCR spectrum observed at Earth can shed light on the underlying physical processes, specifically diffusion and particle drifts. The AMS-02 experiment on board the International Space Station measured with very high accuracy the time variation of the cosmic ray proton and helium flux between May 2011 and May 2017 in the rigidity range from 1 to 60 GV. In this work, a comprehensive 3D steady-state numerical model is used to solve the Parker's transport equation and to reproduce the monthly fluxes observed by AMS-02. Preliminary results on the time dependence of the diffusion coefficient for proton and helium will be presented.

D1.3-0030-18 A MODIFIED FORCE-FIELD SOLUTION TO DESCRIBE COSMIC RAY PROTON AND HELIUM FLUXES OBSERVED BY AMS-02 DURING THE SOLAR MAXIMUM OF SOLAR CYCLE 24

University of Hawaii at Manoa, Honolulu, Hawaii, United States Siqi Wang, siqiwang@hawaii.edu

University of Hawaii at Manoa, Honolulu, Hawaii, United States

Galactic Cosmic Rays (GCRs) entering the heliosphere are disturbed by the magnetic field of the Sun, which varies the shape and intensity of their local interstellar spectrum. The AMS-02 experiment on board the International Space Station measured with very high accuracy the time variation of the cosmic ray proton and helium flux between May 2011 and May 2017 in the rigidity range from 1 to 60 GV. The force-field approximation is a popular way of dealing with solar modulation, expecially for studies focused on galactic transport of cosmic rays. The validity of this approach to reproduce modulated GCR fluxes at Earth is tested, showing that the precision of the new AMS-02 data requires a rigidity-dependent modification of the forcefield approximation. A modified force-field solution is presented, based on a more realistic expression of the diffusion coefficient.

D1.3-0031-18 RECOVERY PHASE OF THE GALACTIC COSMIC RAY 11-YEAR MODULATION AT 1 AU FOR THE SOLAR CYCLE 24

H.S. Ahluwalia, hsa@unm.edu

University of New Mexico, Albuquerque, New Mexico, United States

Galactic cosmic-ray (GCR) modulation at 1 au for the recovery phase of the sunspot number (SSN) cycle 24 is studied using data from a global network of surface and underground detectors as well as the balloon measurements of low-energy ions at high latitudes in Russia, covering a wide range of median rigidity of response (Rm) for the detectors. The observed modulation is modest compared to previous cycles, peak of the interplanetary magnetic-field intensity at 1 au reached a much lower value (about 5 nT). The solar polar field in the northern hemisphere reversed in June 2012 and again in March 2014 while that in the southern hemisphere reversed in July 2013. The double field reversal in northern hemisphere after SSN maximum is not expected from the dynamo theory. The rigidity dependence of the cycle 24 modulation is computed. It is a power law, similar to previous solar cycles; the nearly linear dependence of GCR modulation on Rm over a wide range poses a challenge to the quasi-linear theory of GCR modulation.

Precise measurements of proton spectra between 80 MeV and 50 GeV from 2006 to 2014 by the PAMELA space mission have been a major incentive to test and improve numerical models which describe their transport inside the heliosphere. Starting with a new local interstellar spectrum for protons, placed at 122 AU from the Sun, the solar modulation of these particles is studied and compared to observations at the Earth. This is done from the prolonged solar minimum period up to solar maximum activity in 2014, including the period of the reversal of the polarity of the solar magnetic field during 2013. The insight gained from this comprehensive modelling with a three-dimensional drift model about the relative roles of the four main modulation processes over the mentioned period will be shown and discussed.

The solutions of a comprehensive three-dimensional drift model are compared to PAMELA spectra of electrons and positrons in order to describe and understand their different modulation down to 1 MeV. This is based on newly constructed very local interstellar spectra. The focus of the study is on the period of the prolonged solar minimum from 2006 and 2009. The comparison of observations and modelling provides insight into how the three major diffusion coefficients change during such quiet modulation conditions, and to what extent drift effects occur. The electron to positron ratio is computed from 10 MeV to 50 GeV for this period and a prediction is made for what may be observed in terms of spectra during the next solar minimum.

D1.3-0034-18 EFFECT OF SOLAR ACTIVITY ON COSMIC RAY MODULATION DURING SAME PHASES OF 22, 23, AND 24 SOLAR CYCLES

Ajoy Ghosh, jojobgho2013@gmail.com AISECT University, RAISEN, India Suryanshu Choudhary, csuryansh@gmail.com AISECT University, Bhopal, India

Ashok Kumar Gwal, ashok.gwal@gmail.com Rabindranath Tagore University, Raisen, India

Abstract During the same decreasing or minimum phases of solar cycles, occurs variability in the nature and magnitude of different parameters of Sun. In a time series analysis of three solar cycles at various conditions, variation has been observed in galactic cosmic-ray radiation. Present study is useful to understand the physics of interaction between the charged particles and space plasma. The dynamics of heliospheric structures are mainly responsible for observed variations and to know about a physical mechanism of modulation of cosmic rays. In this study correlation of galactic cosmic ray intensity with parameters shown abnormality and additional solar wind convection effect has been recorded during the period of minimum solar cycle.

D1.3-0035-18 MEASURING THE LOW-ENERGY ELECTRON AND POSITRON SPECTRUM (20-300 MEV) WITH THE AESOP-LITE BALLOON MISSION

AESOP-Lite (Anti-Electron Sub-Orbital Payload) is a high-altitude balloon mission poised to launch from Esrange, Sweden in May 2018. It will measure the cosmic rays electron and positron fractions in the energy range of 20-300 MeV. The data will provide a calibrated reference at 1 AU to be compared with Voyager interstellar electron observations and extending the range of measurements made by PAMELA and AMS on the lower end of the spectrum. This novel measurement will be crucial in order to understand the origin and propagation of low-energy electrons in the heliosphere. I will present on the AESOP-Lite science goals, instrument design, and the status of its very first flight.

D1.3-0036-18 GEOEFFECTIVENESS OF SOLAR ACTIVITIES ORIGINATED FROM AR12673 IN SEPTEMBER 2017

Xiao Xia Yu, xxyu@ihep.ac.cn

Institue of High Energy Physics, Chinese Academy of Sciences, BeiJing, China Xing Hua Dai, xhdai@nao.cas.cn

National Astronomical Observatories, Chinese Academy of Sciences, BeiJing, China

Solar active region (AR) 12673 erupted with a series of flares accompanied by 3 halo CMEs from Sep.4 to Sep.10, 2017. The solar activities cause Forbush Decreases (Fds) on Sep.8 and Ground Level Enhancement (GLE) events on Sep.10, respectively. Based on WIND and DSCOVR observation, we analyze the physical parameters of interplanetary magnetic field and solar wind plasma. The onset time of 8 ground-based NM (Neutron Monitors) counts increasement coincides with the protons flux >100 MeV from GOES 15. Furthermore, we reconstruct the three dimensional plasmas density of the CMEs using genetic algorithm based on the coronagraph observation from STEREO-A and SOHO. Then the reconstruction are put into the Space Weather Modeling Framework (SWMF) to simulate the evolution of interplanetary CMEs. Comparisons of the simulations and in situ measurements from space observation are presented, and we attempt to find the origin of the Fds and GLE. Key words: Coronal Mass Ejections (CMEs), Flare, Ground Level Enhancement (GLE)

Reinhold Mueller-Mellin, mueller-mellin@physik.uni-kiel.de University of Kiel, Kiel, Germany

Among others, shocks are known to be accelerators of energetic charged particles. However, many questions regarding the acceleration efficiency and the required conditions are not fully understood. In particular, the acceleration of electrons by shocks is often questioned. Recurrent energetic particle events are caused by the passage of Corotating Interaction Regions (CIRs) that have been extensively analysed by different instrumentation close to Earth. Measurements of the Solar Electron and Proton Telescope aboard the Solar TErrestrial RElations Observatory are utilized in the solar heliospheric community to investigate electron events. Due to its measurement principle, the magnet foil technique, ions can contribute to the electron channel. This effect is well known. During recurrent energetic particle events the averaged helium to proton ration is enhanced to more than 10%. The energy per nucleon spectra are nearly the same for protons and helium. Although the electron intensity profile is influenced by an ion contamination during the shock crossings it is not obvious that electrons are not enhanced during such periods. Computation using a GEANT4 simulation of the SEPT instrument resulted in response function for ions and electrons. These response functions have been utlzed to analyze the recurrent energetic particle event that was was measured by STEREO B on August 9, 2011. Assuming a constant helium to proton ratio and energy spectra described by a Band function we found that electron and ion measurement

can be explained by the contribution of helium and protons with an helium to proton ratio of about 16%. Thus no electron enhancements are needed to explain the SEPT measurements.

D1.3-0040-18 A STUDY OF GALACTIC COSMIC RAY MODULATION IN THE NEGATIVE SOLAR MAGNETIC CYCLES: SOLAR CYCLES 21/22 AND 23/24

Thana Yeeram, thana.y@msu.ac.th

Mahasarakham university, Maha Sarakham, Thailand

This study focuses on variations in the Galactic cosmic ray (GCR) intensity at two different magnetic cutoff rigidities during the declining to rising phases of the solar cycles 21/22 and 23/24 that are negative solar magnetic cycles. Results reveal that the variations exhibit different features in both cycles and amplitudes of the variations decrease when the magnetic rigidities increase as a power law. In both solar cycles, variation of GCRs exhibit harmonics of 27 days in which the Cycle 23 is more clearly observed. The 27 day variations in the GCR intensity are dominant during the declining and rising phases of the solar activity. In this timescale the variations of GCRs are inversely proportional to the solar wind speed, especially in the Cycle 23 when high speed solar winds are recurrently observed at the Earth. The interplanetary magnetic fields are equally effective for the GCR modulation in both cycles, while the effects are reduced for the high rigidity in the Cycle 23. The tilt angle of the HCS shows a high anti-correlation with the GCR intensity in the Cycle 21, whereas in the Cycle 23, particularly at high cutoff rigidity, the modulation effects by the HCS drift are obscured by the prominent diffusion of GCRs.

D1.3-0041-18 HOW SUN PRODUCES QUASI-BIENNIAL OSCILLATIONS OF COSMIC RAYS?

Agnieszka Gil, gila@uph.edu.pl Siedlce University, Siedlce, Poland
Michael Alania, alania@uph.edu.pl Siedlce University, Siedlce, Poland

Quasi-biennial oscillations (QBO) are the most pronounced midterm periodicity lower than Schwabe cycle and greater than the solar rotation rate. It has been noticed in sunspot number and area, the number of Hα flares, solar radio flux, coronal green line intensity, photospheric magnetic field, solar wind speed, heliospheric magnetic field, solar energetic particle events, cosmic rays, as well as in geomagnetic activity parameters. Although it was intensively studied in the last years the source of the QBO is still unidentified. One of the concepts relates QBO to a high-frequency component of the dynamo operating within the solar interior.

Here we propose that the QBO originates from solar differential rotation. As countless intermediate heliolatitudes rotate with different tempo from 25-27 at the equator to 35-37 days at pools, the effects created on the Sun, being carried by various field lines, might interfere with each other producing oscillations varying from 0.30 to 3.65 years (and their multiples).

D1.3-0042-18 THE STOCHASTIC SOLUTION OF THE PARKER TRANSPORT EQUATION. COMPARISON OF THE BACKWARD-IN-TIME VS. FORWARD-IN-TIME APPROACH IN THE 1D, 2D, AND 3D HELIOSPHERE.

Anna Wawrzynczak-Szaban, awawrzynczak@uph.edu.pl Siedlce University, Siedlce, Poland

Renata Modzelewska, renatam@uph.edu.pl Siedlce University, Siedlce, Poland Agnieszka Gil, gila@uph.edu.pl

Siedlce University, Siedlce, Poland

We present the stochastic simulation of the galactic cosmic ray (GCR) particles transport in the heliosphere based on the solution of the Parker transport equation. The model is grounded on the numerical solution of the set of the stochastic differential equations (SDEs) corresponding to the non-stationary Parker transport equation (PTE). We solve the transport equation applying the forward-in-time and backward-in-time approach. These approaches were applied in the literature by few authors. However, its full comparison in various dimensions was not explicitly discussed up to now. We present the rigidity spectrum, spatial and time profiles of the GCR intensity in one, two and three-dimensional space considering the full 3-D anisotropic diffusion tensor. We compare outputs of the forward and backward approaches and discuss when the outputs of these models coincide with each other.

D1.3-0043-18 GEANT 4 SIMULATION OF THE KIEL ELECTRON TELESCOPE ON BOARD ULYSSES

Bernd Heber, heber@physik.uni-kiel.de

Christian-Albrechts-Universität zu Kiel, Kiel, Germany Patrick Kuehl, kuehl@physik.uni-kiel.de

Christian-Albrechts-Universität zu Kiel, Kiel, Germany Marlon Köberle, koeberle@physik.uni-kiel.de

Christian-Albrechts-Universität zu Kiel, Kiel, Germany Johannes Marquardt, marquardt@physik.uni-kiel.de Germany

Ulysses was the first mission to explore the space environment above the poles of the sun. The mission launched in 1990, made three "fast latitude scans" of the Sun in 1994/1995, 2000/2001, and 2007/2008 providing a wealth of data. The COsmic and Solar Particle INvestigation Kiel Electron Telescope (COSPIN/KET) measures protons and a-particles in the energy range from about 4 to above 2000 MeV/n and electrons in the range from 2 to >300 MeV in dierent energy channels. The telescope consists of two parts: an entrance telescope and the calorimeter, a lead uoride Cherenkov detector and a scintillation detector. The entrance telescope comprises a silica-aerogel Cherenkov detector with an index of refraction of 1.066 inserted between semiconductor detectors. It denes the geometry, selects particles with speeds v/c = b > 0.938 and determines the magnitude of the particle charge. In order to describe the instrument response function we setup a GEANT 4 model and validated it against calibration measurements performed before the launch of the spacecraft. Here we present the model and the corresponding calculations that are in excellent agreement with measurements obtained at different accelerator.

The LAGO (Latin American Giant Observatory) project is a collaborative network formed by eleven countries (Argentina, Bolivia, Brazil, Chile, Colombia, Ecuador, Guatemala, Mexico, Peru, Spain, and Venezuela), forming a network of Water Cherenkov detectors (WCDs) with nodes at sites with different rigidity cut-offs and different altitudes. One of the aims of LAGO is to study the flux of secondary particles at ground level, and to link them with the associated primary fluxes to better understand the modulation of galactic CRs in the heliosphere and the properties of solar particles of high energy, the so-called Ground Level Enhancements, GLEs. Another main purpose is to monitor this flux to provide operative Space Weather information. WCDs have shown to be able to reproduce time structures compatible with those observed with neutron monitors (NMs) and its major advantage compared with NMs is that the former ones can discriminate energy channels for the observed secondary charged particles. From numerical simulations, this energy discrimination can be used for a better understanding of the flux of primary CRs arriving to the terrestrial environment. We present here an update of the state of the art of the LAGO Antarctic node, in the Argentine Marambio base, located at the Antarctic peninsula. This node has the minimum rigidity cut-off (Rc 2 GV for quiet geomagnetic conditions) of the Observatory, and it is the only LAGO node able to observe GLEs. We present the LAGO Antarctic campaign of 2017 in Marambio, where a meteorological station, a thermal control system, a magnetometer, and the telemetry system, were installed.

D1.3-0045-18 SOLAR MODULATION OF DEUTERON

Università di Tor Vergata, Rome, Italy

A comprehensive three-dimensional drift model is used to study the solar modulation of cosmic ray deuteron for the prolonged period of minimum solar activity from 2006 to 2009. Spectra for deuteron from 1 MeV to 50 GeV are computed and compared to the proton spectra for the mentioned period. Differences will be highlighted and comparison with PAMELA observations will be made.

SPACE PLASMAS IN THE SOLAR SYSTEM, INCLUDING PLANETARY MAGNETOSPHERES (D)

COORDINATED OBSERVATIONS AND MODELING OF ACCELERATED PARTICLES AT THE SUN AND IN THE INNER HELIOSPHERE (D2.1)

D2.1-0001-18 PARTICLE ACCELERATION AND TRANSPORT IN THE SOLAR ATMOSPHERE

Eduard Kontar, eduard@astro.gla.ac.uk University of Glasgow, Glasgow, United Kingdom

During periods of sporadic are activity, the Sun releases energy stored in the magnetic field into the plasma of the solar atmosphere. This is an extremely efficient process, with a large fraction of the magnetic energy going into plasma particles. The solar ares are accompanied by prompt electromagnetic emission virtually over the entire electromagnetic spectrum from gamma-rays down to radio frequencies. The Sun, through its activity, also plays a driving role in the SunEarth system that substantially influences geophysical space. Solar are energetic particles from the Sun are detected in interplanetary space by in-situ measurements making them a vital component of the single Sun-Earth system. Although a qualitative picture is generally agreed upon, many processes solar are processes are poorly understood. Specifically, the processes of acceleration and propagation of energetic particles interacting on various physical scales remain major challenges in solar physics and basic plasma physics. In the talk, I will review the current understanding of solar flare energetic particles focusing on recent observational progress in the view of Solar Orbiter and Praker Solar Probe.

D2.1-0002-18 HXI ONBOARD ASO-S: MAPPING SOLAR FLARES IN HARD X-RAY BAND

Zhe Zhang, zhangzhe@pmo.ac.cn

Purple Mountain Observatory, Chinese Academy of Sciences, Nanjing, China Jian Wu, wujian@pmo.ac.cn

Purple Mountain Observatory, Chinese Academy of Sciences, Nanjing, China

The Hard X-ray Imager (HXI) will be mounted in the Advanced Spaced-based Solar Observatory (ASO-S), which is one of Chinese scientific space missions funded by Strategic Pilot Project in Space Science of CAS and to be launched in 2022, with the aim of providing images of solar flaring regions in the energy range from 30 keV to 200 keV. The imaging principle of HXI is based on spatial modulated Fourier synthesis and utilizes about 92 sets of bi-grids sub-collimators and corresponding LaBr3 detectors to obtain Fourier components with an ultimate spatial resolution better than 6 arc sec. HXI is developed to study the mechanism of particle acceleration and energy release of solar flares, thereby understanding the relationships among solar flares, CME and solar magnetic field with help of other two payloads onboard ASO-S, Lyman-alpha Solar Telescope(LST) and Full-Disc Vector Magnetograph (FMG). We will present background, instrument design and a brief status update of HXI.

D2.1-0003-18 AN NEW MHD/KINETIC MODEL FOR EXPLORING PARTICLE ACCELERATION IN SOLAR FLARES

James Drake, drake@umd.edu

University of Maryland, College Park, College Park, Maryland, United States Marc Swisdak, swisdak@umd.edu

University of Maryland, College Park, College Park, Maryland, United States Joel Dahlin, joeltdahlin@gmail.com

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States

A novel MHD/kinetic model is being developed to explore magnetic reconnection and particle energization in macro-scale systems such as the solar corona. The model blends the MHD description with a macro-particle description. The rationale for this model is based on the recent discovery that energetic particle production during magnetic reconnection is controlled by Fermi reflection and Betatron acceleration and not parallel electric fields. Since the former mechanisms are not dependent on kinetic scales such as the Debye length and the electron and ion inertial scales, a model that sheds these scales is sufficient for describing particle acceleration in macro-systems. Our MHD/kinetic model includes macroparticles laid out on an MHD grid that are evolved with the MHD fields. Crucially, the feedback of the energetic component on the MHD fluid is included in the dynamics. Thus, energy of the total system, the MHD fluid plus the energetic component, is conserved. The system has no kinetic scales and therefore can be implemented to model energetic particle production in macro-systems with none of the constraints associated with a PIC model. Tests of the new model in simple geometries will be presented and implications for exploring particle acceleration in impulsive flares will be discussed.

D2.1-0004-18 EVIDENCE OF ACCELERATED PARTICLES IN THE RECONNECTION OUTFLOWS ABOVE TWO FLARE CUSPS

Energetic particles carry a large fraction of released energy in solar flares. Some of them travel downward to the lower atmosphere and heat the local plasma. Others could escape from the corona into interplanetary space and become a component of SEP (Solar Energetic Particles) event. Although particle acceleration have been extensively studied in theory and simulations, observational details of the process in flares are far from complete. The discovery and studies of the above-loop-top source (Masuda et al. 1994, Krucker, Säm Battaglia 2014, Chen et al. 2015) have revealed the acceleration process around the termination shock. Here we report the discovery of above-cusp sources and evidence of accelerated particles therein. The analysis of imaging spectroscopy with RHESSI data and the DEM (Differential Emission Measure) diagnostic with our improved Sparse method (Cheung et al. 2015, Su et al. 2018, submitted) for two flares revealed that the acceleration starts in the current sheet and outflows, at places even higher than the Masuda source. This finding provides important clues for future observations and simulations of magnetic reconnection.

D2.1-0005-18 RADIO OBSERVATIONS OF ENERGETIC ELECTRONS IN ASSOCIATION WITH CORONAL MASS EJECTIONS IN THE SOLAR CORONA

Eoin Carley, eoincarley@gmail.com Trinty College Dublin, Dublin, Ireland Nicole Vilmer, nicole.vilmer@obspm.fr

Observatoire de Paris, LESIA, Meudon, France Peter Gallagher, peter.gallagher@tcd.ie

Trinity College Dublin, Dublin, Ireland

Coronal mass ejections are large eruptions of plasma and magnetic field from the low solar corona into the heliosphere. These eruptions are often associated with energetic electrons that produce various kinds of radio emission. However, there is ongoing investigation into exactly where, when and how the electron acceleration occurs during flaring and eruption, and how the radio emission can be exploited as a diagnostic of the particle acceleration and CME plasma properties. In this talk I will firstly present recent observations from the Nançay Radioheliograph (NRH) that show the sites and kinds of electron acceleration that take place during flaring and eruption, from the destabilisation of a flux rope to development of a CME. This shows evidence for the tether-cutting model and numerous sites of electron acceleration both external and internal to the CME during its development. Secondly, using an analysis of gyrosynchrotron radiation from NRH and a non-thermal electron diagnostic using X-ray observations, I show that radio emission can be produced internal to the CME from nonthermal electrons of energies >1MeV in a CME core magnetic field strength of 4.4G. Overall, this reveals how different types of radio observations can be used as a diagnostic of the locations and kinds of electron acceleration during an eruptive event, and also how radio may be used to both image CMEs and give new insight into their dynamics and internal plasma properties.

D2.1-0006-18 RAYS AND RADIO COUNTERPARTS OF FERMI LONG-DURATION GAMMARAY EVENTS

Karl-Ludwig Klein, ludwig.klein@obspm.fr Observatoire de Paris, Meudon, France Pietro Zucca, zucca@astron.nl

ASTRON, Dwingeloo, Netherlands

The Fermi spacecraft showed a rather frequent occurrence, and sometimes long duration, of γ-ray bursts at photon energies above 100 MeV. They are ascribed to pion-decay photons, which in turn requires protons to be accelerated to energies above 300 MeV. This raises the question why the Sun, which is thought to be a modestly skilled particle accelerator, accelerates protons to energies above 300 MeV rather frequently, and where this can happen on occasion during several, up to ten, hours. The HESPERIA project, funded between 2015 and 2017 by the European Union (H 2020 programme), endeavoured to shed light on these questions by a systematic investigation of X-ray and radio emission during the gamma-ray events. We found that the Fermi γ-ray events are accompanied by signatures of energetic electron acceleration in the corona during the impulsive phase and the early post-impulsive phase. This points to a common acceleration of the relativistic protons with energetic electrons during about an hour, and is in line with earlier findings. γ-ray emission lasting several hours was found to accompany the decay phase of long-lasting soft X-ray bursts, post-flare loop formation and decametric-tokilometric type II bursts, revealing shock waves in the high corona. The presence of a type II burst may suggest shock acceleration of the relativistic protons. But the acceleration far from the Sun poses the problem of how to transport the protons back to the chromosphere against magnetic mirroring. An alternative is prolonged trapping of protons accelerated during the first hours of the solar event. This has then to be reconciled with the absence of simultaneous X-ray and radio emission.

D2.1-0007-18 HARD X-RAYS OBSERVED ASSOCIATED WITH INSTABILITY OF A COLLISIONAL MHD-DRIVEN COLLIMATED PLASMA JET

Paul Bellan, pbellan@caltech.edu

California Institute of Technology, Pasadena, California, United States Ryan Marshall, rmarshal@caltech.edu

California Institute of Technology, Pasadena, California, United States

A mechanism for direct acceleration of electrons to extremely high energy in a cold, collisional plasma has been observed. Detailed timeand space-resolved measurements (including highspeed movies) on an experiment at Caltech reveal the following sequence:

A coaxial magnetized plasma gun forms a dense, cold MHD-driven collimated plasma jet (length 10's of cm, duration 20-40 μs, 100 kiloamp current, T = 2 eV).

The jet becomes kink unstable when it attains a critical length (this happens at about 20 – 30 μs and the kink e-folding time is about 4 μs).

The kink lateral acceleration provides a large effective gravity (~ 1010 m s–2) that instigates a secondary Rayleigh-Taylor (RT) instability (the RT e-folding time is ~ 1 μs).

The RT instability instigates a magnetic reconnection manifested by a breaking of the jet at the location of the RT instability and interruption of the electric current

Associated with the reconnection are wave emission, particle heating, EUV emission, and a hard X-ray pulse measured by a plastic scintillator.

The X-ray pulse lasts a fraction of a microsecond, has about 6 keV energy, and coincides with the RT instability. Because the ~1 micron electron collision mean free path is much shorter than the 10 cm long RT region, electron acceleration to high energy was not expected. It is proposed that despite the short collision mean free path, a sub-Dreicer inductive electric field ˜LdI/dt caused by the current disruption accelerates a small electron subgroup to 6 keV energy without these electrons undergoing collisions and that after being accelerated to high energy, these fast electrons suddenly decelerate via collisions and radiate X-rays. Although this subgroup constitutes only a small fraction of all the electrons, because of the high energy per electron, the subgroup contains substantial kinetic energy. This process could be important in solar corona situations where kinks provide sufficient lateral acceleration to drive secondary Rayleigh-Taylor instabilities.

D2.1-0008-18 THE SOLAR RADIO BURST EVENT WITH MUSER IMAGING-SPECTROSCOPY OBSERVATIONS

Yihua Yan, yyh@nao.cas.cn NAOC, Beijing, China

Linjie Chen, ljchen@nao.cas.cn

National Astronomical Observatories, CAS, Beijing, China Susanta Kumar Bisoi, susantanbisoi@yahoo.co.in

National Astronomical Observatories, Chinese Academy of Sciences, Beijing, India

The radio bursts at decimetric wavelength may reveal important information on primary energy release sites where particle acceleration process can be studied. However, up to now, the detailed sites of impulsive-phase particle acceleration and radio fine structures are still remains uncertain. Mingantu Spectral Radioheliograph (MUSER) is a solar-dedicated interferrometric array with a frequency range from 400MHz to 15 GHz. There are two arrays of 40 4.5m antennas covering 400MHz -2 GHz, and 60 2m antennas covering 2 - 15 GHz which have been established in Mingantu Town, Inner Mongolia of China. The burst event with some fine structures on June 21, 2015 for a C-class flare was observed by MUSER-I in 400MHz-2GHz. The multi-frequency images in decimeter wave ranges of the burst process and fine structures by MUSER-I are obtained and analyzed.

D2.1-0009-18 SOLAR NEUTRON TELESCOPES AND EARTH ORBITING SPACECRAFT OBSERVATIONS OF THE MARCH 7TH AND SEPTEMBER 25TH OF 2011 EVENTS: SOLAR NEUTRON AND GAMMA-RAYS

Solar-Terrestrial Environment Laboratory, Nagoya University, Nagoya, Japan

Being associated with a high energy gamma-ray flux with statistical significance of 6.5 observed by the Large Area Telescope of the Fermi orbiting observatory (FERMI-LAT) on March 7, 2011, the Space Environment Data Acquisition Equipment (SEDA-FIB) onboard the International Space Station (ISS) registered solar neutrons with a statistical significance of 7.5. The Solar Neutron Telescope (SNT) in operation at Mt. Sierra Negra, Mexico (4,600 m) detected increases of the fluxes in a channel registering neutral particles, not necessarily neutrons, from 19:49 to 20:02 UT and from 20:50 to 21:01 UT. The significances were 9.7 and 8.5, respectively. On September 25th, 2011 the SNT located at Yangbajing in Tibet (4,300 m) observed signals very similar to those of the referred Sierra Negra event from 04:37 to 04:47 UT with a statistical significance of 8.0 (by the Li-Ma method).Details of both events are presented in this paper in an effort to produce a unified model that can explain these data. We think that these mountain detectors registered gamma-rays from the Sun anda plausible physical explanation of the results is provided.

D2.1-0010-18 SOLAR ORBITER MEASUREMENTS OF THE HIGHEST ENERGY SOLAR ENERGETIC PARTICLES–NEUTRON MONITORS AND SOLAR ORBITER

James M. Ryan, james.ryan@unh.edu

University of New Hampshire, Department of Physics, Durham, New Hampshire, United States

Neutron Monitors (NM) have been for over sixty years powerful instruments for measuring GeV-energy solar protons. In that time we have learned much about the nature of ground level enhancements (GLE), the signal on the ground from these high energy ions. However, the processes that govern the acceleration of these particles has their roots close to the Sun. Similarly, the transport of these particles to 1 AU is governed by the plasma conditions in the intervening space. As an example, the transition of a GLE from a highly anisotropic event to an isotropic one may be the result of either self generated turbulence or the delayed influence of the progenitor CME shock. In fact, the question still lingers whether there is a flare component to the GLE, as measured with NMs. Thus, particle and plasma measurements at small heliocentric distances will be critical in answering questions like these. In a related question, we know that CMEs are responsible for Forbush Decreases (FD) that are quantified in terms of the effect on NM rates. However, several critical CME measurements can now only be performed at 1 AU, while the oncoming CME still has effect on the galactic cosmic ray intensity and anisotropy at 1 AU. Performing the critical plasma measurements at the Solar Orbiter radius will certainly aid in interpreting the effects of the approaching CME and FD. In this talk I will review the discovery potential in our study of the highest energy cosmic rays and the synergistic and mutual benefits we expect to realize from correlated and coordinated Solar Orbiter measurements and those performed by NMs.

D2.1-0011-18 COMBINED TREATMENT OF PARTICLE ACCELERATION IN SOLAR FLARES AND ASSOCIATED CME SHOCKS

Vahe Petrosian, vahep@stanford.edu

Stanford University, Stanford, California, United States

Solar eruptive events produce flares in the corona and coronal mass ejections (CMEs). Particles are accelerated both in the coronal reconnection sites and in the CME driven shocks. Traditionally, investigations of these phenomena are carried out independently in two communities. The solar community's focus is on flares and radiation producing particles (RPPs), while the heliospheric community's focus is solar energetic particles (SEPs) and the acceleration in the CME-shocks. However, there is considerable observations, in particular in impulsive-prompt events, indicating a close connection between these two processes. This connection will be the focus of this talk. I will review some relevant observations and describe their modeling based on a hybrid stochastic acceleration at the flare site, and re-acceleration of flare particles injected into the CME environment. Such a model seem to be required to explain Fermi observations of up to several GeV gamma-rays from three behind the limb flares. I will emphasize an important aspect that plays a central role in this scenario, which is the processes of escape of accelerated particles up and down from flare site and from downstream and upstream of the CME.

D2.1-0012-18 GLE 72 ON 10 SEPTEMBER 2017 - AN ANALYSIS USING NEUTRON MONITOR AND SPACE-BORNE DATA

Alexander Mishev, alex_mishev@yahoo.com University of Oulu, Oulu, Finland

Ilya Usoskin, ilya.usoskin@oulu.fi University of Oulu, Oulu, Finland Leon Kocharov, leon.kocharov@oulu.fi University of Oulu, Oulu, Finland Eino Valtonen, eino.valtonen@utu.fi University of Turku, Turku, Finland Rami Vainio, rami.vainio@utu.fi University of Turku, Turku, Finland Osku Raukunen, oajrau@utu.fi University of Turku, Turku, Finland Miikka Paassilta, mimapa@utu.fi University of Turku, Turku, Finland

The first ten days of September 2017 were characterized by intense solar activity, producing several X-class flares and coronal mass ejections (CMEs). The second ground level enhancement (GLE) event of solar cycle 24, namely GLE 72 on 10 September 2017, was related to a X8.2 solar flare. The flare peaked at 16:06 UT, leading to a gradual solar energetic particle event measured by spacecraft up to proton energies exceeding 700 MeV and to a very fast CME erupting over the west limb. The GLE onset was observed by several neutron monitor (NM) stations at about 16:15 UT (FSMT and INVK). However, a clearly distinguishable signal, which allows one to derive the spectral and angular characteristics of SEPs with sufficient precision, was observed at 16:30 UT. The strongest increases were observed at the DOMC/DOMB 10-15 %, SOPO/SOPB 5-8 % and FSMT 6%, above the pre-increase levels. The event was characterized by a typical gradual increase.

Here we perform a precise analysis of spectral and angular features of solar energetic particles (SEPs) on the basis of NM data. The method includes several consequitive steps: detailed computation of assymptotic cones and cut-off rigidity of each NM station used in the analysis, an initial guess of the inverse problem by assuming the apparent source position in a convenient way, application of the NM yield function for detector response modelling and optimization procedure in order to derive spectral and angular characteristics of SEPs. In this study we use the Planetocosmics code and realistic magnetospheric models for computations of assymptotic directions and rigidity cut-offs. Here we present results from analysis of GLE 72, namely SEP spectra and pitch angle distributions, which are obtained in their dynamical development throughout the event. An interpretation of the derived findings is performed.

D2.1-0013-18 SOLAR ENERGETIC PARTICLE EVENTS WITH PROTONS ABOVE 500 MEV BETWEEN 1995 AND 2015 MEASURED WITH SOHO/EPHIN

Patrick Kühl, kuehl@physik.uni-kiel.de

Christian-Albrechts-Universität zu Kiel, Kiel, Germany Nina Dresing, dresing@physik.uni-kiel.de

University of Kiel, Kiel, Germany Bernd Heber, heber@physik.uni-kiel.de

Christian-Albrechts-Universität zu Kiel, Kiel, Germany Andreas Klassen, klassen@physik.uni-kiel.de

University of Kiel, Kiel, Germany

The Sun is an effective particle accelerator producing solar energetic particle (SEP) events during which particles up to several GeVs can be observed. Those events observed at Earth with the neutron monitor network are called ground level enhancements (GLEs). In this work, SEP events with protons accelerated to above 500 MeV have been identified using data from the Electron Proton Helium Instrument (EPHIN) aboard the Solar and Heliospheric Observatory (SOHO) between 1995 and 2015. The compliled list of 42 SEP events is discussed based on the fitted spectral slopes and absolute intensities with special emphasis on whether or not an event has been observed as GLE. Furthermore, a correlation between the derived intensity at 500 MeV and the observed increase in neutron monitor count rate has been found for a subset of events.

D2.1-0014-18 THE ORIGIN OF ELECTRONS IN SOLAR ENERGETIC PARTICLE EVENTS AND THEIR RELATION TO PROTONS

Nariaki Nitta, nitta@lmsal.com

Lockheed Martin Solar and Astrophysics Laboratory, Palo Alto, California, United States Linghua Wang, wanglhwang@gmail.com

Peking University, Beijing, China

Raul Gomez-Herrero, raul.gomezh@uah.es SRG. Universidad de Alcala, Spain

One of the observables that is used to distinguish gradual and impulsive solar energetic particle (SEP) events is the electron to proton ratio. The ratio is higher in impulsive SEP events that are often enriched in 3He and/or heavy ions and are generally attributed to magnetic reconnection in solar flares or jets. But electrons are always present even in gradual SEP events that are due to acceleration at shock waves driven out by coronal mass ejections (CMEs). A question arises as to whether electrons in gradual SEP events have the same (CME-driven shock) origin and injection as protons or they are still produced in the flare site through magnetic reconnection. If CME-driven shocks are responsible for both protons and electrons in gradual SEP events, are they accelerated at the same or different portions of the shock? If not, what is the relation between magnetic reconnection in flares and shock waves driven by CMEs? We study electron events that have different levels of similarities/proportionalities to and differences from concurrent proton events in terms of the peak flux and onset and peak times, using L1 and STEREO observations. We note the comparisons depend on energy ranges both electrons and protons. The characteristics of the source regions and associated flares and CMEs are investigated for SEP events that have different relations between protons and electrons, with additional information such as metric and decametric radio bursts.

D2.1-0015-18 PARTICLE ACCELERATION STUDIES WITH ADITYA-L1 MISSION

Sankarasubramanian Kasiviswanathan, sankark@isac.gov.in Indian Space Research Organization, Bengaluru, India Aditya Particle Team

J. K. Abhishek, Anil Bhardwaj, Aveek Sarkar, Bhas Bapat, D. Chakrabarty, M. B. Dhanya, Govind G. Nampoothiri, P. Janardhan, Nandita Srivastava, Prashant Kumar, Santosh Vadawale,

R. Satheesh Thampi, Srikar Paavan Tadepalli, K. Subhalakshmi, K. P. Subramanian, and Vipin

K. Yadav

Aditya-L1 is a first dedicated and approved solar mission from India. The main scientific objective of this mission is to study the solar coronal dynamics. The satellite will be placed at the Sun-Earth Lagrangian – L1 in order to observe the Sun uninterruptly. This mission carries seven payloads with four remote sensing and three in-situ instruments. While the remote sensing payloads observe the chrmospheric and coronal dynamics, the in-situ payloads measures the particles and magnetic fields at L1 point which are modified by the activities originating from the Sun. There are two particle payloads and one set of three axis magnetometer for in-situ measurements. In this presentation, the details about the payloads on-board Aditya-L1 will be discussed specifically. The connection between the in-situ payloads along with the X-ray payloads on-board Aditya-L1 will also be brought out. It is also planned to use ground based radio observations of the Sun for the studies related to particle acceleration and propagation. The connection between the in-situ observations along with X-ray and Radio observations will be discussed for the study of heliospheric physics.

D2.1-0016-18 OBSERVATIONS OF THE 3D CME SHOCKS AND THE PRODUCTION OF SOLAR ENERGETIC PARTICLES

Chuan Li, lic@nju.edu.cn

Nanjing University, Nanjing, China Zigong Xu, xuzg@smail.nju.edu.cn Nanjing University, Nanjing, China Lulu Zhao, zhaolulumier@gmail.com

Florida Institute of Technology, Melbourne, Florida, United States

The acceleration source/mechanism of solar energetic particles (SEPs) is still a controversy during the onset of a large SEP event. Here, we present both a case study (Xu, Li Ding, 2017, ApJ, 840, 38) and a statistical investigation (Xu et al. in preparation) to clarify the release of SEPs, the multi-wavelength flare emission, and the 3D CME evolution. Our results show that:

(1) the CME shocks rather than the flares play the key role in particle acceleration during the onset of the large SEP events; (2) the in-situ onset times of electrons are systematically earlier than the protons with an averaged time difference of 15 minutes; (3) the time difference of the in-situ observed electrons and protons probably arises from their scattering propagation in interplanetary space.

D2.1-0017-18 INVERSION OF SOLAR ENERGETIC PARTICLE EVENTS IN THE PARKER SOLAR PROBE AND SOLAR ORBITER ERA

Neus Agueda, agueda@fqa.ub.edu Universitat de Barcelona, Barcelona, Spain

In past decades, measurements by space-borne instrumentation have been exploited to learn about the sources, the extent and the propagation conditions of solar energetic particles (SEPs). Inversion modeling has revealed to be a powerful tool to unravel the source release time profile of SEPs and characterize their transport in the interplanetary medium. I will review the pros and cons of this methodology, learned from the study of near-relativistic electron (>50 keV) events observed by the ACE, Wind, STEREO and Helios spacecraft assuming focused transport in the heliosphere.

The inversion problem is an optimization problem where the difference between the model and the data points is minimized. One of the powerful aspects of the methodology is that it allows us to infer the source release time profile of SEPs without making any a priori assumption about its onset or functionality. This is done by fitting the evolution of the measured angular distributions (i.e. sectored intensities), taking the angular response of the particle experiment into account. In many cases, the large amount of data makes it a well-constrained problem. However when the range of pitch angles observed by the particle experiment is poor, the results of the inversion are inconclusive. The pitch-angle coverage depends on the particle experiment (i.e. number of sectors or fields of view) and time (due to fluctuations of the interplanetary magnetic field). It can vary from event to event and even during the evolution of one. Thus a careful event selection is needed.

The main obstacle that the methodology has faced so far is the sparsity of the solution when data is noisy, as well as the lack of a quantitative description of the systematic errors. In the new Solar Orbiter and Parker Solar Probe era, denoising and regularization methods should be mandatory to avoid overfitting. In addition, the energy response should be taken into account, which would require the unprecedented public release of the particle detector responses along with the particle angular distributions measured in space.

D2.1-0018-18 ENERGETIC PARTICLE MEASUREMENTS WITH SOLAR ORBITER

George Ho, george.ho@jhuapl.edu

Johns Hopkins University Applied Physics Laboratory, Laurel, Maryland, United States Glenn M. Mason, glenn.mason@jhuapl.edu

Applied Physics Laboratory Johns Hopkins University, Laurel, Maryland, United States Robert Wimmer-Schweingruber, wimmer@physik.uni-kiel.de

Christian-Albrechts-Universität zu Kiel, Kiel, Germany Javier Rodriguez-Pacheco, javier.pacheco@uah.es

Universidad de Alcala de Henares, Madrid, Alcalá De Henares, Spain

Solar Orbiter, a joint ESA/NASA mission, is designed to study the Sun and inner heliosphere in greater detail than ever before. At the closest point on its heliocentric orbit, the Solar Orbiter spacecraft will be just closer than 0.3 AU from the Sun. In addition to providing high-resolution images of the solar surface, perihelion passes at these distances occur in near co-rotation with the Sun, allowing the instruments to track features on the surface for several days. The mission profile also includes a latitude cranking phase that will allow observations above the solar equator. The combination of near-Sun, quasi-heliosynchronous and out-of-ecliptic observations by remote-sensing and in-situ instruments makes Solar Orbiter a unique platform for the study of the links between the Sun and the inner heliosphere.

Understanding the physical processes operating in Solar Energetic Particle (SEP) events is a major goal of the Solar Orbiter mission because of the importance of acceleration processes in solar system and astrophysical sites, and because of the potential impact of these events on space hardware. The Energetic Particle Detector (EPD) investigation on Solar Orbiter is a suite of four different sensors plus the instrument control unit to measure the energetic particles from slightly above solar wind energies to hundreds of MeV/nucleon. The EPD addresses one of the key science objectives of ssolar Orbiter, namely “How do solar eruptions produce energetic particle radiation that fills the heliosphere?” In addition, EPD tackles three primary goals of Solar Orbiter:

How and where are energetic particles accelerated at the Sun? 2) How are energetic particles released from their sources and distributed in space and time? 3) What are the seed populations for energetic particles?

We describe progress possible with EPD on achieving the science goals of the mission.

D2.1-0019-18 ENERGETIC PARTICLE TRANSPORT AND ACCELERATION WITHIN THE INTERPLANETARY MEDIUM

Silvia Dalla, sdalla@uclan.ac.uk

University of Central Lancashire, Preston, United Kingdom

The propagation through space of energetic particles accelerated at the Sun and in the inner heliosphere is governed by the characteristics of the interplanetary magnetic field. At large scales, the average Parker spiral configuration, on which transient magnetic structures may be superimposed, dominates the transport, while at smaller scales turbulence scatters the particles and produces field line meandering. This talk will review the classical description of interplanetary transport, mainly applied to Solar Energetic Particles (SEPs), as well as more recent models which allow for effects such as transport perpendicular to the average magnetic field and field line meandering. The recently emphasized role of drifts in the propagation of SEPs will be discussed. The talk will also review processes by which particle acceleration takes place within the interplanetary medium and the overall way in which acceleration and transport shape in-situ observations of energetic particles.

D2.1-0020-18 WHAT THE HIGH-ENERGY FLARES AND CMES OF 2012 MARCH 7 CAN TELL US ABOUT LONG DURATION GAMMA-RAY FLARES

James M. Ryan, james.ryan@unh.edu

University of New Hampshire, Department of Physics, Durham, New Hampshire, United States Georgia De Nolfo, georgia.a.denolfo@nasa.gov

NASA Goddard Space Flight Center, Greenbelt, Maryland, United States

Two X-class flares occurred on 2012 March 7, an X5.3 and an X1.1. The earlier X5 flare gathered much attention, initiating a powerful and fast CME from the eastern hemisphere. The "forgotten" X1 flare exhibited much smaller CME from the same active region one hour later. However, extended high-energy gamma emission was present for almost the entire day of 2012 March 7. We have resolved the gamma emission into two separate, but overlapping extended occurrences, being from the two sequential X-class flares. Somewhat surprisingly, we find that the later X1 event was twice as prolific in gamma emission, mostly due to its duration, despite being much weaker in soft x rays. We attribute the entirety of the gamma emission from particle precipitation from the footpoints two separate quasi-static large-scale (of order 1 solar radius) coronal loops and not from either of the associated CMEs accelerating the high-energy particles. Using constraints from ancillary data, we estimate the bounds in parameter space of the loop sizes and embedded turbulence necessary to accelerate protons and ions to high energies producing the gamma emission.

Acute space radiation hazards pose one of the most serious risks to future human and robotic exploration. Large solar energetic particle (SEP) events are dangerous to astronauts and equipment. A fundamental question remains as to how large SEP events are formed, how they are related to coronal mass ejections (CMEs) and active region eruptions, and what factors control the differential

fluxes incident at Earth and other observers during SEP events. The current evolution of the Sun between solar cycles 23 and 24 and during cycle 24 remains highly anomalous compared to previous periods of the space age. The Sun has been abnormally quiet over a relatively long solar minimum when galactic cosmic rays (GCRs) achieved the highest flux levels observed in the space age, and the power, pressure, flux and magnetic flux of the solar wind were at the lowest levels. Despite the continued paucity of solar activity, one of the hardest solar events in almost a decade occurred in September 2017 after more than a year of all-clear periods. The 2017 September event demonstrates the importance of large fluxes of suprathermal seed populations and fast, large CMEs that drive shocks and compressions low in the corona (<5 Rs) where large SEP events are accelerated. The Coronal-Solar Wind Energetic Particle Acceleration (C-SWEPA) modeling effort and the SPE Threat Assessment Tool (STAT) combine the Earth-Moon-Mars Radiation Environment Modules (EMMREM) that describe energetic particles and their effects, with the CORHEL (Corona-Heliosphere) modeling suite developed by the Predictive Science, Inc. (PSI) group. C-SWEPA has also developed coupling between EMMREM and Enlil at the CCMC. The C-SWEPA and STAT projects have resulted in coupled models that describe the conditions of the corona, solar wind, CMEs, associated shocks, particle acceleration, and propagation via physics-based modules. Recent simulations demonstrate how CMEs form powerful compressions and shocks low in the corona that rapidly accelerate high energy particles often up to the GeV energies required for Ground Level Enhancements (GLEs). The most pronounced acceleration of the CME occurs very close to the Sun (<2 Rs) causing extremely strong compression on the flanks and nose of the CME. Results from recent modeling and observational studies demonstrate that the size of the shock or compression limits the break energy and longitudinal distribution of SEPs. The new capabilities afforded by STAT and C-SWEPA highlight the pathway toward prediction for large SEPs, and provide an important resource for answering fundamental new questions likely to arise from Parker Solar Probe and Solar Orbiter measurements.

D2.1-0022-18 THREE-DIMENSIONAL MODELLING OF SOLAR ENERGETIC PARTICLE EVENTS WITH EUHFORIA

Nicolas Wijsen, nicolas.wijsen@kuleuven.be KU Leuven, Leuven, Belgium

Angels Aran, aaran@am.ub.es

Universitat de Barcelona, Barcelona, Spain Jens Pomoell, jens.pomoell@gmail.com University of Helsinki, Helsinki, Finland

Stefaan Poedts, stefaan.poedts@wis.kuleuven.be

Centre for Plasma Astrophysics - KU Leuven, Leuven, Belgium

The main sources of solar energetic particles (SEPs) are shock waves propagating in front of coronal mass ejections (CMEs) and solar flares. Once particles escape from their acceleration site, they travel through the heliosphere, spiralling around the interplanetary magnetic fieldlines. On their voyage through space, they may encounter the Earth where they can e.g., disrupt the microelectronics of satellites and produce radiation hazard for astronauts in extravehicular activity. Therefore, it is crucial to understand and thereby build models capable of predicting the characteristics of SEP events.

The trajectories followed by SEPs in interplanetary space are determined by the electromagnetic forces acting on the particles. These forces result from the presence of magnetic fields in the background solar wind, which are a combination of the large-scale magnetic field originating from the sun and small-scale magnetic turbulence due to e.g., Alfvén waves and meandering field lines. One expects thus the properties of SEP events to be strongly influenced by the varying conditions of the solar wind. To study these effects, we developed a three-dimensional (3D) model for the description of SEP events that couples a new Monte Carlo particle transport code to the newly developed data-driven heliospheric model, EUHFORIA. The particle transport code computes heliospheric SEP distributions by solving the focused transport equation with perpendicular diffusion in a stochastic manner, whereas EUHFORIA solves the magnetohydrodynamic (MHD) equations, allowing us to obtain complex solar wind configurations in which we can propagate the energetic particles. In this talk, we present the first results of the coupling of the particle code with EUHFORIA, and in particular we focus on the effects of different background solar wind and scattering conditions on SEP events observed at different positions in the heliosphere.

D2.1-0023-18 PSEUDOSTREAMERS AND WIDELY DISTRIBUTED SEP EVENTS

Olga Panasenco, panasenco.olga@gmail.com

Advanced Heliophysics, Inc., Pasadena, California, United States Marco Velli, mvelli@ucla.edu

University of California, Los Angeles, Los Angeles, California, United States Aram Panasenco, panasencoaram@gmail.com

University of California, Los Angeles, Los Angeles, California, United States

Our analysis of the pseudostreamer magnetic topology reveals new interesting implications for understanding SEP acceleration in CMEs. The possible reasons for the wide distribution of some SEP events can be the presence of pseudostreamers in the vicinity of the SEP source region which creates conditions for the existence of strong longitudinal spread of energetic particles as well as an anomalous longitudinal solar wind magnetic field component. We reconstructed the 3D magnetic configurations of pseudostreamers with a potential field source surface (PFSS) model, which uses as a lower boundary condition the magnetic field derived from an evolving surface-flux transport model. In order to estimate the possible magnetic connections between the spacecraft and the SEP source region, we used the Parker spiral, ENLIL and PFSS models. We found that in cases of the wide SEP distributions a specific configuration of magnetic field appears to exist at low solar latitudes all the way around the sun, we named this phenomenon a pseudostreamers belt. It appears that the presence of the well developed pseudostreamer or, rather multiple pseudostreamers, organized into the pseudostreamer belt can be considered as a very favorable condition for wide SEP events.

D2.1-0024-18 PERPENDICULAR DIFFUSION OF SOLAR ENERGETIC PARTICLES IN PLASMA WAVE TURBULENCE; MODEL RESULTS AND IMPLICATIONS FOR ELECTRONS

Nicholas Engelbrecht, 12580996@nwu.ac.za

North-West University, Potchefstroom, South Africa

The processes responsible for the effective longitudinal transport of solar energetic particles (SEPs) are still not completely understood. We address this issue by simulating SEP propagation using a spatially 2D transport model that includes perpendicular diffusion. By implementing, as far as possible, the most reasonable estimates of the transport (diffusion) coefficients, we compare our results, in a qualitative manner, to recent observations. We illustrate the effects of perpendicular diffusion on the model solutions and discuss the viability of this process as a dominant mechanism by which SEPs are transported in longitude. The streaming SEP electrons can either grow or damp the background solar wind fluctuations; an effect also included in the present model. Our results suggest that wave amplification by streaming SEP electrons is indeed possible and may even significantly alter the background turbulent field. However, the simulations show that this process is much too weak to produce observable effects at Earth's orbit, but such effects may well be observed in future by spacecraft closer to the Sun, presenting an intriguing observational opportunity for either the Solar Orbiter or the Parker Solar Probe spacecraft.

D2.1-0025-18 REMOTE SHOCK CONNECTION CONTRIBUTIONS TO SEP EVENTS

Janet G. Luhmann, jgluhman@ssl.berkeley.edu

University of California, Berkeley, Berkeley, California, United States Hazel M. Bain, hazel.bain@noaa.gov

Colorado, United States

We recently published comparisons of observed multipoint SEP events with model counterparts (Space Weather, 2017) based on the assumption that ICME shocks in the WSA-ENLIL-cone model represent moving sources where diffusive shock acceleration is taking place, and that observer magnetic connection to those shocks determines their distinctive SEP time profiles. These results also provide information of interest regarding the occurrence of an observed SEP event in the absence of the corresponding shock arrival. We use the events that we have modeled to investigate how common it is for SEP events to occur solely or mainly by remote shock source connections. Such results are of interest for both the identification of observed SEP event sources, as well as for the use of SEP events as a precursor for geomagnetic storms in space weather forecasting.

D2.1-0026-18 3-D MODELLING OF SOLAR ENERGETIC PARTICLE TRANSPORT THROUGH ENLIL FIELDS.

Simon Thomas, sthomas17@uclan.ac.uk

University of Central Lancashire, Preston, United Kingdom Silvia Dalla, sdalla@uclan.ac.uk

University of Central Lancashire, Preston, United Kingdom

Solar Energetic Particles (SEPs) are accelerated by solar flares and shock waves driven by coronal mass ejections. SEP events are an important space weather hazard due to the significant radiation doses these particles can impart on humans and human technology in space. In this study, we simulate the transport of SEPs through the heliospheric magnetic field, via a 3-D test particle approach and using magnetic and electric fields from the 3-D ENLIL solar wind model. We compare previous results of the SEP test-particle model, produced using an ideal Parker Spiral magnetic field, with our new simulations. We discuss ways to interpolate the ENLIL outputs for test-particle trajectory calculations. Using the ENLIL model output as input for our SEP simulations, we can study how the energetic particles react to more realistic and spatially inhomogeneous magnetic and electric fields. Our results therefore show the effects of energetic particle drifts and diffusion in the presence of natural curvatures and gradients contained within realistic heliospheric structures from ENLIL, and thus how particle trajectories evolve in the presence of more inhomogenities compared to with a simple Parker spiral geometry. We will discuss how these heliospheric fields could be included operationally, for use in the real-time forecasting of SEP events.

D2.1-0027-18 MULTI-SPACECRAFT OBSERVATIONS OF SOLAR ENERGETIC PARTICLES WITH STEREO

Nina Dresing, dresing@physik.uni-kiel.de University of Kiel, Kiel, Germany

Bernd Heber, heber@physik.uni-kiel.de

Christian-Albrechts-Universität zu Kiel, Kiel, Germany Andreas Klassen, klassen@physik.uni-kiel.de

University of Kiel, Kiel, Germany

Raul Gomez-Herrero, raul.gomezh@uah.es SRG. Universidad de Alcala, Spain

Multi-point observations by the two STEREO spacecraft in combination with close-to-Earth observers have changed our understanding of the longitudinal distribution of solar energetic particles in the inner heliosphere. The so-called widespread events, which sometimes fill the space all around the Sun, still challenge current acceleration, injection, and transport theory. The strongly varying characteristics of those events suggest that there must be various mechanisms, which can contribute to the wide angular particle spreads. Among these mechanisms i) strong cross-field transport in the interplanetary medium and ii) extended injection regions close to the Sun are proposed. However, more complex scenarios involving the interaction of CMEs can also play a significant role for these events. We will discuss case studies as well as statistical results of solar energetic electron events observed by multiple spacecraft well separated in space.

D2.1-0028-18 MODELLING THE QUIESCENT GAMMA-RAY SOLAR EMISSION AND THE COSMIC RAY ELECTRONS IN THE INNER HELIOSPHERE

Elena Orlando, orlandele@gmail.com

Stanford University, Stanford, California, United States Andrew Strong, aws@mpe.mpg.de

Max Planck Institute for Extraterrestrial Physics, Garching, Germany

The Sun is a known quiescent gamma-ray source. Its quiescent gamma-ray emission is produced by Galactic cosmic rays (CRs) interacting with its surface (disc component) and with its photon field (spatially extended diffuse component). This extended component, by inverse Compton scattering of CR electrons on the solar photons of the heliosphere, extends to the whole sky and it is above the background even at large angular distances from the Sun. It was studied already with EGRET, and now with Fermi LAT with higher significance. Observations of the inverse-Compton component allow obtaining information of CRs close to the Sun and in the Heliosphere as a function of different periods of solar activity. However, precise model calculations are needed.

StellarICs (Stellar Inverse Compton scattering) is a software to compute gamma-ray emission from inverse-Compton scattering by CR electrons in the Heliosphere and in the photospheres of stars. The software is publicly available and it is under continuing development. After reviewing past and present studies on the solar emission, we will present our software including also up-to-date models.

D2.1-0029-18 ELEMENTAL COMPOSITION IN SOLAR ENERGETIC PARTICLES

Olga Malandraki, omaland@astro.noa.gr

IAASARS, National Observatory of Athens, Athens, Greece

In situ particle composition measurements over a wide range of species and energies in the heliosphere are a powerful tool in investigating the acceleration processes that produce solar energetic particles (SEPs). Minor heavy ions (with atomic number Z > 2) are particularly useful in this regard since they are genuine 'test' particles, too few in number to generate a feedback effect on the acceleration and transport processes. These minor ions also have various chargeto-mass (Q/A) ratios, which serve to identify seed populations and to probe the velocityand rigidity-dependent effects that govern injection, acceleration and transport of SEPs. In this work, an overview of recent key observations and results on elemental composition, derived from the data analysis of numerous missions in the heliosphere will be presented and discussed. Particular emphasis will be placed on the variability of the elemental composition as a proxy for the investigation of the accelerating shock properties as well as the explanation of large SEP events with uncommonly high Fe/O ratios, using measurements from widely separated spacecraft in solar longitude and latitude in the heliosphere. Furthermore, the future expected advances in view of the unique measurements provided by the upcoming Solar Orbiter and Parker Solar Probe missions in the inner heliosphere will be discussed.

D2.1-0030-18 UNDERSTANDING THE SPATIAL SPREADS AND SPECTRAL BREAKS OF GRADUAL SEP EVENTS: APPLYING IPATH SIMULATIONS TO SEP OBSERVATIONS.

The University of Alabama in Huntsville, Huntsville, Alabama, United States Gary Zank, garyp.zank@gmail.com

University of Alabama in Huntsville, Huntsville, United States

Recent observations from multi-spacecraft including STEREO show that gradual solar energetic particle (SEP) events can have significant longitudinal and radial spreads. One possible explanation is the cross-field transport of energetic particles in the interplanetary medium. Besides a large spatial spreading, spectra of SEP events often show spectral breaks with solar cycle dependence. The spectra breaks observed in cycle 24 are about 3 times lower in energy/nucleon compared with cycle 23.

In this work, we utilize the improved Particle Acceleration and Transport in Heliosphere (iPATH) model to help us understand these observational features. The iPATH model simulates particle acceleration at a CME-driven shock based on the diffusive shock acceleration (DSA) mechanism in a 2D domain. Transport of the accelerated particles is followed using the backward stochastic differential equation method. Both parallel and perpendicular diffusion are included in the transport process. Several large SEP events that are well observed by multiple spacecraft at different locations are examined using the iPATH model, with a focus on examining the role of the cross-field diffusion in the spatial distribution of SEP events. This can help us better predict and explain the Parker Solar Probe observations in the future. We also investigate the nature of the spectral breaks and examine their dependences on some of the solar wind and CME variables, by comparing iPATH simulations with observations.

Understanding the origin and transport of energetic particles of keV-MeV energies throughout the heliosphere still represents one of the biggest problems of space physics. Our knowledge of the propagation of energetic particles is mostly based on theoretical predictions compared with spacecraft observations at low heliolatitudes. Meanwhile, the occurrence of energetic particles at high heliolatitudes is even more puzzling since only one spacecraft, Ulysses, flew over the poles of the Sun and provided information on the energetic particle properties far above the ecliptic plane.

Ulysses observations show that energetic particle flux enhancements occur at heliolatitudes over 40 degrees at both solar maximum and minimum conditions (see, e.g., Smith et al. 2001; Sanderson et al. 2003; Lario et al. 2004; Sanderson 2004; Malandraki et al. 2009). This suggests various scenarios of particle transport. Energetic particles of keV-MeV energies should propagate mainly along magnetic field lines, but if a source is an active region at low latitudes or an ICME, their detection at high latitudes can be explained by particle diffusion across magnetic field lines either in the solar wind or in the corona. In any event, sources of energetic particles observed above the ecliptic during solar maxima are more or less well identified. Interpretations of observations of keV-MeV energetic particles in polar regions during solar minima are more complicated. The association of energetic particle flux enhancements in the polar heliosphere with corotating interaction regions, the main sources of accelerated particles in quiet times, is sometimes unsuccessful since there are no signatures of cross-field diffusion or particle streaming from distant heliocentric distances back to the Sun as it was presumed.

The existence of long-lived conic (or cylindrical) current sheets (CCSs) in the polar solar wind can naturally solve this problem (Khabarova et al. 2017). It has been recently found that CCSs are low-beta and low-speed structures formed within polar coronal holes. CCS stability is supported by the tornado-like magnetic field. The occurrence of magnetic separators near the poles in solar minima is confirmed independently by reconstructions of the coronal magnetic field based on photospheric magnetic field charts. We show evidence for association of energetic particles observed by Ulysses above the pole with reconnection polar jets located at the circleshaped touchdown of a CCS. Therefore, it is demonstrated that CCSs might serve as channels for energetic particles accelerated in the solar corona by magnetic reconnection, which sheds light on the mystery of energetic particles observed at high heliolatitudes.

This work is partly supported by the International Space Science Institute (ISSI) in the framework of International Team 405 entitled “Current Sheets, Turbulence, Structures and Particle Acceleration in the Heliosphere.” and RFBR grants 16-02-00479, 17-02-00300 and 17-02-01328.

Since the early seventies it is known that the Jovian magnetosphere is a source of low MeV electrons dominating the population in the inner Heliosphere. Therefor Jovian electrons have often been utilized as test particles to model charged particle transport and the corresponding transport parameters. It is evident that the results depend on both the assumed source spectrum as well as the general model setup. In our work we present an updated Jovian source spectrum based on flyby data and in agreement with measurements obtained at Earth orbit in the last 30 years. Furthermore we show first results of modelling spacecraft data via a stochastic differential equation (SDE) approach based on CUDA.

PAN is a scientific instrument suitable for deep space and interplanetary missions. It can precisely measure and monitor the flux, composition, and direction of highly penetrating particles (> 100 MeV/nucleon) in deep space, over at least one full solar cycle (11 years). A possible mission opportunity is the Deep Space Gateway (DSG). The science program of PAN is multiand cross-disciplinary, covering cosmic ray physics, solar physics, space weather and space travel. PAN will fill an observation gap of galactic cosmic rays in the GeV region, which is crucial for improving our still limited understanding of the origin of cosmic rays, and of their propagation through the Galaxy and the Solar system. It will provide precise information of the spectrum, composition and timing of energetic particle originated from the Sun, which is essential for studying the physical process of solar activities, in particular the rare but violent solar events that produce intensive flux of penetrating particles. The precise measurement and monitoring of the energetic particles is also a unique contribution to space weather studies, in particular to the development of a predictive solar activity model in a multi-wavelength and multi-messenger approach, using observations both space and ground based. As indicated by the terminology, penetrating particles cannot be shielded effectively. PAN will map the flux and composition of these particles precisely and continuously, providing valuable input for the assessment of the related health risk, and for the development of an adequate mitigation strategy. PAN has the potential to become a standard on-board instrument for deep space human travel.

PAN is based on the proven detection principle of a magnetic spectrometer, but with novel layout and detection concept. It will adopt advanced particle detection technologies and industrial processes optimally for deep space application. The device will require limited mass (20 kg) and power (20 W) budget. Dipole magnet sectors built from high field permanent magnet Halbach arrays, instrumented in a modular fashion with high resolution silicon strip detectors, allow to reach an energy resolution better than 10% for nuclei from H to Fe at 1 GeV/n. The charge of the particle, from 1 (proton) to 26 (Iron), can be determined by scintillating detectors and silicon strip detectors, with readout ASICs of large dynamic range. Low power pixel detectors will maintain the detection capabilities for even the strongest solar events. Fast scintillator with silicon photomultiplier (SiPM) readout will provide timing information to determine the entering direction of the particle, and some isotope identification capability of light nuclei. Low noise, low power and high density ASIC will be developed to satisfy the stringent requirement of the position resolution and the power consumption of the tracker.

The PAN instrument concept has been invited for oral presentations at the ESA Deep Space Gateway Science Workshop on December 5-6, 2017 at ESTEC in Noordwijk, The Netherlands, and the NASA Deep Space Gateway Science Workshop on February 27 - March 1, 2018 in Denver, Colorado, USA.

D2.1-0034-18 THE EVOLUTION OF ENERGETIC PARTICLES OVER THE SOLAR CYCLE

Richard Mewaldt, rmewaldt@srl.caltech.edu

California Institute of Technology, Pasadena, California, United States Christina Cohen, cohen@srl.caltech.edu

California Institute of Technology, Pasadena, California, United States Gang Li, gang.li@uah.edu

University of Alabama in Huntsville, Alabama, United States Junxiang Hu, junxianghu@gmail.com

The University of Alabama in Huntsville, Huntsville, Alabama, United States

Solar Cycle 24 has been somewhat surprising in that the level of solar activity as measured by the number and fluence of large solar energetic particle (SEP) events has been significantly lower than in the two previous cycles. For example, after the first nine years of cycle 24, the integrated fluence of >10 MeV protons is lower than in cycle 23 by a factor of 3.4; the >100 MeV proton fluence is reduced by a factor of 5.4; and the number of ground-level events (GLEs) is lower by a factor of 6.5. The number of 3He-rich SEP events is also somewhat lower in this cycle. This talk will compare measures of SEP production from the last three cycles and discuss possible solar/interplanetary properties that may explain the lower cycle 24 output, including a weaker interplanetary magnetic field strength, a reduced number of fast CMEs and X-Class flares, and lower densities of suprathermal seed particles. Recent results from the Improved Particle Acceleration and Transport (iPATH) model will be used to test these ideas and illustrate how the upcoming Parker Solar Probe and Solar Orbiter missions can investigate these processes near the Sun.

D2.1-0035-18 SOLAR FLARE PEAK TEMPERATURES AS A FORECASTING TOOL FOR SOLAR ENERGETIC PARTICLE EVENTS

Stephen Kahler, stephen.kahler@us.af.mil

AFRL, Kirtland AFB, New Mexico, United States Alan Ling, aling@aer.com

Atmospheric Environmental Research, Inc., Albuquerque, New Mexico, United States

Solar flare X-ray peak fluxes and fluences in the 1-8 A band are often used in models to forecast solar energetic particle (SEP) events. Garcia (2004) used the 0.5-4 and 1-8 A bands of the Xray instrument on the GOES spacecraft to plot inferred peak flare temperatures versus peak 1-8 A fluxes from 1988 to 2002. Flares associated with SEP events had statistically lower peak temperatures than those without SEP events and therefore offered a possible empirical forecasting tool for SEP events. We have repeated that work over the period 1998 to 2016, comparing the peak ratios of the 0.5-4 and 1-8 A band fluxes of flares > M3 to the occurrence of associated E > 10 MeV proton events with peak intensities Ip > 1 proton flux unit (pfu). We further distinguish small SEP events of 1 to 10 pfu from the larger events of > 10 pfu. We also find statistically lower X-ray band ratios for SEP events, confirming the earlier result. However, the ratio of the two peak X-ray fluxes may be a better diagnostic than their peak ratios.

D2.1-0036-18 THE SUN RADIO INTERFEROMETER SPACE EXPERIMENT (SUNRISE) MISSION CONCEPT

Joseph Lazio, joseph.lazio@jpl.nasa.gov

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California, United States

Justin Kasper, jckasper@umich.edu

University of Michigan, Ann Arbor, Michigan, United States SunRISE Science Team

Radio emission from coronal mass ejections (CMEs) is a direct tracer of particle acceleration in the inner heliosphere and potential magnetic connections from the lower solar corona to the larger heliosphere. Energized electrons excite Langmuir waves, which then convert into intense radio emission at the local plasma frequency, with the most intense acceleration thought to occur within 20 RSun. The radio emission from CMEs is quite strong such that only a relatively small number of antennas is required to detect and map it, but many aspects of this particle acceleration and transport remain poorly constrained. Ground-based arrays would be quite capable of tracking the radio emission associated with CMEs, but absorption by the Earth's ionosphere limits the frequency coverage of ground-based arrays (nu > 15 MHz), which in turn limits the range of solar distances over which they can track the radio emission (< 3 RSun). The state-of-the-art for tracking such emission from space is defined by single antennas (Wind/WAVES, Stereo/SWAVES), in which the tracking is accomplished by assuming a frequency-to-density mapping; there has been some success in triangulating the emission between the spacecraft, but considerable uncertainties remain.

We describe the Sun Radio Interferometer Space Experiment (SunRISE) mission concept, currently a NASA Phase A study: A proposed constellation of small spacecraft in a geostationary graveyard orbit designed to localize and track radio emissions in the inner heliosphere. Each spacecraft would carry a receiving system for observations below 25 MHz, and SunRISE would produce the first images of CMEs more than a few solar radii from the Sun.

Part of this research was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration.

Using the Low Frequency Array (LOFAR), we analyse the source sizes and locations of the fine frequency structures in a solar radio burst. The high time resolution allows us to determine the location and the size of the radio emission source, and its evolution with time, following the radio emission propagation through the solar corona. It is found that intrinsically very small radio sources have an apparent size that is a thousand times larger than the actual region where the radio waves originate [1]. The observations suggest that it is radio wave propagation effects, rather than the intrinsic properties of the emission source, that determine the observed spatial characteristics of the plasma emission radio bursts. In addition, the observations provide a new opportunity for diagnostics of small-scale plasma fluctuations by imaging the radio source halos as the radio waves move in the solar corona.

[1] Kontar et al.: Imaging Spectroscopy of Solar Radio Burst Fine Structures, Nature Communications 8, Article number: 1515 (2017) DOI: 10.1038/s41467-017-01307-8

D2.1-0038-18 PROTOTYPE DESIGN OF DATA ACQUISITION SYSTEM FOR HXI ON BOARD ASO-S MISSION

Purple Mountain Observatory, Nanjing, China

Advanced Space-based Solar Observatory satellite (ASO-S), the first solar observation mission of China, is scheduled to be launched on the eve of the next solar maximum year (about by the end of 2021). HXI is an essential payload for ASO-S, observing the X-ray image of solar flare in 30KeV-200KeV with high energy resolution and high time resolution. It consists of 4 parts: collimator, sun aspect system, calorimeter, and electronics control box. The collimator has a group of grid pairs, providing information about dozens of spatial scales of the X-ray emission. This information will be combined on ground to construct an image of the source in each energy band. The calorimeter contains an array of LaBr3 (lanthanum bromide) sensors and 4 front-end electronics boards, detecting the solar X rays from the collimator, and accumulating energy of each event into energy spectrum for each sensor with 0.1s minimum time resolution. The sun aspect system will offer the coordinates of the solar center during the observation. Electronics control box is mainly responsible for scientific data collection and packaging, telemetry-acquisition, power supply for other parts of HXI, etc. This paper will introduce the whole process of data acquisition, including readout of LaBr3 sensors, pre-process of the readout data (e.g. accumulation of the sensors' energy spectrum, packaging data, and so on), and science data collection from calorimeter and sun aspect system to electronics control box.

D2.1-0039-18 RADIO DIAGNOSTICS OF ENERGETIC ELECTRONS WITH GROUND -BASED INSTRUMENTATION IN SUPPORT OF THE PARKER SOLAR PROBE AND SOLAR ORBITER MISSIONS.

Nicole Vilmer, nicole.vilmer@obspm.fr Observatoire de Paris, LESIA, Meudon, France

Ground-based radio observations provide a wealth of information on the energetic electrons produced in the solar corona in association with solar flares or eruptive events. These observations will be complementary to the in-situ measurements of energetic particles that will be obtained aboard the Parker Solar Probe and Solar Orbiter missions as well as to the radio and X-ray diagnostics of energetic electrons provided by the FIELDS and RPW radio experiments on the Solar Probe and Solar Orbiter and the STIX X-ray instrument on Solar Orbiter. Decimetric/metric/ decametric radio observations will be routinely observed in Nançay (Paris Observatory) with a set of three instruments: the Nançay Radioheliograph (NRH) which will provide images of the solar corona between 450 and 150 MHz, and two spectrographs covering the complete frequency band from 1GHz to 10 MHz (with the solar-dedicated spectrograph ORFEES and the Nançay Decameter Array, NDA looking at both solar and jovian emissions). The combination of data from these three instruments can provide unique complementary observations on the propagation of electron beams from the flare site to the interplanetary medium as well as on the onset of coronal mass ejections and shocks. We will show a few examples of the complementarity of the observations and discuss how to coordinate the ground-based observations with satellite measurements.

(presentation on behalf of the NRH, NDA and ORFEES teams of Nançay)

D2.1-0040-18 FULL INVERSION OF ELECTRON EVENTS MEASURED BY HELIOS IN THE INNER HELIOSPHERE

We present a study of a sample of 300-800 keV electron events observed by Helios-1 and Helios2 in the inner heliosphere during 1976-1982. We model these events taking into account the detailed angular distributions measured by the E6 experiment in eight different sectors. The results of a focused interplanetary transport model combined with an inversion procedure are used to fit the observations. Unlike in previous studies, we consider both the energy and angular responses of the detector. This method allows us to extract the electron release time profile at the source and infer the electron interplanetary transport conditions. We discuss the characteristics of the release time profiles and the values of the electron mean free path, and compare them with the values reported previously in the literature using older approaches. We highlight the importance of revisiting SEP events observed by Helios in order to better characterize the radiation environment that Solar Orbiter and the Parker Solar Probe will encounter.

D2.1-0041-18 PROPERTIES OF ALPHA PARTICLES IN STREAM INTERACTION REGIONS

Tereza Durovcova, durovcova.t@gmail.com

A corotating interaction region (CIR) forms when the fast solar wind emanating from coronal holes at low heliographic latitudes pushes up against the slow solar wind ahead of it, creating a compression region in the heliosphere that co-rotates with the Sun. Arising pressure perturbations decrease the speed difference between both streams and the pressure waves steepen into forward and reverse shocks, typically at solar distances larger than a few AU. The shocks can accelerate ions via Fermi acceleration but the accelerated particles are often observed in the stream interaction regions at 1 AU even if boundary shocks are not present. In the paper, we study a behavior of alpha particles in CIR compressed regions, using measurements of the spacecraft in the L1 point. Our study focuses on properties of the solar wind plasma nonequilibrium features: velocity and temperature ratios of alpha particles and protons and their relative flow speed. In the slow solar wind in front of CIRs, the relative helium abundance is low and the alpha-proton differential speed is close to zero. On the other hand, in the high-speed stream, both these parameters are higher and a significant correlation between the proton-alpha velocity ratio and magnetic cone angle is often observed. Inside CIRs, close to the leading edge, the fast solar wind is slowed down and compressed, whereas the accelerated slow solar wind is observed close to the trailing edge. These regions are characterized by large variations of IMF, thus their study sheds a light on the evolution of the alpha-proton differential motion.

D2.1-0042-18 MECHANICAL DESIGN FOR HARD X-RAY IMAGER ONBOARD SATELLITE ASO-S

Purple Mountain Observatory, Chinese Academy of Sciences, Nanjing, China

Satellite ASO-S (Advanced Space-based Solar Observatory), a Chinese satellite for solar observation during the maximum years of the solar activity cycle 25, is now under developing for the Strategic Priority Research Program on Space Science of Chinese Academy of Sciences. Under CAS's new Innovation 2020 program, the engineering qualification model of ASO-S will be done in next year. Three payloads, Full-disc vector Magneto Graph, Lyman-alpha Solar Telescope and Hard X-ray Imager, are onboard ASO-S to observe solar flares, CMEs and solar magnetic field at the same time. As the largest one of the three payloads, HXI is aimed to get the image of hard x-ray at energy range from 30keV to 200keV with 98 pairs of Fourier collimation units. Prototype mechanical design and finite element analysis of HXI have been done to make the structure of HXI stable against vibrations during launch.

D2.1-0043-18 THERMAL DESIGN FOR HXI ON BOARD ASO-S MISSION

Purple Mountain Observatory, Chinese Academy of Sciences, Nanjing, China

ASO-S is being developed as a scientific satellite aimed to observe solar flares, CMEs and solar magnetic field at the same time. Hard X-ray Imager (HXI), one of the three major sub-detector, mainly focuses on the solar flares with about 100 pairs of grid stacked by tungsten foil fabricated in different pitches. As the highly accuracy of the HXI collimator (HXI-C in short) for imaging is of vital significance, for example, a relative shift of one grid with respect to the others larger than 6m could change the position of the image, thus, the thermal control design could play a key role for HXI-C in space for the huge impact on the imaging of the deformation. This paper first introduces the major sections of the HXI-C from the viewpoint; in the second part, both the influence of the deformation for HXI-C imaging and the latest thermal design according to physical requirements will be present in detail. Also, some FEM analysis will be performed based on the launch and space environment in accordance with the thermal design. Conclusion will be proposed in the end that HXI collimator could meet the demands while some suggestions of optimization still needs to be carried out in detail.

D2.1-0044-18 ESTIMATES OF THE ENERGETIC PROTON ENVIRONMENT AT L1 POINT

Tommaso Alberti, tommasoalberti89@gmail.com IAPS/INAF, Roma, Italy

Monica Laurenza, monica.laurenza@iaps.inaf.it IAPS/INAF, Roma, Italy

The interplanetary space is permeated by 'thermal' solar wind plasma and by a higher energy particle component, which increases of several orders of magnitude during Solar Energetic Particle (SEP) events. The estimation of this high energy particle background is essential for any mission profile. For instance, protons with energies in the range 50 - 500 keV (the so called soft protons) are of particular interest for the ATHENA mission, as they enter the mirrors, being concentrated towards the focal plane instruments. Here, proton flux data obtained from both ACE and IMP-8 spacecraft, covering the 1997-2015 interval (solar cycles No. 23 and 24) and the 1973-2001 interval (solar cycles No. 21, 22, and 23), respectively, have been used to estimate the energetic proton environment at L1 point. In particular, cumulative distribution functions (CDFs) have been obtained for the 8 differential energy channels (in the energy range 0.70 - 4.75 MeV) of the EPAM/LEMS120 experiment onboard ACE as well as for two energy channels of CPME experiment on board IMP-8. Since the EPAM/LEMS120 first energy channel (P1') is affected by an unphysical quasi-periodic modulation, it has been filtered by using the HilbertHuang Transform (HHT) approach, based on both Empirical Mode Decomposition (EMD) and Hilbert Spectral Analysis (HSA). In this way, a corrected (filtered) P1' signal has been derived from which CDFs can be properly evaluated, showing that the unphysical modulation tends to increase values of a factor ranging between 1.2 and 2. Moreover, both ACE and IMP-8 proton fluxes are compared on similar energy channels showing a similar CDFs behavior, although solar cycles behavior was different in the different time intervals.

D2.1-0045-18 PROTOTYPE DESIGN OF PIXELATED CALORIMETER FOR HXI ON BOARD ASO-S MISSION

Zhang Yan, yzhang@pmo.ac.cn

Purple Mountain Observatory, Chinese Academy of Sciences, Nanjing, China Zhe Zhang, zhangzhe@pmo.ac.cn

Purple Mountain Observatory, Chinese Academy of Sciences, Nanjing, China Jian Hua Guo, jhguo@pmo.ac.cn

Purple Mountain Observatory, Chinese Academy of Sciences, Nanjing, China Yongqiang Zhang, yqzhang@pmo.ac.cn

Purple Mountain Observatory, Chinese Academy of Sciences, Naijing, China

The Hard X-ray Imager (HXI) is one of the three core instruments on Chinese first Solar Observation Satellite: Advanced space-based Solar Observatory (ASO-S). This satellite to be launched around 2021 belongs to the second batch of missions under the Strategic Pilot Project in Space Science of CAS. HXI applies a Fourier-imaging technique using a set of tungsten grids in front of LaBr3 Calorimeter arrays to provide imaging spectroscopy of solar thermal and non-thermal hard X-ray emissions from 30 to 200 KeV. The calorimeter consists of arrays of LaBr3 crystals & PMTs, Front Ended Electronics and High Voltage Distributers. Prototype design of the calorimeter will be reviewed in this paper with some critical problems & solutions in handling the great changes of solar x-ray flux being discussed. Particular emphasis is given to the Adaptive Spectrum Accumulator & Solar X-ray Burst Trigger System.

D2.1-0046-18 MODELLING OF THE INJECTION FUNCTION OF SOLAR ENERGETIC PARTICLES

Petrus Johannes Steyn, 25261630@nwu.ac.za

North-West University, Potchefstroom, Potchefstroom, South Africa Du Toit Strauss, dutoit.strauss@nwu.ac.za

North-West University, Potchefstroom, South Africa

Solar energetic particles (SEPs) are accelerated at the Sun during either short-lived, impulsive events called solar flares or gradual events called coronal mass ejections (CMEs). An injection function is used to model the injection of SEPs from a source region on the Sun into interplanetary space. Previously, injection functions were modelled by using ad-hoc expressions, but it has become increasingly important to base the injection function on more realistic parameters and constrain it with available spacecraft data. This study investigates the particle intensities from transient events by varying parameters related to the injection function used in our SEP transport model. The importance of the onset and decay-times, and the longitudinal extent of the injection function are discussed while comparisons are drawn between single and multiple Gaussian injections from the same active region. We propose that the injection profile can be constrained further by incorporating remote sensing observations using a multi-wavelength approach. Implications for Solar Orbiter and Parker Solar Probe observations will also be discussed.

Energetic particles in the heliosphere obtain their elevated energetic status after three processes: injection, acceleration, and transport. Suprathermal seed particles have speeds well above the fast magnetosonic speed in the solar wind frame of reference and can vary from location to location and within the solar activity cycle. Acceleration sites include reconnecting current sheets in solar flares or magnetspheric boundaries, shocks in the solar corona and heliosphere and at planetary obstacles, as well as planetary magnetospheres. Once accelerated, particles are transported from the acceleration site into and through the heliosphere. Thus, by investigating properties of energetic particles such as their composition, energy spectra, pitch-angle distribution, etc. one can attempt to distinguish their origin or injection and acceleration site. This in turn allows us to better understand transport effects whose underlying microphysics is also a key ingredient in the acceleration of particles. In this poster we will present the Energetic Particle Detector (EPD) on Solar Orbiter, its status and capabilities, and consider implications for the key science goal of Solar Orbiter and Parker Solar Probe - How the Sun creates and controls the heliosphere.

D2.1-0048-18 AN UPDATED DEFINITION OF GLE AND SUB-GLE EVENTS

Ilya Usoskin, ilya.usoskin@oulu.fi University of Oulu, Oulu, Finland

Stepan Poluianov, stepan.poluianov@oulu.fi University of Oulu, Oulu, Finland Alexander Mishev, alexander.mishev@oulu.fi University of Oulu, Oulu, Finland

Margaret Shea, sssrc@msn.com

Air Force Research Laboratory, Bedford, Massachusetts, United States Don Smart, donsmart100@msn.com

Air Force Research Laboratory, Bedford, Massachusetts, United States

The concept of the ground-level enhancement (GLE, http://gle.oulu.fi) of the neutron monitor (NM) count rate, caused by solar energetic particles (SEP), plays an important role for many statistical and scientific studies. The classical definition says that a GLE has been identified when a near simultaneous increase (typically associated with solar activity) is registered by at least two differently located NMs regardless of their atmospheric and geomagnetic cutoff properties. This included NMs at a high-altitude polar site with the reduced total cutoff (SOPO/B at the Amundsen-Scott station, South Pole, Antarctica, elevation 2835 m asl), and Vostok NM (Vostok station, 3500 m, operating only 1963-1969). However, a new high-altitude polar NM (DOMC/B) was installed at Concordia station (Dome C, Antarctica, elevation 3233 m asl) in 2015. As a result, there is a pair of exceptionally sensitive instruments (SOPO/B and DOMC/B) that can formally register a near simultaneous increase from a relatively weak SEP event below the full atmospheric cutoff, which would have not been detected at any other NM station and, accordingly, not accepted as a GLE before 2015. This would potentially distort the homogeneity of the present GLE list by more frequent detections due to the enhanced sensitivity of the global NM network.

In order to maintain the homogeneity of the events previously listed as ground-level enhancements, we propose to modify the presently used GLE definition as follows: "A GLE event is registered when there are near-time coincident and statistically significant enhancements of the count rates of at least two differently located neutron monitors, including at least one neutron monitor near sea level and a corresponding enhancement in the proton flux measured by a space-borne instrument(s)." We also propose to classify SEP events under the full atmospheric cutoff, which are seen only in data of high-altitude polar NMs, as sub-GLEs. We note that this definition does not affect the present list of GLEs.

D2.2-0001-18 THERMAL INSTABILITY AND GALACTIC PRECIPITATION

Mark Voit, voit@pa.msu.edu

Michigan State University, East Lansing, Michigan, United States

The feedback cycles that regulate the evolution of massive galaxies depend critically on condensation of cold clouds out of hot circumgalactic gas. I will review the observational evidence and theoretical models indicating that condensation and infall of cold clouds–a process sometimes called galactic precipitation–fuels the central supermassive black hole of a massive galaxy, producing energetic outflows that regulate the rate of condensation. Much of that evidence comes from observations and models of the central galaxies of galaxy clusters. Some of these galaxyscale precipitation processes may resemble the production of coronal rain, and I will attempt to compare and contrast those phenomena.

D2.2-0002-18 THE PHYSICS OF THERMAL NONEQUILIBRIUM

Judy Karpen, judy.karpen@nasa.gov

NASA/GSFC Heliophysics Science Division, Greenbelt, Maryland, United States
